In Finland, a breeding project was initiated in 1979 with the primary objective to select high yielding and winter hardy cultivars of *C. japonica*. Selected genotypes have been propagated by tissue culture and are presently being compared in clone tests (Tigerstedt 1996, pers. commun.).

In Ukraine, domestication of chaenomeles began in 1913, which resulted in the first industrial plantation in 1937. However the crop never became very popular, and in 1981 a new project was started for reintroduction of chaenomeles. In this new project, variability was measured for several fruit morphological and chemical characters, and possibilities for early selection were estimated through calculation of correlation coefficients between characters and years (Mezhenskij 1989, 1996). Besides studies on interspecific (*C. japonica*, *C. speciosa*, and *C. cathayensis*) and intergeneric hybridization (*Pyrus*), research was conducted on propagation and marketable products. The crop was considered promising but so far this has not resulted in any new commercial plantations (Mezhenskij 1996, pers. commun.).

In Moldavia, research on intraspecific variation in morphological characters and in some fruit biochemistry characters of *C. japonica* was initiated in the 1980s. Correlation coefficients and variability coefficients were estimated and it was concluded that *C. japonica* had good possibilities for improvement through breeding (Ponomarenko 1996, pers. commun.). So far no commercial plantations have, however, been established.

In Latvia, research on *C. japonica* was initiated in 1951 (Tiits 1989; Tics 1992) and the first large plantations were established in the 1970s. In 1993 the plantations in Latvia covered approximately 300 ha, with a maximum yield of 20–30 t/ha (Ruisa 1996) and an average yield of 12–15 t/ha. The interest in *C. japonica* as a fruit crop had also spread to Lithuania (Ratomskyte 1996; Rumpunen and Kviklys 1996). The plant material used in the Baltic countries was propagated only by seed and very heterogeneous. A few generations of mass-selection, however, succeeded in reducing the frequency of plants with thorns (to about 4%), promoting early ripening, and increasing the yield (Ruisa 1996). Nevertheless, fruit quality was not sufficient to enable production of high quality and competitive products. The need for improved plant material became obvious, and a joint Latvian-Lithuanian-Swedish plant breeding program was initiated in 1992 (Rumpunen et al. 1998). A link between the Swedish-Latvian-Lithuanian program and the Finnish plant breeding project was established in 1998, and multidisciplinary research was at the same time started, aimed at studying the potential of *C. japonica* as a fruit crop (Rumpunen et al. 2000).

In the current plant breeding program, selection has taken place in orchards, the selected plants have been micropropagated, and clone trials have been established in Finland, Italy, Latvia, Lithuania, and Sweden. In addition, breeding populations have been created, including offspring from interspecific and intergeneric crossings. Floral biology (development of micro- and macrogametophytes, pollen viability, pollen germination, pollen tube growth, embryo sac viability, fertilization, the effective pollination period, period of flowering, functionality of flowers with stunted pistils, fruit set following self-pollination, the effect of emasculation, and bagging on fruit set) has been studied (Kaufmane and Rumpunen 2002a,b). The content and composition of dietary fiber of the fruit of *C. japonica* has been investigated (Thomas et al. 2000), and a method for screening of pectin in chaenomeles fruits has been developed (Rumpunen et al. 2002). The chemical composition of the fruit fragrance and flavor, and the characteristics of the fruit juice, have been investigated during development and storage. In addition, consumer preferences have been evaluated for a number of products based on chaenomeles fruits. Furthermore, an ideotype has been defined for the fruit crop *C. japonica*, and breeding strategies have been developed (Rumpunen 2001). Important traits to be specifically considered during selection and breeding of *C. japonica* are: adaptation and hardiness, disease resistance, thorns, suckering, growth, rooting of cuttings, time of ripening, yield, amenability for mechanical harvesting, and fruit quality.

FUTURE PROSPECTS

The large phenotypic and genetic diversity in the genus *Chaenomeles*, as inferred from morphological and biochemical traits, and from molecular markers, is advantageous for crop improvement through breeding and selection. The high content of dietary fiber and pectin in the fruit makes *C. japonica* a promising candidate for the manufacture of dietary fiber-containing food products and pectin. The pleasant flavor and high acidity of the fruit, make the crop interesting as raw material for development of a range of sweetened food products. At present, the absence of selected cultivars limits the possibility for large-scale product development. The first cultivars should be available for marketing within a few years. It will then be possible to establish pilot plantations, yielding high quality fruits for further product development and marketing of this new crop.

Chamaelirium

Chamaelirium luteum (L.) A. Gray.

Chamaelirium

Figure 38.—Chamaelirium (*Chamaelirium luteum*)

Other common names.—Helonias, unicorn root, false unicorn root, blazing-star drooping starwort, starwort, devil's-bit, unicorn's-horn. This plant is frequently confused with *Aletris farinosa* L., not because it bears much resemblance to the latter but probably on account of a similarity in some of the common names by which they are sometimes designated. In the drug trade it is perhaps best known as Helonias, but the use of that name is likely to lead to confusion because the plant has no relation to the genus *Helonias*.

Habitat and range.—This native plant is found in open woods from Massachusetts to Michigan and south to Florida and Arkansas.

Description.—Chamaelirium is an erect, fleshy herb. The male and female flowers are borne on separate plants. The male plants grow to a height of 1 1/2 to 2 1/2 feet, while the female plant is sometimes 4 feet tall and is more leafy. The leaves which are from 2 to 8 inches long, are spoon shaped, being wider at the top than at the base. The white starry flowers are produced from June to July. The flowers of the male plant are borne on plumelike spikes from 3 to 9 inches long and those of the female plant in erect spikes. The rootstock is from one-half to 2 inches in length and usually curved upward at one end in the form of a horn. The rootlets penetrate to the center of the rootstock. This and its disagreeable bitter taste distinguish it from Aletris root.

Part used.—The rootstock. collected in autumn.

New Industrial Crops: Northwestern Argentina Regional Project

Ricardo Ayerza (h) and Wayne Coates

The goal of the Northwestern Argentina Regional Project is to identify and bring into commercial production new industrial crops which can help diversify agricultural production and increase profits for farmers in northwestern Argentina. Both private and government organizations in the United States and Argentina have been working cooperatively on this project since its inception.

The project started in 1991 with an agreement between Partners of the Americas Inc., a non-profit organization headquartered in Washington DC, and Agropecuaria El Valle S.A., an agricultural enterprise with offices in Buenos Aires and Catamarca, Argentina. This technical cooperation was made possible through the Farmer to Farmer program, financed by the Congress of the United States as a part of the 1990-95 Farm Bill (Public Law 480), and the Agency for International Development (USAID).

Subsequently, The University of Arizona, the University of California, the National University of Catamarca, the Rural Group Pulares, and the government of the province of Salta joined the project. In 1995 four grower organizations from the province of Jujuy also joined. These are CREA Los Lapachos, Union Caneros Independientes de Jujuy and Salta, Cooperativa de Tabacaleros de Jujuy, and La Camara del Tabaco de Jujuy.

NEW CROP COMMERCIALIZATION

The development of any new crop goes through four distinct phases: (1) market assessment; (2) identification of the most appropriate species; (3) domestication of the species; (4) commercial production.

Growers, processors and marketing agencies must be involved and share the risks in all four phases of this development process for it to be the most effective. Under these conditions all of the involved parties are unified through contracts, a common information base, and personal involvement. Because this concept of widespread involvement and responsibility is an integral part of the Northwestern Argentina Regional project, the growers, processors and marketing agencies have all assumed a degree of the cost, and hence risk, with it.

Ecosystems

Northwestern Argentina consists of five provinces: Salta, Jujuy, Tucuman, Santiago del Estero, and Catamarca. The region can be divided into three general ecosystems which run parallel to each other in a north and south direction. The eastern most ecosystem is called Chaco, and is a wide plateau approximately 300 to 700 m in elevation. The climate is warm and dry, and naturally supports an open woodland ecosystem. Directly to the west is a long sloping region which rises from 200 to 4000 m in elevation, over a distance of 50 to 100 km. This center ecosystem is called the Yungas, is frost free in most years, and receives more than 1200 mm of rainfall annually. This area is suitable for tropical fruit production. The western ecosystem is a high plateau called Puna, and is at an elevation of 4000 m or more. It is a cold and dry grassland, having no naturally occurring tree species.

The work reported in this manuscript took place in the Yungas and Chaco ecosystems, within the provinces of Catamarca, Jujuy, Salta, and Tucuman. The project began in 1991 and is planned for continuation at least through 1996, with the objective being to evaluate potential industrial crops and then bring them into production. Ancillary objectives are to bring about a better public understanding of how new crops can improve the economic situation in northwestern Argentina, and to promote closer cooperation between northwestern Argentina and the southwestern United States.

Education and Information Exchange

Establishing research plots, providing on-farm technical advice, and conducting workshops, conferences, and seminars for growers, university faculty, and technical personnel have all been part of the program. During 1995 alone, 12 different topics were presented in a series of workshops, conferences, and seminars held at various locations in northwestern Argentina.

Seventeen scientists, growers and company managers have been brought from the U.S. to Argentina to provide technical assistance. Areas of expertise have included agronomy, genetics, plant physiology, mechanization, processing, economics, and marketing.

Nineteen professors from the National University of Catamarca and three from the University of La Rioja travelled to the U.S. for specialized training programs lasting from 2 to 3 months. The time was spent at either the University of Arizona, or the University of California. In 1994, two members of a women's agricultural cooperative from Catamarca participated in the exchange program and spent time in California, Arizona and Northern Mexico, where they were able to exchange ideas on new crop production with growers and researchers.

IDENTIFICATION OF SUITABLE NEW CROPS

The research plots, as well as the demonstration plantings, have been located on private farms, thus directly involving the farming public in the project. The tests have been conducted in the four provinces of Catamarca, Jujuy, Salta, and Tucuman, (Table 1) providing wide public exposure to the project.

Through the trials, six species have been identified which appear to hold significant potential for the region. These are: chia, lesquerella, vernonia, and chan which are sources of industrial oil; guayule, a source of rubber, resins, and latex; and kenaf, a raw material for paper and newsprint. Of these crops, only lesquerella and chia have been grown commercially. For the others, trials are continuing to evaluate cultivars and/or sites in order to identify those crops and locations which hold the greatest commercial potential for northwestern Argentina. Some of the results are presented here.

Chan (*Hyptis suaveolens*, Labiatae)

This plant is native to southern Mexico and Central America, and was used as a food by pre-columbian people in the region. The seed contain 77%-80% linoleic acid, and little or no linolenic acid. Yields in Argentina have reached 1770 kg/ha (Coates and Ayerza 1995). The data in Table 2 summarize the results obtained from four-row plots which were harvested in June 1995. No statistically significant difference between sites, either in terms of total biomass or amount of seed harvested, was detected. This tends to indicate that either site would be equally suited for growing chan. Table 2 also shows that total oil content as well as percent alpha-linoleic fatty acid in the seed were similar at both locations. This also indicates that either site would prove equally suitable for growing chan.

The total oil yield is very low compared to other commercially grown oil seed crops. Because this is a new crop, it is necessary to conduct further tests and examine the analysis techniques which were used in the laboratory to determine oil quantity and distribution. Environmental factors which might have affected the results also need to be investigated before a sound conclusion can be drawn regarding the quantity and quality of oil contained in the seed.

Kenaf (*Hibiscus cannabinus*, Malvaceae)

Kenaf, a native of tropical Africa, is a fast-growing annual which is grown for its fiber. It can reach heights of 4 to 6 m in one growing season, and has yielded up to 17.5 t/ha of dry matter in Argentina (Ayerza and Cook 1996). Table 3 presents results from a series of kenaf trials that were conducted over a number of years, at five sites. Sumalao and Pichanal were both irrigated, while the other sites were not. Dry matter yields ranged from 4.3 to 13.3 t/ha, with the yields being quite variable. Yields have been influenced by both location and climate. One cultivar has not proven superior to the others at all locations, indicating that site influences are significant and will need to be taken into account when selecting cultivars for commercial production. These tests clearly indicate the need for additional cultivar and location trials, and consequently these are underway.

Kenaf was first planted in Argentina on a commercial scale in late 1995. Plans called for planting 25 ha using three cultivars, with the idea being to use the plantings not only to determine the production potential of the three cultivars which had demonstrated the best performance in the plots, but also to evaluate alternative harvesting technologies and determine which might be the most appropriate for the region. After harvest, the material was to be sent to a commercial operation to be pulped, and was then to be blended with bagasse pulp and made into paper. Unfortunately early 1996 was one of the driest summers on record in northwestern Argentina, and the extended trial had to be abandoned. As a consequence only two hectares were sown. Plans still call for this field to be used to test alternative harvesting methodologies, although in a more limited scale. Pulping will take place provided that a commercial entity can be located that is willing to work with a limited amount of material.

Vernonia (*Vernonia galamensis*, Asteraceae)

Vernonia, a member of the sunflower family, is native to tropical Africa. Its seed contain an unusual oil which, because of its low viscosity, can be used as a solvent in paint. Over 70 other potential uses for the oil have been identified. Table 4 presents the results from the vernonia trials conducted in 1995 at Pichanal and Yuto. At Pichanal significant differences in seed yield were detected among the cultivars, with more than a ten fold difference being found between the most and least productive. No statistically significant differences in 1000 seed weight were detected, and some cultivars had significantly lower oil content than others. As insufficient seed was available to plant a replicated trial at Yuto, only one block was sown. As a consequence only mean seed yields are presented in Table 4, and no statistical analysis of the data was conducted. The mean values, however, indicate that this site may be the best of the two for growing vernonia.

In general the vernonia yields are low, on a per hectare basis, as compared to other oilseed crops. The values were determined for rows planted 1 m on center. This spacing conforms to USDA test plots, and allows comparison with their data. In a commercial situation, row spacing would be on the order of 150-200 mm, significantly increasing yields. Pest and disease problems at both sites also decreased yield.

Guayule (*Parthenium argentatum* Gray, Asteraceae)

Guayule, a plant native to the Chihuahuan desert of Mexico, produces rubber that is almost identical to that from the rubber tree. It also produces several co-products, including resins, low-molecular weight rubber, and bagasse, each of which have potential uses. The rubber (or latex) from guayule can be used where synthetic materials are not satisfactory. Table 5 presents the analysis which was conducted on two year old guayule harvested in Catamarca in 1995. Significant differences in biomass yields were detected among varieties, however no differences in rubber yield were found on a dry matter basis. When the biomass yields are combined with the rubber content, rubber production ranged from 17 to 60 g per plant. Thus although percentage of rubber in a plant can influence processing costs, total rubber production on an area basis would probably be the governing factor used to select the best varieties.

Results of this study show that additional trials are required to determine not only the highest producing varieties, but also to assess yields as influenced by time of harvest. Plans call for these tests to be undertaken starting in June 1996.

Jojoba [*Simmondsia chinensis* (Link) Schneid., Simmondsiaceae]

Jojoba, which is native to the southwestern United States and northern Mexico, produces seeds which contain a liquid wax that has uses in the cosmetic industry, and it also serves as high quality lubricant. Jojoba has been grown commercially for a number of years in La Rioja and Catamarca provinces. The development of equipment to mechanize its production has been an integral part of the Northwestern Argentina Regional Project. Equipment has already been developed for transplanting cuttings, pruning the plants, and preparing the soil surface for harvest. A new type of jojoba harvester is under development, with a prototype having been built and tested.

Lesquerella (*Lesquerella fendleri*, Brassicaceae)

Lesquerella is an annual plant native to the southwestern United States. The seed of lesquerella contain an unusual fatty acid which is similar to that of castor bean. This fatty acid can be converted to many products which have both industrial and cosmetic potential. The meal remaining after the oil is removed contains a good amino acid balance, and can be used in livestock feed.

Chia (*Salvia hispanica*, Labiatae)

Like chan, chia is native to southern Mexico and has been used by pre-columbian inhabitants of Central America as a food source and a medicine. Oil from chia was also used in paints. The seed contain the highest known natural source of linolenic acid (60%), with linolenic acid having many uses in industry and cosmetics. The meal remaining after the oil is expressed is high in protein and fiber, and can be used for human and animal food. Seed yields in plots of up to 1602 kg/ha, and oil contents as high as 38.6% have been reported in Argentine trials (Ayerza, 1995).

Chia and lesquerella have been commercially produced in the provinces of Catamarca, Salta, and Tucuman. The seed produced has been exported to the United States, with contracts for its production being signed between the growers and commercial enterprises from Argentina and the U.S. Table 6 lists the sites and number of growers that have been involved in the commercial production of these crops.

From Table 6 it can be seen that the number of farms and growers involved in the production of chia and lesquerella on a commercial basis has varied. The reasons for this have been the degree of success realized by each grower, and the level of satisfaction arising from being involved with the introduction of a new crop.

The commercial yields of both chia and lesquerella have varied from year to year, and from location to location. This is due to a number of factors including cultural practices, climate, weed infestations and harvesting techniques used. Cultural practices purposely have not been standardized across farms, as it is the intent of the project to allow farmers to use those cultural practices with which they are familiar to grow the new crops, while providing them with overall guidance as to how best to produce each crop.

Analyses of the chia seed which was commercially harvested in 1995 showed viability to range from 78% to 87%. Purity ranged from 84% to 97.5%. This is considered excellent, especially given the small size of the seed and the difficulties which were encountered with the harvesting and cleaning processes. These data demonstrate that chia can be commercially produced in northwestern Argentina.

Table 7 provides a comparison of the returns that can be realized from chia production, as compared to two traditional crops found in the region. The higher returns from chia have in large part prompted a significant increase in acreage planted in 1996.

LONG RANGE OUTLOOK

Over-production of traditional crops continues worldwide. It is therefore likely that prices and profit margins for these will remain very low, except when shortages arise because of war or climatic disasters. Furthermore, the consumption of many non-renewable resources continues, and environmental policies are already beginning to favor markets for many new industrial crops.

The success of the program is clearly demonstrated by the increasing numbers of hectares of chia being grown in northwestern Argentina. It is anticipated that this trend will continue and that the same thing will occur for lesquerella and kenaf. Such success is possible because the program is dynamic. Many organizations and growers are already a part of this project and they expect to take advantage of the conditions which exist to benefit their own enterprises. Others in the community benefit as a result of improved economics. The dynamic, open nature of the Northwest Argentina Regional Project means that other organizations and growers interested in the benefits of new industrial crops, including diversification of their cropping practices, are welcome to join the program at any time.

Potential Nutritional and Health Benefits of Tree Spinach*

Joseph O. Kuti and Eliseo S. Torres

The tree spinach (*Cnidoscolus chayamansa* McVaughn, Euphorbiaceae), called "chaya" in south Texas, is popular in Mexico and Central America and has been introduced into the United States (mainly South Texas and Florida) for potential uses as a leafy vegetable and/or as a medicinal plant. The plant is an attractive shrub, 3 to 5 m tall (Breckon 1979). The leaves are broad and may consist of 3 or more lobes with fleshy petioles (Fig. 1). The white-colored flowers, which are usually borne on cyme-branched inflorescences, may contain 3-forked arrangements in which the pistillate flowers are located on the basal fork. The staminate flowers are expanded distally from the base of the lobes. Mature seeds and fruit are rare and unknown (McVaugh 1944).

The young shoots and tender leaves of chaya are cooked and eaten like spinach. They comprise part of the staple diet and are the main dietary source of leafy vegetable for the indigenous people of Yucatan peninsula of Mexico and Kekchi people of Alta Verapaz in Guatemala (Harris and Munsell 1950; Booth et al. 1992). There are many underexploited native leafy plants with potential as a traditional food source (NAS 1975). With current renewal of interest in household gardens, attention is being focused on promoting some of these plants as leafy green vegetables among populations in the developing countries (FAO 1987). The edible parts of chaya plant, which taste like spinach when cooked, provide important nutritional sources for protein, vitamins (A and C), minerals (calcium, iron, phosphorus), niacin, riboflavin, and thiamine among populations that cannot afford expensive foods rich in these nutrients (Yang 1979). The plant may also constitute a potentially valuable leafy green vegetable here in the United States and elsewhere.

Chaya traditionally has been recommended for a number of ailments including diabetes, obesity, kidney stones, hemorrhoids, acne, and eye problems (Diaz-Bolio 1975). Chaya shoots and leaves have been taken as a laxative, diuretic, circulation stimulant, to improve digestion, to stimulate lactation, and to harden the fingernails (Rowe 1994). Like most food plants such as lima beans, cassava, and many leafy vegetables, the leaves contain hydrocyanic glycosides, a toxic compound easily destroyed by cooking. Even though some people tend to eat raw chaya leaves, it is unwise to do so.

While the nutritional value of chaya has been demonstrated (Martin and Ruberte 1978; Booth et al. 1992), none of the purported therapeutic values of chaya leaves has been substantiated with scientific experimentation. Therefore, the present study reports on nutritional composition of raw and cooked chaya leaves and the results compared with the nutritional composition of spinach leaves. Also a possible antidiabetic effect of the aqueous leaf extracts or chaya tea, administered through drinking water to streptozotocin-induced diabetic rabbits, was evaluated.

METHODOLOGY

Nutritional Composition

Young leaves and shoots of *C. chayamansa* were collected from greenhouse-grown plants. Raw and cooked (in microwave oven for 5 min) samples of the leaves and shoot were analyzed for their moisture content, crude fiber, fat, and ß-carotene using the AOAC standard methods (1984), for the protein content (N_2 content multiplied by 6.25) using modified semi micro-kjeldahl method of Searle (1974), for mineral contents using an atomic absorption spectrohotometer and for total carbohydrate using gas chromatography. All samples were analyzed in triplicate. Nutritional components and average nutritive value (ANV) of chaya leaves were compared to spinach leaves. The ANV was calculated using the empirical formula proposed by Grubben (1978): ANV/100g = g protein/5 + g fiber + mg Ca^{++}/100 + mg Fe^{++}/2 + mg carotene + mg vit C/40

Possible Antidiabetic Effect

The experimental animals (rabbits) for this study were supplied by Dr. Steven Lukefahr of the Department of Animal and Wildlife Sciences, Texas A&M University-Kingsville. All animals were housed and maintained in compliance with Texas A&M University-Kingsville IACUC policy on animal care and use. The rabbits were fed with standard rabbit chow and given water *ad libitum*. Diabetes was induced by a single subcuteanous injection of 60 mg/kg streptozotocin (STZ), after fasting for 18 h, according to the method described by Bonner-Weir et al. (1981). The rabbits exhibited post-STZ blood glucose levels that were at least double that of the pre-STZ levels one week after diabetes had been induced.

The leaves of *C. chayamansa* were collected from plants grown in the greenhouse. About 10 g of the leaves was extracted with boiling water (1000 mL) for 30 min until the volume of the water had been reduced to 90% of the original. The tea (900 mL) was filtered and used in the subsequent experiments. Two groups of 8 rabbits each were used. The first group of 8 rabbits were normoglycemic (non-diabetic). Four of the normoglycemic rabbits recieved water (control) only and the remaining 4 received chaya tea treatment only. The second group of 8 rabbits were hyperglycemic (diabetic). Four of the diabetic rabbits received water only and the remaining 4 received chaya tea only.

Before administering the tea or water (control), blood samples were obtained from the ears of 18 h fasted nondiabetic and diabetic rabbits using a capillary tube. Then the tea or water was administered orally through drinking water bottles *ad libitum*. Blood sampling was repeated at hourly intervals for 6 h after the oral administration. Blood glucose was determined using a blood glucometer (Miles Inc., Diagnostic Division, Elkhart, IN, U.S.). The mean blood glucose values ±SE were determined and the significance of the difference between the means of treated and control groups was established by Student's *t*-test.

RESULTS

Nutritional Composition

The nutritional analysis of chaya (*C. chayamansa*) leaves and spinach (*Spinacia oleracea* L.) are presented in Table 1 for comparison. Chaya leaves were found to contain substantially greater amounts of nutrients than the spinach leaves. The chaya leaf is especially high in protein (5.7%), crude fiber (1.9%), calcium (199.4 mg/100 g), potassium (217.2 mg/100 g), iron (11.4 mg/100 g), vitamin C (164.7 mg/100 g), and carotene (0.085 mg/100 g). The levels of chaya leaf nutrients, in this study, agree with published reports (Martin and Ruberte 1978; Munsell et al. 1949; Booth et al. 1992) and are two to threefold greater than most edible leafy green vegetables. In terms of the average nutritive value, chaya leaves [14.9] is by far superior to other leafy green vegetables such as spinach [6.4], amaranth [11.3], Chinese cabbage [7.0], and lettuce [5.4] (Grubben 1978). While some edible leafy green vegetables are usually good sources of mineral macronutrients (Levander 1990), chaya leaf furnishes appreciable quantities of several of the essential mineral macronutrients necessary for human health maintenance. For example, potassium has been shown to be an important mineral nutrient in the control of hypertension and in the reduction of risks of stroke (NRC 1989), calcium is important for ossification and iron is necessary for normal hematopoiesis (Hodges et al. 1978). Brise and Hallberg (1962) reported that vegetables, such as chaya, with high vitamin C content may enhance absorption of nonheme iron.

Analysis of raw and cooked samples of chaya leaves revealed that cooking may increase the relative composition of carbohydrate and fat and decrease relative composition of crude fiber and protein (Fig. 2). On the other hand, cooked samples of chaya leaves were considerably higher in calcium, phosphorus and iron while the potassium content was relatively lower than in the raw samples (Fig. 3). The increase in some of the mineral nutrients may be due to the cooking process, which allows extraction of the nutrients from the tissues, therefore increasing the percentage of mineral elements while decreasing moisture content (Booth et al. 1992).

Possible Antidiabetic Effect

Following the oral administration of chaya tea, the blood glucose levels of the diabetic rabbits were gradually lowered from a high of 118 (baseline at 0.0 h) to 87 six hours after administration. The blood glucose level of 87 is similar to blood glucose levels of normoglycemic rabbits on drinking water (Table 2). The blood glucose levels of non-diabetic control rabbits that were given chaya tea showed a slight increase (i.e. hyperglycemia) above the baseline 85 at 1 to 2 h after administration, but rapidly stabilized thereafter (Table 2). The reason for this transient hyperglycemia is unknown and needs to be investigated. The results obtained in this study suggest that in STZ-induced diabetic rabbits, aqueous leaf extracts of *C. chayamansa* may be effective for treatment of non-insulin dependent diabete mellitus (NIDDM) symptomatology. This is a first report on hypoglycemic effect of chaya plants. The present report is preliminary in nature and additional studies will be needed to properly characterize the antidiabetic potential of chaya in diabetic animals. Also further studies will be necessary to determine the effective dosage, mechanism of the hypoglycemic activity and the active hypoglycemic principle present in the leaves of *C. chayamansa*.

CONCLUSION

The potential of *C. chayamansa* for human food and health has a significant implication for the plant as a horticultural crop. Although demand for chaya, as a medicinal plant, has recently increased among the Hispanic population in the United States, the plant has the potential to make a significant nuritional contribution to the vegetable diet as well, because of its high nutrient content. The development of chaya as a new horticultural crop would transcend the ethnic popularity and create a worldwide market for the plant and its products, whether as a leafy green vegetable and/or as a therapeutic herbal tea.

It is noteworthy that the chaya plant is drought resistant, which is of a particular value in areas with short seasonal rainfall and shortage of green vegetables (Peregrine 1983). Growth of the plant is rapid and edible leaves and shoots could be produced within a short period (8 to 10 weeks). Propagation by cutting is easy and the woody stem sections readily root. Few pests and diseases are known to be of any significance in the cultivation of chaya plants. One disadvantage is the presence of toxic hydrocyanic glucosides in the leaves. However, cooking, which is essential, inactivates the toxic compound. Other *Cnidoscolus* (chaya) species are being examined in our laboratory at Texas A&M University-Kingsville to genetically select species with high leaf and shoot biomass yield and lower hydrocyanic glycoside content. Additionally, we are conducting research on genetic improvement, propagation, field production, potential for processing and marketing of chaya and its products in south Texas.

Turtlehead

Chelone glabra L.

Figure 109.—Turtlehead (*Chelone glabra*)

Other common names.—Balmony, white turtlehead, turtle bloom, fishmouth codhead, salt-rheum weed snakehead, bitter herb, shellflower.

Habitat and range.—This native plant grows in swamps and along streams from Newfoundland to Manitoba and south to Florida and Kansas.

Description.—Turtlehead is an erect, slender herb with a 4-angled stem 1 to 4 feet in height and short-stemmed, sharp-toothed leaves from 3 to 6 inches in length. The flower clusters, which are produced in late summer or early fall consist of showy, whitish or pinkish flowers about an inch in length, resembling in form the head of a turtle or a snake.

Part used.—The herb, especially the leaves, collected during the flowering period.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Wormseed

Chenopodium ambrosioides anthelminticum (L.) A. Gray.

Synonym.—*Chenopodium anthelminticum* L.

Other common names.—Chenopodium, American wormseed, Jerusalem-oak.

Habitat and range.—Wormseed occurs in waste places from New England to Florida and westward to California.

Description.—This common weed has a much-branched stem from 2 to 3 feet in height and numerous, lance-shaped leaves, the lower ones 1 to 3 inches in length and the upper ones much smaller. The greenish flowers are produced from July to September in closely crowded spikes mixed with leaves and are followed by small, green, roundish fruits each of which contains a very small black seed. The entire plant has a strong, disagreeable odor due to the volatile oil which is present.

Figure 123.—Wormseed (*Chenopodium ambrosioides anthelminticum*)

Part used.—The fruit, collected when ripe, and the volatile oil distilled from the fruit or from the entire plant. Wormseed is grown commercially mainly in central Maryland for the production of the oil.*

Information on the extraction of volatile oils from plants is contained in the following publication: Sievers, A.F. Methods of extracting volatile oils from plant material and the production of such oils in the United States. U.S. Dept. Agr. Tech. Bul. 16, 36 p. illus. 1928.

Good King Henry

Mercury, Markery, Fathen, Wild spinach

Chenopodiaceae *Chenopodium bonus-henricus* L.

Source: Magness et al. 1971

The plant is a stout, erect herb, up to 2.5 feet, with broad, triangular or ovate leaves. Leaves have wide spreading basal points, and are entire or undulate. Plants are sparingly cultivated for the leaves, used as pot herbs. The plant is similar to spinach both in general growth habit and use.

Season, seeding to first harvest: about 2 months.

Production in U.S.: No data. Apparently not commercial.

Use: As pot herb.

Part of plant consumed: Leaves and young stems.

Prunus cerasus L.

Rosaceae

Sour cherry

We have information from several sources:

Magness, J.R., G.M. Markle, C.C. Compton. 1971. Food and feed crops of the United States.

Exploration and Exploitation of New Fruit and Nut Germplasm—Maxine M. Thompson

Growing Cherries in Indiana—Cooperative Extension Service, Purdue University, West Lafayette, Indiana

Cherry—from Mark Reiger, Dept of Horticulture, University of Georgia.

Sour cherry kernel oil
Plum oil

Rosaceae *Prunus* sp.

Source: Magness et al. 1971

The pits of sour cherries contain about 28 percent of kernel, and the kernel contains 32 to 40 percent of a semi-drying oil. Pits from cherry processing plants are cracked, and kernels and shells separated mechanically. The expressed oil, after refining, is used as a salad oil and in the manufacture of cosmetics. There is some extraction of cherry kernel oil in the U.S.

Plum kernel oil is extracted and used in Europe in ways similar to those for cherry oil, but appears not to be extracted in the U.S. Plum and prune kernels contain 30 to 40 percent of semi-drying oil.

Last update February 18, 1999 by ch

Cherry, Sweet

Rosaceae *Prunus avium* L.

Source: Magness et al. 1971

The sweet cherry tree is an upright grower, medium in size, up to 40 or more feet, but usually held to 20 feet or less by pruning. The deciduous leaves are oblong-ovate. Fruits have smooth, thin skins which adhere to the fleshy pulp. They are globose to heart shaped, depressed at the stem, 0.75 to an inch in diameter. They are borne on 1 to 3 inch stems, in groups of 1 to 5. Color varies in different varieties from light red to near black, a few yellow.

Season, bloom to harvest: 80 to 100 days.

Production in U.S.: About 90,000 tons.

Use: Fresh eating, canned, maraschino.

Part consumed: All except pit.

Red fescue

Gramineae *Festuca rubra* L.

Chewing's fescue

***F. rubra* var. *commutata* Gaud.**

Source: Magness et al. 1971

Red fescue was introduced from Europe. It differs from sheep fescue in that it creeps by underground stems and forms a sod rather than growing in tufts. It is extensively used for lawns and erosion control in northern parts of the United States. Plants are hardy and vigorous. It is not highly palatable and is not generally used for pastures or hay. Chewing's fescue is a closely related kind but grows in clumps instead of forming a dense sod. It is also used for lawns and general purpose turf in shaded areas.

Scientific Name: *Mimosa pudica* Linn.
Family: Mimosoideae
English Name: Sensitive Plant, Bashful Mimosa, Humble Plant, Touch-me-not
Hindi Name: Chhui-Mui, Lajwanti, Lajjawati, Lajalu, Lajak

Botanical differences among the major species of *Mimosa*.

Characters	*M. pudica*	*M. himalayana* syn. *M. rubicaulis*	*M. hamata*
Plant	Small woody herbs or low-spreading undershrub with hairy and prickly branches, hairs glandular	A large straggling shrub, studded with straw-coloured, hooked prickels	A much branched, armed shrub, branches downy, with numerous straw-coloured, curced or straight prickles
Leaves	Bipinnate, sensitive to touch, pinnae 1-2 pairs, leaflets 10-20 pairs, linear, glabrous	Bipinnate, main rachis with hooked prickles, pinnae 5-11 pairs, linear-oblong	2-pinante, main rachis pubescent, some timely prickly, leaflets 6-10 pairs
Flowers	Heads small, peduncled, globose, axilalry, pink-purple, Calyx campanulate, Petals crenate towards base	Numerous, in globose heads, peduncles crowded at the ends of branchlets	4-merous in globose heads, peduncles axillary, crowded at the end of branches
Pods	1.5-2.5 cm long, closely prickly on the sutures	7-10 cm long, falcate, glabrous, one seeded joints, persistant but not prickly	5-7 cm long, falcate, consisting 4-8 one seeded joints, pubescent

Flowering and Fruiting time	Sept.-March in Indian conditions	August-Sept. and October in Indian conditions	Aug.-Nov. and Dec.-Feb. in Indian conditions

Useful Parts: Roots, leaves and flower heads.

Traditional Medicinal Uses: According to Ayurveda, root is bitter, acrid, cooling, vulnerary, alexipharmic and used in treatment of biliousness, leprosy, dysentery, vaginal and uterine complaints, inflammations, burning sensation, fatigue, asthma, leucoderma, blood diseases etc. According to the Unani system of medicine, root is resolvent, alternative, useful in diseases arising from blood impurities and bile, bilious fevers, piles, jaundice, leprosy etc.

Chemical Constituent: Contains an alkaloid Mimosine. Roots contain tannin, ash, calcium oxalate crystals and mimosin.

Other Uses
Grown as garden herb
Useful for green manuring
Fixes nitrogen
Can be used as fodder.
Suitable for growing in wastelands
Seed yield an oil like Soybean oil with similar properties

Chicken corn

Gramineae *Sorghum drummondii* (Steud.) Millsp. & Chase

Source: Magness et al. 1971

Chicken corn was apparently introduced by chance and became naturalized on black soils of Alabama around the middle of the last century. Later it largely disappeared as a naturalized plant. A selection has been increased recently, primarily for use in wild life plantings. It is a sweet sorghum of medium size. The seed shatters in late summer, remains dormant over winter, and germinates the following spring. Seed is in limited commercial production.

Pipsissewa

(1) *Chimaphila umbellata* (L.) Barton; (2) *C. maculata* (L.) Pursh.

Synonyms.—(1) *Pyrola umbellata* L., *Chimaphila corymbosa* Pursh; (2) P. *maculata* L.

Pipsissewa

Figure 84.—Pipsissewa (A, *Chimaphila umbellata* B, *C. maculata*)

Other common names.—(1) Common pipsissewa, prince's pine pyrola, rheumatism weed, bitter wintergreen, ground holly, king's-cure, love-in-winter, noble pine, pine tulip; (2) striped pipsissewa, spotted pipsissewa, spotted wintergreen, spotted piperidge, ratsbane, dragon's-tongue.

Habitat and range.—Common pipsissewa is found in dry, shady woods, especially in pine forests, from New Brunswick to British Columbia and south to Georgia, Mexico, and California. Spotted pipsissewa occurs in similar places, but its range extends only to Minnesota and south to Georgia and Mississippi.

Description.—Common pipsissewa is a small herb a foot or less in height with a long, running, partly underground stem and shining, dark-green, evergreen, somewhat leathery leaves, 1 to 2 inches long, rather crowded toward the top of the stem. From about June to August its handsome, waxy-white or pinkish fragrant flowers are borne in nodding clusters from the top of the erect stem.

The spotted pipsissewa is readily distinguished from the former by its leaves, which are olive green marked with white along the midrib and veins

Part used.—The leaves and the herb of both species.

Chinese artichoke

Chorogi, Knotroot

Labiatae *Stachys sieboldii* Miq.

Source: Magness et al. 1971

The plant is mint-like, up to 18 inches, with ovate to lanceolate leaves. It produces numerous small, slender tubers, the edible part, just under the soil surface. These tubers are white, with crisp flesh which can be eaten raw or cooked. The plant and edible parts are comparable to potatoes, both in culture and exposure to pesticides. The tubers do not store well. Chinese artichoke is not grown commercially in the United States, but may be found occasionally in home gardens.

Cabbage, Chinese

Celery cabbage, Wong Bok, Pe-Tsai, Bok Choy, Repollo chino, Peking cabbage, Kim chee

Cruciferae *Brassica campestris* L. (Pekinensis group)

Source: Magness et al. 1971

The general growth habit of Chinese cabbage is similar to cabbage, but both leaves and heads are elongated and relatively narrow. Heads are less densely packed, and leaves are much thinner than in cabbage. Heads range from densely packed (Wong Bok or Chee-foo) to semi- or loose-heading (Shantung or Santo) varieties. As with cabbage, initial leaves are somewhat spreading. These, as well as leaves immediately surrounding the edible portion, are usually discarded. The Wong Bok type head is up to 20 inches long and 4 inches wide and is quite dense. The Chinese word "Bok Choy" refers to all leaf-heading vegetables.

Production in U.S.: 1,200 acres reported 1959 census. Possibly 10,000 tons.

Use: Fresh, as salad or as pot herb.

Parts of plant consumed: Inner leaves.

Last update February 18, 1999 by ch

Jujube

Ber, Chinese date

Rhamnaceae *Ziziphus jujuba* Mill.

Source: Magness et al. 1971

The jujube or Chinese date, introduced into this country from China, is a medium size tree, up to 25 or more feet, with glossy green, deciduous foliage.

It thrives best in warm, dry climates; but will withstand winter temperatures down to -20 F. Fruit is generally dark brown when ripe, oval to pyriform in shape, 1 to 2 inches diameter, with a single stone. Fruit will dry if left on tree, similar to figs. Skin is smooth and thin until drying of fruit occurs, then becomes wrinkled. Pulp is dryer than in most fruits.

Season, bloom to mature: 2 to 4 months, depending on kind and climate.

Production in U.S.: Not commercial. Scattered trees, mostly home gardens.

Use: Some fresh eating, confections.

Part of fruit consumed: All except stone.

Last update June 31, 1996 by aw

Fringetree

Chionanthus virginica L.

Other common names.—American fringetree, white fringe, flowering ash, poison ash, graybeard tree, old-man's-beard, shavings, snowdrop tree, snowflower.

Figure 53.—Fringetree (*Chionanthus virginica*)

Habitat and range.—The fringetree is found in moist thickets and along streams from Delaware to Florida and Texas.

Description.—The fringetree is from 6 to 20 feet in height, with the trunk covered with a light-colored bark. It has smooth entire leaves. The white flowers, which from their drooping character give a fringelike appearance, are produced in May and June, are borne in dense clusters, and are followed by fleshy, bluish-black fruits containing a 1-seeded nut.

Part used.—The bark of the root.

Safed Moosli (*Chlorophytum borivilianum* L.): Medicinal and Wonder Crop

Pankaj Oudhia
Society for Parthenium Management (SOPAM)
28-A, Geeta Nagar, Raipur - 492001 India
pankaj.oudhia@usa.net
www.celestine-india.com/pankajoudhia

Copyright © 2001. All Rights Reserved. Quotation from this document should cite and acknowledge the contributor.

India is bestowed with a wealth of medicinal plants, most of which have been used in *Ayurveda*, *Unani* systems of medicines, and by tribal healers. Safed moosli (*Chlorophytum borivilianum* L., Liliaceae) holds an important position in Indian herbal medicine. The roots are widely used as a natural "sex tonic" and is an integral part of more than 100 herbal drug formulations (Oudhia 2001a). Although Indian forests are rich in *safed moosli* demand is increasing rapidly in Indian and international drug markets. Foreign demand has been estimated as 300-700 tonnes annually (Bordia et al. 1995), a quantity that Indian forests cannot sustain. This has created a pressure on Indian forests and if steps for timely conservation are not taken, the Indian forests will lose this valuable plant (Oudhia 2001b). At present the availability of *Chlorophytum* is decreasing and obnoxious weeds like *Parthenium hysterophons* and *Lantana* are taking its place (Oudhia 1996).

Dried roots of *Chlorophytum* contain 42% carbohydrate, 80–9% protein, 3–4% fiber and 2–17% saponin (Bordia et al. 1995). Research studies on *Chlorophytum* conducted in India and elsewhere indicate that saponins are responsible for medicinal properties. Saponins are thought to be highest in roots of forest origin.

More than 175 species of *Chlorophytum* have been reported in the world. *Chloophytum comosum* is widely used as ornamental plant where it is commonly known as spider ivy, spider plant, aeroplane plant, or walking anthericum. Thirteen species of *Chlorophytum* have been been reported in India. All these species differ in appearance, native species are sold as *sufed moosli* in the Indian drug market. *Chlorophytum boriviliahum* produces the highest yield and highest saponin content. Other native Indian *Chlorophytum* species (Table 1) include *C. arundinaceum, C. tuberosu, C. laxum,* and *C. breviscapum* (Oudhia 2000a).

Table 1. Different species of *Chlorophytum* available in India.

Species	Distribution
C. arundinaceum Baker	All districts of Chota Nagpur, Vindhya, Satpura and Aravali Hills, parts of Central India. Taria region of N-E Himalayas in Assam. West Bengal and Bihar.
C. attenuatum Baker	Western Ghats, southwards to Comibatore, West Peninsula.
C. borivilianum	Dangs Forests (Gujarat). Aravali Hills
C. laxum R.Br.	Katki Hills, Belgaum, Dharwar, North and South Kanara, Deccan peninsula in India.
C. tuberosum (Rox b.) Baker	Parts of Konkan to Travancore in Kerala, Eastern Himalaya, Bihar and West Bengal.
C. hreviscapum	Sikkim Himalaya, Belgaum and South Peninsula.

In nature, Moosli propagates vegetatively through its fleshy roots., rarely by seed. The black angular seed is similar to onion seed in appearance. Seed have poor germination and low viability. Seed rates of 3 quintals/hectare is considered optimum for growers.

Chlorophytum is found in soils rich in organic matter. It requires bright sunlight for good growth (Oudhia and Tripathi 2001). Many tribal communities of India use the fresh leaves of Safed Moosli as potherb. (Oudhia and Joshi 2000) but the roots are the useful part of the plant for medicinal purposes. Once the root is harvested reseeding rarely occurs.

Innovative Indian farmers have initiated commercial cultivation of safed moosli. The crop is a popular rainy season (kharif crop) in India and a commercial root harvest can be obtained in 3–4 months. Spacing 30 × 15 cm is optimum. The crop seems adapted to a wide range of conditions. Few insect pests have been reported (Oiudhia 2000b, 2001e). Saponin content may be affected by fungicides and synthetic phyrethroides. Many moosli farms have started selection of cultivars.

There is now a heavy demand of organically grown safed moosli with high saponin content in national and international drug market. In India moosli-based products are coming regularly to the market. The area under this crop is increasing rapidly in India.

Xanthium strumarium

Contributor: Pankaj Oudhia

Copyright (c) 2002. All Rights Reserved. Quotation from this document should cite and acknowledge the contributor.

Chotagokhru or Kuthua, *Xanthium strumarium* L.

Xanthium strumarium L., Compositae, is a common weed found in India (Oudhia 2001; Oudhia and Dixit 1994). In different Indian languages *Xanthium* is known as banokra, chotadhatura, chotagokhru, kuthua (Hindi) godrian (Gujrati), aristha, itara, kambu-vanamalini, sarpakshi (Sanskrit), dumundi, dutundi (Marathi), maruloomatham (Tamil), maruluummatti (Kanarese), and marulam athangi (Telugu). The reason behind its common name chotagokhru is the shape of its fruit, which look likes the cow's toe (chota - small; go - cow; khuru - toe). In many parts of India, it is known as adhasisi (in English adhasisi means hemicrania; as this weed is used for the treatment of this common disease). In English, *Xanthium* is known as cocklebur or burweed. The genus *Xanthium* includes 25 species, all of American origin *X. spinosum* Linn and *X. strumarium* Linn are used medicinally in Europe, North America and Brazil; *X. canadens* Mill. is used in North America and Brazil and *X. strumarium* Linn in China, India and Malaya (Caius 1986). Two species of *Xanthium*, *X. indicum* and *X. strumarium* have been reported in India. The origin of *X. strumarium* is North America. It was introduced in India and spread like weed. It commonly grows in wasteplaces and along river banks in warmer parts.

X. strumarium is an annual herb with a short, stout, hairy stem. Leaves broadly triangular-ovate or suborbicular; flower heads in terminal and axillary racemes; white or green; numerous; male upper most; female ovoid, covered with hooked bristles; Fruit obovoid, enclosed in the hardened involucre, with 2 hooked beaks and hooked bristles. Flowering time in India is August-September. It can be propagated through seeds. This weed is easily dispersed through animals as the fruits have hooked bristles and 2 strong hooked beaks (Agharkar 1991).

The whole plant, specially root and fruit, is used as medicine. According to Ayurveda, *X. strumarium* is cooling, laxative, fattening, anthelmintic, alexiteric, tonic, digestive, antipyretic, and improves appetite, voice, complexion, and memory. It cures leucoderma, biliousness, poisonous bites of insects, epilepsy, salivation and fever. The plant of *Xanthium* yields xanthinin which acts as a plant growth regulator. Antibacterial activity of xanthinin has also been reported. Seed yields a semi-drying edible oil (30-35%) which resembles sunflower oil and used in bladder infection, herpes, and erysipelas. Cake can be used as manure whereas shell can be used as activated carbon (Oudhia and Tripathi 1998; Sastry and Kavathekar 1990). The plant has been reported as fatal to cattle and pigs.

Simon, J.E., N. Beaubaire, S.C. Weller, and J. Janick. 1990. Borage: A source of gamma linolenic acid. p. 528. In: J. Janick and J.E. Simon (eds.), Advances in new crops. Timber Press, Portland, OR.

Borage: A Source of Gamma Linolenic Acid

James E. Simon, Nancy Beaubaire, Stephen C. Weller, and Jules Janick

Borage (*Borago officinalis* L.) is an annual herb of recent interest because the seeds are a rich source of gamma linolenic acid (GLA; gamma-18:3Δ6,9,12). As an intermediate fatty acid in the biosynthesis of prostaglandins, GLA, an unusual fatty acid, is of medicinal value. The oil also appears promising in treating atopic eczema. GLA is obtained principally from seeds of the evening primrose (*Oenothera biennis*) and selected *Ribes* spp., although borage seed appears to be the highest known plant source of GLA (17-25% gamma-18:3 from a total seed oil content of 28-38%).

Large-scale commercial production of this crop presents unique challenges because of the plants indeterminate vegetative growth, lack of concentrated flowering and seed set and non-uniform seed maturation. Since 1984, we have investigated borage seed production and GLA metabolism. Field studies were conducted to determine the optimum plant population and nitrogen levels and a prototype mechanical harvester to vacuum seed from the soil surface was built. Experimental seed yields of 753 kg/ha were obtained when multiple nondestructive harvests of seeds were periodically collected from the soil surface, plus a single destructive harvest where plants were cut and seeds harvested. Simulation of a single destructive harvest yielded only 35-40% of the total potential seed yield because of significant seed loss due to seed shattering.

Borage is susceptible to a wide range of insects and disease pests, and is a weak competitor with weeds. Supporting weed control studies identified several promising preemergent herbicides and other compounds that could eradicate the plant No satisfactory postemergent herbicides were identified.

Studies on the genetic variation of seed lines indicated a wide range of total fatty acids and GLA content. Nonshattering types were not found among the more than 50 accessions evaluated. The development of nonshattering seed fines high in fatty acid and GLA would overcome the present production limitations. However, in the interim, the refinement of a seed harvesting unit which can follow a mechanical combine could make the commercial production of borage a more attractive enterprise.

McDaniel, R.G. 1990. Breeding arid-adapted pyrethrum for insecticide production in the desert

southwest. p. 529. In: J. Janick and J.E. Simon (eds.), Advances in new crops. Timber Press, Portland, OR.

Breeding Arid-adapted Pyrethrum for Insecticide Production in the Desert Southwest

Robert G. McDaniel

Dried pyrethrum flowers are a source of biorational insecticides called pyrethrins which show minimal mammalian toxicity and biodegrade rapidly in the environment. In combination with synergists, pyrethrins are extremely effective for control of insects in human habitations, dairy and horse barns, and food manufacture. At present, all pyrethrins used in the United States are imported. Most are supplied in bulk by East African Countries including Kenya. These sources can be very unreliable, which in turn precipitates wide swings in supply and price. This limits the utility of pyrethrins in domestic pesticides.

Following an eight year breeding program we have, developed pyrethrum (*Chrysanthemum cinerariaefolium*) germplasm adapted to environmental stresses inherent to desert irrigated agriculture. Moderate winters, combined with wide differences in day/night temperatures (a result of the dry desert climate) somewhat mimic the high elevation equatorial environments of East Africa and Equador where high pyrethrin contents are achieved. Arid adapted, stress-resistant pyrethrum clones have been bred which show a good balance of pyrethrins and which yield greater than 2% pyrethrins (dry weight basis) analyzed by HPLC. At Arizona latitude, pyrethrum behaves as a perennial showing a single flush of blooming in April. Simultaneous flowering makes mechanized harvesting feasible. Favorable climatic conditions coupled with intensive irrigated agriculture technology of the American Southwest make it probable that *C. cinerariaefolium* will become a viable perennial crop in Arizona. It is hoped that our work will promote new domestic production of this high value insecticide crop.

Japanese greens

Chopsuey greens, Skungiku, Edible-leaved chrysanthemum

Compositae *Chrysanthemum coronarium* L.

Crown Daisy

Garland chrysanthemum

C. *spatiosum* Bail.

Source: Magness et al. 1971

These two species are used sparingly as pot herbs. For that purpose young plants are harvested when 4 to 6 inches high. Leaves are glabrous, lobed, and grow as a rosette. They are aromatic and are cooked like spinach. In exposure of edible parts they are comparable to spinach.

Chufa

Ground almond, Edible rush, Rush nut

Cyperaceae *Cyperus esculentus* L.

Source: Magness et al. 1971

Chufa plants are grown for the edible tubers. The top is grass-like, with simple leaves and flower stalk rising from the ground surface, up to 3 feet. Tubers are small, 1/2 to 3/4 of an inch long, cylindrical and hard, produced entirely underground. They are eaten raw or baked. Plants are propagated by planting the tubers, similar to potatoes. They are a minor crop, grown mainly in the southern states.

See chufa oil.

Season, planting to harvest: 5 to 6 months.

Production in U.S.: No data. Mainly home gardens, a minor crop.

Use: Tubers eaten raw or baked. Sometimes used as coffee substitute.

Part of plant consumed: Tubers only.

Last update February 18, 1999 by ch

Chufa oil

Cyperaceae *Cyperus esculentus* L.

Source: Magness et al. 1971

The tubers of Chufa contain 20 to 28 percent of a non-drying oil. The oil is obtained by pressing the cleaned tubers and has a mild, pleasant flavor. The separated emulsion of oil and juice, obtained by pressing, is consumed in quantity in Europe, especially Spain, as a drink (Horchata de Chufas).

Cinnamon

Canela

Lauraceae *Cinnamonium zeylanicum* Garc. ex Blume

Source: Magness et al. 1971

This is a small semi-tropical tree, 20 to 30 feet high, with thick ovate to lanceolate leaves 4 to 7 inches long. It is hardy in the Gulf States of the U.S. Most of the cinnamon of commerce comes from Ceylon. It is the ground bark of the tree. The best quality of bark is from branches at least 2 years old. Cinnamon is widely used in cookery and confections. The flavor is due to a volatile oil contained in the bark. The cinnamon oil of commerce is extracted from inferior bark, not suitable for grinding.

Last update February 18, 1999 by ch

Ciruela de Madagascar

Governor's plum

Flacourtiaceae *Flacourtia indica* (Burm. f.) Merr.

Source: Magness et al. 1971

Tropical shrub or small tree, sometimes sparsely armed with sharp, stout thorns. Fruits are subglobose and may be slightly over 1 inch in diameter. The fruits are purplish red or blackish, and are surmounted by the remains of the pistils. The reddish juicy pulp encloses 8 to 10 small seeds. The fruits may be eaten fresh or used in jams and jellies.

Hadjod or Hadjora [*Cissus quadrangula* (L.)]

Contributor: Pankaj Oudhia

Copyright (c) 2002. All Rights Reserved. Quotation from this document should cite and acknowledge the contributor.

Scientific Name: *Cissus quadrangula* L.
syn. *Vitis quadrangula* (L.) Wallich ex Wight & Arn.

English Names: edible-stemmed vine

Common (Indian) Names
Sanskrit: asthisonhara; vajravalli Hindi: hadjod; hadjora; harsankari
Bengali: hasjora; harbhanga
Marathi: chaudhari; kandavela
Gujrati: chadhuri; vedhari
Telugu: nalleru
Tamil: pirandai
Canarese: mangaroli

Family: Vitaceae

Related Species
The genus *Cissus* include over 350 species. Some important species are:
Cissus adnata Roxb. syn. *Vitis adnata* Wall. ex. Wight. (Malyalam: nadena; Telugu: kokkita yaralu)
Cissus discolor Blume syn. *Vitis discolor* Dalz.
Cissus pallida Planch. syn. *Vitis pallida* W & A. (Canarese: kondage; Telugu: nalltige; Oriya: takuonoil)
Cissus repanda Vahl. syn. *Vitis repanda* W & A.
Cissus repens Lan. syn. *Vitis repens* W & A.
Cissus setosa syn. *Vitis setosa* Wall.

Distibution: In India, it grow as wild plant. Also under cultivation in fairly large areas.

Botany: Climbing herb, tendrils simple, opposite to the leaves, leaves simple or lobbed, sometimes 3-folialate, dentate. Flowers bisexual, tetramerous, in umbellate cymes, opposite to the leaves, Calyx cup-shaped, obscurely 4-lobed. Fruit globose or obovoid fleshy berries, one seeded, dark purple to black; seeds ellipsoid or pyriform. Flowering and fruiting time May-June.

Medicinal Properties and Uses: It is mainly used as healer of bone fractures. It is one of the very frequently used herb by traditional bone setters of India. (In Hindi Hadj=bone; Jod=to fix). It is also used for piles, asthma, digestive troubles, cough, and loss of appetite.

Ayurvedic formulations: Asthisamharaka juice, powder and decoction of dried stalks.

Chemical constituents: Stem isolates include 3- keto steroids, onocer-7-en-3α, 21β-diol (I) and onecer-7-en-3α, 21α-diol (II).

Other Uses: Stems and roots yield strong fiber. Young shoots are used in curries.

Cultivation: In India, it is mainly grown in fence and in between tree plantations. The fence wire and trees act as support to this climbing herbs. In many parts, it is grown as field crop and given support with the help of Bamboo sticks.

Climate: It requires warm tropical climate.

Soils: It can be grown in various soils but prefers loamy soils.

Planting Season: Kharif (after commence of monsoon rains in June-July in India).

Propagation: Stem cuttings.

Spacing: 30 × 30 cm.

Nutrients: In general it is grown organically. Initially, farm yard manure is applied (10-12 tonnes/ha.)

Pest Infestation: No major insects or diseases have been reported.

Harvest: It is a perennial crop. Stems are cut and air dried 11 months after sowing. Fresh stem cuttings are sold as planting material.

Citron

Stock melon, Preserving melon

Cucurbitaceae *Citrullus lanatus* var. *citrioides* (Bailey) Mansf.

Source: Magness et al. 1971

Citron is a plant of the same species as watermelon, but the fruit flesh is white, hard and inedible in the raw state. The plant is prostrate growing. The fruits are round to oval, up to 6 inches long, with smooth surface, resembling small watermelons. The flesh is used for making conserves and pickles. Citrons are sometimes used as feed for hogs.

Season, planting to harvest: 4 to 5 months.

Production in U.S.: No data. Very minor.

Use: Conserves, pickling, stock feed.

Part of plant consumed: White flesh

Citronella Horsebalm

Collinsonia canadensis L.

Other common names.—Stoneroot, Collinsonia, knob-root, knob glass, knobweed, knotroot, horseweed, richweed, richleaf, ox balm.

Habitat and range.—Citronella horsebalm is found in moist shady woods from Maine to Wisconsin and south to Florida and Kansas.

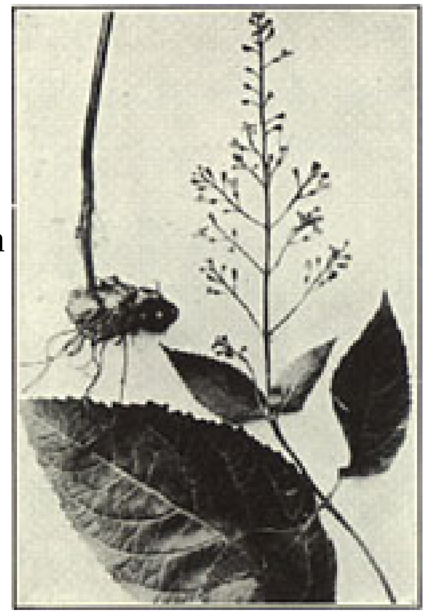

Figure 39.—Citronella horsebalm (*Collinsonia canadensis*)

Description.—This plant is a tall herb growing as high as 5 feet with a stout, erect, branched stem, smooth or the upper part hairy. The leaves are from 3 to 8 inches long, pointed, sometimes heart-shaped at the base, and coarsely toothed. From July to October the plant produces large, loose panicles of small pale-yellow, lemon-scented flowers. The entire flowering herb possesses a pleasant, lemonlike odor. The root, even when fresh, is very hard, hence the name stoneroot. It is horizontal, large, thick, and woody, the upper side rough, knotty, and irregularly branched. It has a rather disagreeable odor and a spicy, pungent taste.

Part used.—The root, collected in autumn.

Cloves, Clove Tree, Clavos

Syzygium aromaticum (L.) Merr. & Perry

syn. *Eugenia caryophyllus* (Spreng.) Bullock & Harrison.

syn. *E. aromatica* (L.) Baill.

syn. *Jambosa Caryophyllus* (Spreng. Niedenzu)

Myrtaceae Source: Magness et al. 1971

The clove tree is a small, tropical evergreen, up to 20 feet tall, with oblong leaves, 5 to 10 inches long and 2 to 4 inches wide. It is native in the Philippines and nearby islands, but has been introduced into all tropical countries. Zanzibar and Pemba are the principal producers of cloves and clove oil. The tree is not hardy in continental U.S. The cloves of commerce are the dried flower buds, which grow in clusters at the ends of branches and are harvested and dried before they open. Cloves are widely used in cookery and confections. The extracted clove oil is widely used in cosmetics and confections. By oxidation, it produces vanillin.

Sainfoin

Esparcet, Holy clover

Leguminosae *Onobrychio viriaefolia* Scop.

Source: Magness et al. 1971

Sainfoin was introduced from Turkey recently and is showing promise as a hay and pasture crop for the Northern Plains, particularly Montana and Western North Dakota. It is a perennial legume, growing to three to four feet, with pinnate-compound leaves. Under tests in the above area it has out-yielded alfalfa and has not caused bloat in cattle. It appears to be about equal to alfalfa in palatability and nutritive value. It does not compete well with weeds as regrowth after mowing is limited.

Alsike clover

Swedish clover

Leguminosae*Trifolium hybridum* L.

Source: Magness et al. 1971

Alsike clover is believeed native to northerrn Europe. It was introduced into the United States about 1839 and is now mainly grown in states bordering on the Great Lakes, in northerrn California and in Oregon. Its special merit is its adaptation to wet soils, even tolerating some flooding. It is more tolerant to both acid and alkaline soils than other clovers. The stems are quite slender, up to 3 feet long, and tend to be prostrate except in dense stands. The trifoliate leaves are long stemmed with obovate leaflets. Flower heads are not at the terminal of the main stem but are at the terminals of branch stems. They are white or pink in color. Both stems and leaves are smooth. Alsike clover is valuable both for pasture and hay on soils too wet or too acid for other clovers.

Sweet clovers

Leguminosae, Fabaceae *Melilotits* sp.

Source: Magness et al. 1971

The sweet clovers are native to temperate Europe and Asia. Although reported as found in Virginia as early as 1739, it was not until the present century that their great value for soil improvement, pasture, hay and silage became recognized. During the decade 1948-57, seed production in the United States averaged about 46,000,000 pounds annually with near 16,000,000 additional pounds imported - sufficient to seed more than 5,000,000 acres. Since 1960, however, seed production has declined in this country to an annual average of about 21,600,000 pounds. Most of the sweet clovers grown here are biennial, although some annual kinds are grown. They are adapted only to soils that are near neutral in acidity. Major production is in a belt from the Great Lakes west to Montana and south to the Gulf of Mexico in areas baving 17 inches or more annual precipitation. All the biennial sweet clovers fix large amounts of atmospheric nitrogen. The deep-penetrating tap roots decompose after the second year, so the crops are very useful for opening up subsoil. They are therefore probably the best of the crops for soil improvement.

The sweet clovers have a high content of coumarin which reduces palatability. More important, in hay spoiled due to excess moisture when stored or in improperly prepared silage, dicoumarol, which reduces the clotting of blood, is formed. Animals fed such hay or silage are subject to excessive external or internal bleeding.

The species of *Melilotus* of most value agriculturally are described as follows.

White sweet clover

Leguminosae *Melilotus alba* Desr.

Source: Magness et al. 1971 In general, the white-flowered forms of sweet clover are somewhat ranker growing, heavier yielding, and have coarser stems than the yellow-flowered. They are later maturing so are generally preferred for pastures in areas of ample moisture. The more vigorous growth and heavier yields make them somewhat superior for soil improvement. In growth habit and appearance the two are similar except for flower color. Most of the *M. alba* grown is so-called common white. Two selected varieties in addition to common are in the trade. Spanish is leafier and somewhat more productive than common and is recommended for higher rainfall grain areas of the Pacific Northwest, as well as the Great Plains. Evergreen is late maturing, providing long grazing and heavy forage yields. It is generally adapted in the Corn Belt. Penta is a low-coumarin variety, bred in Wisconsin. Annual forms of *M. alba* are also in the trade. Hubam, Floranna, and Israel are such kinds. They are most useful in the central and southern regions where the growing season is relatively long.

Last update June 26, 1996

Yellow-flowered sweet clover

Leguminosae *Melilotus officinalis* (L.) Lam.

Source: Magness et al. 1971

The yellow-flowered sweet clovers grown in the United States are all biennial. As compared to white-flowered *M. alba*, the yellow-flowered is finer stemmed, matures earlier in summer, is more tolerant to drought and competition with companion crops, and gives a better quality but lower yield of hay. Because of better drought tolerance the yellow-flowered is better adapted to the Great Plains. The first season, a central much-branched stem is produced with a deep tap root which becomes fleshy in the fall. The second year, crown buds start growth early with vigorous, rather coarse stems. Leaves are trifoliate, the leaflets being long-oval in shape. For hay, the second season crop should be cut early. Several varieties are in the trade. Madrid makes strong seedling growth, is leafy and later maturing the second year, well adapted to the Great Plains. Gold Top is vigorous and late maturing, giving longer pasture. Erector, developed in Canada, makes good growth in the Northeastern Great Plains.

Leung, A.Y. 1990. Chinese medicinals. p. 499-510. In: J. Janick and J.E. Simon (eds.), Advances in new crops. Timber Press, Portland, OR.

Chinese Medicinals

Albert Y. Leung

INTRODUCTION

Natural products have been used for medicinal purposes since ancient times. These include materials from plant, animal, and mineral sources, with the majority derived from plants.

Traditions of materia medica differ among different cultures. Some are rudimentary and primarily verbal while others are extremely extensive and well documented. Examples of the former include medicine as practiced in the jungles and remote regions of Asia, Africa, Australia, and tropical America. This form of medical practice still incorporates a sizable amount of magic or witchcraft but is the one that has captured and continues to capture a major part of our attention. This is due to a number of reasons, including the following two. One, it satisfies the pioneering American spirit where one goes after something exciting that can produce headlines; the end result, which is to seek leads to effective drugs, often appears to be secondary. Two, due to the lack of easy access to non-English or non-European medicinal records, jungle medicine seems to be the only alternative for most American or Western researchers.

In contrast to the primitive practice of herbal medicine and its verbal tradition as currently found in the jungles, there are some very extensively documented medical traditions that are out of reach of most Western researchers. This is not due to a separation by physical distance, but rather by the language barrier. The most extensive and best documented source of materia medica can be found in traditional Chinese medicine. I hope this paper can serve as an introduction to this so far largely untapped resource.

HISTORY

Although Chinese materia medica may not have as long a history as those of Egypt or India, it is the most well-documented and enjoys the most continuous use. Today, the majority of Chinese sill depend on it regularly for their health care and so far little of it has been "rationalized" out of existence by modern science, a contrast to traditional medicinals of some other cultures. It is extremely tempting for us to rationalize the effects of an herb or herbal preparation based on the often limited chemical or biological data on it. When we cannot capsulize our rationalization in a familiar mold, we often tend to label the herb as worthless. Conversely, if our rationalization fits a preset mold that we can understand, we tend to consider the problem solved and pronounce the medicines either "active" or "inactive." Examples of such medicinals include rhubarb, aconite, and cinnabar.

When we see the word rhubarb (root/rhizome), we instinctively think of it as a cathartic because we in America tend to judge the value of a plant drug by its best known chemical components which in this case happen to be cathartic anthraglycosides. We also associate aconite and cinnabar with strong poisons because of the toxic chemicals they normally contain (aconitine and mercuric sulfide). Yet in Chinese medicine, all three are commonly used for purposes other than those most Westerners know. For example, rhubarb is one of the most used medicinals for upper gastrointestinal bleeding in China, as evidenced by the large number of clinical reports on this use (Jiao et al. 1980, Jiao et al. 1988, Sun et al. 1986); processed aconite is an ingredient in some Chinese tonics; and cinnabar is a commonly used sedative, although we normally would consider it an antiseptic for external applications only.

Chinese herbal medicine is empirically based. It is the accumulated knowledge of more than four thousand years of practical experience. Based on ancient literary records, we now know that back in 1100 BC during the West Zhou era, Chinese medicine had already developed into different branches, including disease therapy, ulcer therapy, diet therapy and veterinarian medicine.

The following are some of the most well-known documents on Chinese medicinal plant use:

Wu Shi Er Bing Fang (Prescriptions for Fifty-two Diseases)

The first written record exclusively devoted to disease treatment was compiled sometime between 1065 and 771 BC (Sun 1986). It is the *Wu Shi Er Bing Fang (Prescriptions for Fifty-two Diseases)*, which was only discovered in 1973 during the excavation of the Ma Wang Dui tomb at Changsha, Hunan. Prior to that discovery, the *Shen Nong Ben Cao Jing (Shennong Herbal)*, compiled sometime between the 1st century BC and the 2nd century AD, had been the earliest record of Chinese materia medica.

During the excavation of the *Ma Wang Dui* tomb (dated 168 BC), numerous drugs were found in sachets, two of which were clutched in the hand of a skeleton. The drugs positively identified include cassia or Chinese cinnamon, magnolia flower bud (*xinyi*, *Magnolia* spp.), sour date kernel (*suanzaoren*, seeds of *Ziziphus* spp.), ginger [*ganjiang*, *Zingiber officinalis* (Willd.) Rosc.], *gaoben* (rhizome of *Ligusticum* spp.), eupatorium herb [*peilan*, *Eupatorium fortunei* Turcz.], and Sichuan peppercorn [*huajiao*, fruit of *Zanthoxylum bungeanum* Maxim.]. Among other finds were some well-known Chinese classics and the silk scroll copy of the *Prescriptions for Fifty-two Diseases.*

The Prescriptions lists 52 diseases, with 283 known prescriptions for their treatment; over two-thirds of the prescriptions contained two or more components (Chen 1987b). Some of the identified diseases along with the number of prescriptions indicated for each disease are given below:

Disease	No. of prescriptions
Skin ulcers and carbuncles	42
Urinary problems	29
Hernia	24
Wounds and injuries	17
Frostbite	14
Snake bites	13
Warts/tumors	10
Internal hemorrhoids	9
External hemorrhoids	4
Poison arrow wounds	7
Lacquer sores (dermatitis)	7
Convulsions from wounds	6
Male sexual disease(s)	5

Mad dog bites	3
Infantile convulsions	2
Malaria	2

Based on preliminary studies, there are 247 drugs listed, many of which have not been identified or found in later herbals such as the *Shennong Herbal*. One third are derived from mineral or animal sources. Among the identified plant drugs are the following:

Qinghao [herb of *Artemisia annua* L.]
Magnolia flower bud [*Magnolia* spp.]
Licorice [root of *Glycyrrhiza* spp.]
Baizhi [root of *Angelica dahurica* (Fisch. ex Hoffm.) Benth. et Hook. f.]
Fuling [sclerotium of *Poria cocos* (Schw.) Wolf]
Huangqi [root of *Astragalus* spp.]
Ginger [rhizome of *Zingiber officinale* (Willd.) Rosc.]
Aconite [main root of *Aconitum carmichaeli* Debx.]
Fangfeng [root of *Ledebouriella divaricata* (Turcz.) Hiroe]
Shaoyao [root of *Paeonia lactiflora* Pall.]

All above drugs are still commonly used in traditional Chinese medicine. Some have been extensively studied by modern scientific methods, including chemical analysis and biological assays, while others have barely been examined. The most extensively studied and well known to American scientists are probably *qinghao,* licorice and *huangqi*. Although modern studies of these ancient drugs have yielded the new antimalarial qinghaosu (artemisinin) from *qinghao,* they have not been able to derive any exciting new "modern" drugs from the other two. Yet, these herbs continue to be two of the most widely consumed in China.

One of the most widely used drugs in treating rhinitis, including allergic rhinitis (e.g. hay fever), is magnolia flower bud. Its written use record dates back to the *Prescriptions* and its efficacy has been repeatedly reported in modern biomedical literature, though rarely in combinations containing less than three drugs (Ren 1985). Despite the universal occurrence of hay fever and the continued interest in treating this condition, the time-tested magnolia flower has not been exploited by Western drug developers.

Shen Nong Ben Cao Jing (Shennong Herbal)

While the *Prescriptions* is the earliest Chinese record devoted to diseases treated with drugs, the *Shennong Herbal* is the earliest record on Chinese drugs. This herbal, compiled about two thousand years ago, records 365 drugs, describing their sources, properties and uses as well as many cases of their incompatibilities. The drugs are divided according to properties into three categories: superior (120 drugs), medium (120 drugs) and inferior (125 drugs). Superior drugs are those considered at that time to be nontoxic, which could be safely taken in large amounts for extended periods; they are what we now know as tonics. Medium drugs are those that could be toxic or nontoxic, depending on usage. Inferior drugs are toxic, and are used for treating diseases and should not be used for extended periods.

Superior drugs include such well-known ones as ginseng, licorice, *gandihuang* (root of *Rehmannia glutinosa* Libosch.), *huangqi* (root of *Astragalus* spp.), *huanglian* (rhizome of *Coptis* spp.), *wuweizi* [fruit of *Schisandra chinensis* (Turcz.) Baill.], sesame seed, magnolia flower, *lingzhi* (*Ganoderma* spp.), *fuling* or poria [sclerotium of *Poria cocos* (Schw.) Wolf], Chinese date (fruit of *Ziziphus jujuba* Mill.), Job's tears [seed of *Coix lacryma-jobi* L. var. *mayuen* (Roman.) Stapf] and *duzhong* (bark of *Eucommia ulmoides* Oliv.).

Medium drugs include ginger, *mahuang* or ephedra herb (*Ephedra* spp.), *danggui* [root of *Angelica sinensis* (Oliv.) Diels], *jixuecao* or gotu kola [*Centella asiatica* (L.) Urb.], *kuandonghua* or coltsfoot flower (flower of *Tussilaqo farfara* L.), *yinyanghuo* (herb of *Epimedium* spp.), *haizao* (*Sargassum* spp.), *hehuan* (bark of *Albizzia julibrissin* Durazz.), *gaoben*, and zhuling or polyporus [sclerotium of *Polyporus umbellatus* (Pers.) Fries].

Inferior drugs include fuzi and *wutou*, which are lateral and main root respectively of aconite (*Aconitum carmichaeli* Debx.), rhubarb root (root and rhizome of *Rheum* spp.), *baitouweng* [root of *Pulsatilla chinensis* (Bge.) *Regel*], *lianqiao* or forsythia fruit [*Forsythia suspensa* (Thunb.) Vahl], *qinghao*, croton seed (fruit of *Croton tiglium* L.), *guanzhong* (rhizome of *Dryopteris crassirhizoma* Nakai and other ferns), and *langdangzi* or henbane seed (*Hyoscyamus niger* L.).

Many of the drugs in the *Shennong Herbal* are still being used today including all the ones listed above. Some of these uses have not changed after more than two thousand years and their rationale can be scientifically justified. For example, the use of *haizao* (*Sargassum* spp.) in the treatment of swelling of the neck (goiter) can be explained by its high content of iodine; the use of *guanzhong* (Dryopteris) in the treatment of intestinal worms certainly has its counterpart in the West, so does the use of *langdangzi* (henbane seed) as a muscle relaxant.

Tang Ben Cao (Tang Herbal)

The *Tang Herbal* is considered the first official Chinese pharmacopeia which was compiled in the 7th century (659 AD). It was a work compiled by a team of twenty-two high officials and court physicians under the edict of the emperor. It describes 850 drugs, including some foreign ones introduced since the era of the *Shennong Herbal*, such as benzoin, asafoetida, turmeric, black pepper and hezi (fruit of *Terminalia chebula* Retz.). Compared to the *Shennong Herbal*, the *Tang Herbal* records more drugs and in more detail; new uses and properties of old drugs are also described and the number of drugs more than doubled that in the *Shennong Herbal*.

Ben Cao Gang Mu (Herbal Systematics)

The most well-known Chinese herbal is the *Ben Cao Gang Mu* compiled by Li Shi-Zhen in the later part of the 16th century (1590 AD). This work is considered the most extensive work on materia medica ever compiled by a single author. It took Li 38 years to complete. It was based on his own medical and herbal expenence and on data from earlier herbals, such as the well-known 11th-century herbal named *Zheng Lei Ben Cao*. Li's herbal describes 1892 drugs (with 1110 drawings), including 11,096 prescriptions, for treating hundreds of illnesses, ranging from the common cold to drunkenness and food poisoning (Chen 1982). The prescriptions in this herbal have recently been categorized and published as a separate volume, making the information much easier to access (Shaanxi 1983). Now a researcher no longer needs to laboriously search the original herbal to locate a treatment for a particular condition. All one has to do is to look up the index in the new book.

When the *Ben Cao Gang Mu* was introduced overseas in the 17th century, it was promptly translated into numerous languages, including Latin, French, German, English, Russian, Japanese and Korean, indicating its usefulness and importance in the field of materia medica.

Zhong Yao Da Ci Dian (Encyclopedia of Chinese Materia Medica)

Although several well-known herbals had appeared since the *Ben Cao Gang Mu*, none can be compared to the *Encyclopedia* in scope and depth. This encyclopedia was compiled by the Jiangsu Institute of New Medicine and was published in 1977. It is the most extensive work ever, in the field of materia medica, consisting of three volumes, one of which is an appendix/index, and comprising a total of 3518 pages. It describes 5767 drugs with 4500 drawings, many in great detail. Of these, over 4800 are of plant origin, the remaining being animal and mineral drugs. In keeping with modern scientific progress, this modern work has many modern features. The information on each long-used medicinal typically contains the following:

Synonyms
Drug Source [plant family, species, and part(s) used]
Description of Plant Species [including habitat and distribution]
Cultivation Method(s)
Collection [including initial treatment]
Crude Drug Description [including production regions]
Chemical Composition
Pharmacology
Processing
Traditional Taste Properties
Traditional Channel Affiliations
Traditional Properties and Uses
Dosages and Methods of Administration Precautions
Selected Traditional Prescriptions Clinical Reports
Quotations/Comments from Traditional Herbals or Medical Treatises
Historical Identification and Sources

The modern botanical, chemical, pharmacological and clinical data included in this book are from the world literature up to and including 1972. It provides the reader with concise information on most Chinese medicinals currently used in traditional medicine. The detailed Appendix/Index allows the researcher to identify drugs of a particular pharmacologic category or drugs that treat a particular disease; it also provides chemical structures of compounds reported present or isolated from drugs described in the *Encyclopedia.*

CONTEMPORARY SOURCES OF INFORMATION ON CHINESE MEDICINALS

During a period of 2500 years, more than 2000 volumes of herbal records have been written by some 330 herbalists/physicians (Hao 1986). The works described above constitute only a few of the dozens of wellknown texts that are frequently consulted by traditional physicians, herbalists and modern researchers who read Chinese.

Books

In addition to the *Encyclopedia*, contemporary works on Chinese medicinals are abundant. They include treatises on general materia medica such as *Zhong Yao Zhi* (*Manual of Chinese Materia Medica*) and *Quan Guo Zhong Cao Yao Hui Bian* (*National Collection of Chinese Herbal Drugs*) as well as works on regional medicinals such as *Sichuan Zhong Yao Zhi* (*Manual of Chinese Drugs of Sichuan*), *Hubei Zhong Cao Yao Zhi* (*Manual of Chinese Herbal Drugs of Hubei*), *Hunan Yao Wu Zhi* (*Manual of Materia Medica of Hunan*), *Chang Bai Shan Zhi Wu Yao Zhi* (*Manual of Plant Drugs of Chang Bai Mountain*), *Fujian Yao Wu Zhi* (*Manual of Materia Medica of Fujian*), and *Chinese Medicinal Herbs of Hong Kong* (Chinese/English; 5 volumes; total 943 pp.). These are all sizable compilations covering information generally contained in the *Encyclopedia*, but with a slightly different approach and/or regional accent; some also contain medicinals not found in the *Encyclopedia*. Compared to others, the *Chinese Medicinal Herbs of Hong Kong* is the least extensive as it describes in brief only 500 herbs, each with a colored photograph.

Like books on single herbal drugs, there is an equally large number of books that are exclusively devoted to herbal formulas, some of which date back at least 2000 years. Many well-known classical formulas can now be found in the *Zhong Yi Da Ci Dian: Fang Ji Fen Ce* (*Encyclopedia of Traditional Chinese Medicine. Prescriptions*), published in 1980. This formulary incorporates and describes from traditional medical treatises and formularies 7500 selected prescriptions, including 1320 that have duplicate names but different ingredients. Information in each formula includes its classical literature source, the amounts of its component herbs, conditions for which it is used, method(s) of preparation, and method(s) of administration and dosages. The prescriptions included in this work have been selected from such well-known classics as the *Pu Ji Fang* (*Prescriptions for Healing the Masses*, published in the 14th century with 61,739 formulas) and the *Tai Ping Sheng Hui Fang* (published in 992 AD with 16,834 formulas). Examples of well-known classical formulas that are still widely used today include the *Yu Ping Feng San* Oade Screen Powder) and *Yin Qiao San* (Honeysuckle Forsythia Powder) for the prevention and treatment of the common cold and other illness; and the *Da Huang Mu Dan Tang* (Rhubarb Peony Decoction) for treating conditions known as *changyong* ("intestinal carbuncle") which includes acute appendicitis. For more recent formulas, one can consult the *Zhong Yao Zhi ji Hui Bian* (*Collection of Chinese Herbal Preparations*) and *Qian lia Miao Fang* (*One Thousand Superb Prescriptions*). The former describes 3873 prescriptions collected from published data during the past 50 years while the latter, published in 1982, describes some 1 100 formulas collected from 600 famous traditional Chinese physicians and/or clinics throughout China.

For those who are interested in herbal veterinarian medicinals, there is the recently published *Min jean Shou Yi Ben Cao* (*Folk Veterinarian Herbal*). It describes over 600 herbs (with 461 drawings) and about 10,000 prescriptions for treating more than 1000 diseases in domesticated animals, including pigs, cattle, sheep, horses, donkeys, mules, rabbits, dogs, cats, chickens, ducks, geese, and camels, among others. Information contained in this herbal is based on traditional works on herbal veterinarian medicine compiled over the past 2000 years plus the experience of the author who is a leading authority in herbal veterinarian medicine in China.

For those with mycological interests, *Zhong Guo Yao Yong Zhen Jun* (*Chinese Medicinal Fungi*) has become a standard reference in this field since its publication in 1974. This book documents

121 fungi used in Chinese traditional medicine, including such highly priced edible fungi as the *Morchella* spp. (for indigestion, excessive phlegm and shortness of breath) to the highly toxic *Amanitopsis volvata* Sacc. (in combination with other fungi for treating backache, numbness in the limbs, and muscle tightness/spasms).

Another area of popular interest is diet therapy A very useful book on this field is the *Zhong Guo Shi Liao Xue* (*Chinese Diet Therapy*). Published in 1987, this book deals with the treatment and prevention of illnesses by using common Chinese medicinals that serve the dual functions both as food and medicine. Information in this book is derived from close to 200 books on diet therapy and related fields, which have been published over the past 2500 years. Food/medicinal plants described in this volume include lily buds (*Hemerocallis fulva* L.), mung bean, chrysanthemum flower, black sesame seed, green onion (*Allium fistulosum* L.), and many other common food/medicinal substances. This book should be useful to both the health products industry and to regulatory agencies as it might help answer some questions relating to the history of herbal foods.

Also, the currently official *Chinese Pharmacopeia* of natural drugs (1985), containing monographs on 506 single drugs and 207 formulas, can serve as a handy reference on common Chinese medicinals.

Journals

In addition to contemporary books, there are at least 100 journals that deal directly with traditional Chinese medicine and the use of Chinese herbal drugs. They include those published at the national, provincial, and city levels as well as those published by traditional medical institutions. The following is a partial list of these journals.

National:

Acta Botanica Sinica (some English abstracts)—botanical and chemical
Acta Chimica Sinica (most with English abstracts)—chemistry
Acta PhartnaceuHca Sinica (most with English abstracts)—general
Acta Phartnacologica Sinica (most with English abstracts)—general
Bulletin of Chinese Materia Medica—general
Chinese Journal of Integrated Traditional and Western Medicine (some English abstracts)—clinical & pharmacological
Chinese Medical Abstracts-Traditional Medicine—general
Chinese Pharmaceutical Bulletin—general
Chinese Traditional and Herbal Drugs—chemical & pharmacological
Journal of New Chinese Medicine—general
Journal of Traditional Chinese Medicine (English version available)—general
National Medical Journal of China (some English abstracts)—clinical & pharmacological Plants—botanical sources

Regional:

Acta Botanica Yunnanica (most with English abstracts)—botanical and chemical
Beijing Journal of Traditional Chinese Medicine—clinical
Fujian Journal of Traditional Chinese Medicine—clinical
Henan Traditional Chinese Medicine—clinical

Hubei Journal of Traditional Chinese Medicine—clinical
Jiangsu Journal of Traditional Chinese Medicine—clinical
Jiangxi Journal of Traditional Chinese Medicine and Pharmacology—clinical
Journal of Traditional Chinese Medicine and Chinese Materia Medica of Jilin—clinical
Liaoning Journal of Traditional Chinese Medicine—clinical
Shaanxi Journal of Chinese Traditional Medicine—clinical
Shandong Journal of Traditional Chinese Medicine—clinical
Shanghai Journal of Traditional Chinese Medicine—clinical
Shanxi Journal of Traditional Chinese Medicine—clinical
Sichuan Journal of Traditional Chinese Medicine—clinical
Tianjin Journal of Traditional Chinese Medicine—clinical
Yunnan Journal of Traditional Chinese Medicine—clinical
Zhejiang Journal of Traditional Chinese Medicine—clinical

Institutional:

Journal of Anhui College of Traditional Chinese Medicine—general
Journal of Beijing College of Traditional Chinese Medicine—general
Journal of Chengdu College of Traditional Chinese Medicine—general
Journal of Guiyang College of Traditional Chinese Medicine—general
Journal of Hunan College of Traditional Chinese Medicine—general
Journal of Nanjing College of Traditional Chinese Medicine—general
Journal of Shaanxi College of Traditional Chinese Medicine—general
Journal of Shandong College of Traditional Chinese Medicine—general
Journal of Shenyang College of Pharmacy—general
Journal of Yunnan College of Traditional Chinese Medicine—general
Journal of Zhoiang College of Traditional Chinese Medicine—general

Reports published in these journals are mostly on clinical use of herbs and herbal combinations, although there are a sizable number of research reports as well. The latter can be found primarily in nationally published joumals at the top of the above list.

Apart from above journals that primarily deal with natural drugs, reports on these medicinals can also be found in national, regional and institutional joumals that cover general medical and pharmaceutical topics. A partial list of such journals follows.

Chinese Journal of Cancer (some Enghsh abstracts)
Chinese Journal of Cardiology (some English abstracts)
Chinese Journal of Clinical Pharmacology Chinese Journal of Dermatology (some Enghsh abstracts)
Chinese Journal of Hematology (some English abstracts)
Chinese Journal of Internal Medicine (some English abstracts)
Chinese Journal of Microbiology and Immunology (most with English abstracts)
Chinese Journal of Oncology (most with English abstracts)
Journal of Marine Drugs (some Enghsh abstracts)
National Medical Journal of China (some English abstracts)

SCOPE OF CHINESE MATERIA MEDICA

Single Drugs

The Chinese constitute a fifth of the world's population. Due to the empirical nature of traditional Chinese medicine, most of the effective Chinese medicinals and their combinations as we now know them have been well tested in humans over a period of hundreds to thousands of years. A rough estimate based on available information indicates that there are at least 5000 single plant drugs used in China that have readily accessible documentation. The ones that have not yet been recorded in major works probably also number in the thousands.

One major feature that distinguishes Chinese medicinals from those of most other countries is the specific and often elaborate treatment given Chinese medicinals. Over a period of centuries, crude drugs have often been processed according to specific methods to yield the desired effects. Whether they are simply boiled or heated or mixed with other herbs such as licorice, ginger, or black beans, the purpose is often to reduce toxic side effects and/or accentuate the drugs' beneficial effects. Thus, for example, unprocessed aconite is rarely used internally. In order to render it less toxic and yet retain its desired cardiac effects, it is usually soaked for days and boiled for hours. Recent studies have revealed that under these processing conditions, the most toxic alkaloid, aconitine, can be destroyed or greatly reduced. The resulting processed aconite has cardiotonic activities and is used to treat cardiac failure and other heart diseases. Another processed aconite (lateral root), called fuzi, is also used in tonic preparations. Consequently, when one intends to study Chinese medicinals, one should bear in mind the nature of their source, because simply knowing their correct taxonomic origin is not enough. The same plant part from the same species, if obtained by different processing methods, can produce widely different pharmacological effects.

Combinations

Chinese drugs are normally used in combinations for various reasons. Two major ones are: to enhance the action of the main drug(s); and to mitigate the toxic side effects of principal component drugs. Since Chinese medicinals are normally used in combinations, the number of herbal prescriptions used by the Chinese people are countless. An educated guess is that they are in the low to middle six figures, as prescriptions in the *Pu Ji Fang* (*Prescriptions for Healing the Masses*) alone number close to 62,000.

Current Evaluation and Documentation of Chinese Medicinals

Drugs of practically any pharmacological category can be found among Chinese medicinals. During the past twenty-five years, the Chinese have made much progress in bringing their traditional medicines into a modern environment. While scrutinizing traditional medicines with modern methods on the one hand, they continue to expand their traditional uses on the other. Thus, one finds a steady flow of a considerable number of research publications and at the same time huge numbers of clinical reports on use of traditional prescriptions in treating diseases ranging from the common cold to cancer. Most of the published information during the past 150 years has so far been abstracted in a series of three volumes called *Zhong Yao Yan Jiu Wen Xian Zhai Yao*

(*Research on Chinese Materia Medica: Literature Abstracts,* 1820-1961, 1962-1974, 1975-1979). Also, research and clinical data on about 250 important Chinese medicinals are summarized in the *Zhong Yao Yao Li Yu Ying Yong* (*Pharmacology and Applications of Chinese Drugs*). The most active areas of current research and practice in Chinese materia medica include medicinals used in the treatment of cancer and cardiovascular, viral and irnmunological diseases.

The following are some data on recent studies on Chinese medicinals. As the information is so extensive, the examples given in the following only represent a very small fraction of what actually is available.

Antitumor drugs. There must be thousands of herbal formulas currently used for treating cancer in China. Over 400 of these can be found in three recently published books on anticancer medicinals (Chang 1987, Yang 1981, Hu and Xuan 1982), which were compiled primarily from modern published data; they are prepared from more than 200 single drugs. The prescriptions range from ones that contain medicinals with known antitumor chemicals to those whose components have not yet been chemically and/or pharmacologically studied. Examples are many and the f ollowing are a few selected at random (Cheng and Xu 1985, Cheng et al. 1984, Guo et al. 1985, Huang 1987, Jiang 1984, Jiang and Yan 1986, Li 1982, Liu et al. 1985, Ren and Hong 1986, Wang 1987, Yu 1983):

Cephalotaxus fortunei Hook. f, *C. sinensis* (Relid. et Wils.) Li, *C. hainanensis* Li [bark, root, twigs]—hainanolide, harringtonines, etc.

Camptotheca acuminata Decne. [root, bark fruit, twigs, leaves]—camptothecine, etc.

Iphigenia indica Kunth [bulb]—colchicine

Curcuma zedoaria Rosc., *C. aromatics* Salish., *C. kwangsietisis* S. Lee et C.F. Liang [rhizome]—curdione, curcumol

Crotalaria sessiliflora L., *C. assamica* Benth. [whole plant]—monocrotaline

Sophora subprestrata Chun et T. Chen, *S. flavescens* Ait. [root/rhizomel—matrine, oxymatrine, sophocarpine, etc.

Trichosanthes kirilozvii Maxim, *T. uniflora* Hao [root]—trichosanthin

Strobilanthes cusia (*Nees*) O. Kuntze, *Isatis indigotica* Fort., *Indigofera suffruticosa* Mill., *Polygonum tinctorium* Ait., etc. [qingdailnatural indigo]—indirubin

Rabdosia rubescens (Hemsl.) Hara and other *Rabdosia* spp. [whole plant]—diterpenoids (rubescensines, oridonin etc.)

Cucumis melo L. [pedunclel—cucurbitacins B and E

Ailanthus altissima (Mill.) Swingle [root/stem bark, fruit]—lactones

Cardiovascular drugs. A considerable number of traditional drugs and prescriptions are used in conditions related to the heart and blood. They include those grouped under the categories of *huo xue hua yu* (invigorating blood circulation and dispersing stasis), blood tonics, and hemostatics. The following are a few examples of such medicinals (Chai et al. 1985, Chen 1987a, Deng and Gong 1987, Huang 1986, Jiang 1984, Li et al. 1983, Liu and Chen 1984, Ou et al. 1987, Shan

1988, Shan et al. 1986, Song et al. 1988, Wang and Ba 1985, Wang and Jing 1984, Yang 1988, Yue et al. 1985, Zhang 1985, Zhou 1984):

> *Pueraria lobata* (Willd.) Ohwi [root]—antiarrhythmia, hypotensive, hypoglycemic (e.g. puerarin.)
>
> *Ephedra* spp. [root/rhizome]—hypotensive (ephedranin A, mahuanin A & B, alkaloids)
>
> *Aconitum carmichaeli* [*fuzi,* lateral root]—cardiotonic, anti-thrombin, etc. (e.g. higenamine)
>
> *Salvia miltiorrhiza* Bunge [root]—anticoagulant, vasodidator (e.g. tanshinones, danshensu)
>
> *Ligusticum chuanxiong* Hort. [rhizome]-vasodilator, anti-thrombin, anti-atherosclerotic (e.g. tetramethylpyrazine)
>
> *Lentinus edodes* (Berk.) Sing. [fruiting body]—antiplatelet aggregation, etc. (hydro-alcoholic extract).
>
> *Panax pseudo-ginseng* Wall. var. *notoginseng* (Burk.) Hoo et Tseng [rhizomel—anti-arrhythmia (saponins)
>
> *Polygonum multiflorum* Thunb. [root tuber]—anti-atherosclerotic (alcohol extractives)
>
> *Polygonum cuspidatum* Sieb. et Zucc. [rhizome]—antiplatelet aggregation (polydatin)

Antivital drugs. Antivital drugs can be found in several categories of traditional medicinals. They include the so-called heat-dispersing drugs (antipyretics) and those for treating "exterior symptom complex" (diaphoretics). These drugs are frequently used in prescriptions along with tonics (immunomodulating drugs). The following two formulas are worth noting as they have been in use for centuries:

1. *Yu Ping Feng San* (*Jade Screen Powder*)
Huangqi (astragalus root)
Fangfeng (root of *Ledebouriella divaricata*)
Baizhu (rhizome of *Atractylodes macrocephala* Koidz.)
2. *Yin Qiao San* (*Honeysuckle Forsythia Powder*)
Honeysuckle flower (*Lonicera* spp.)
Forsythia fruit (*Forsythia suspensa*)
Mint (*Mentha haplocalyx* Brig.)
Jingjie (herb of *Schizonepeta tenuifolia* Briq.)
Dandouchi (fermented black soybean)
Niubangzi (fruit of *Arctium lappa* L.)
Jiegeng [*Platycodon grandiflorum* (Jacq.) A. DC]
Danzhuye (herb of *Lophatherum gracile* Brongn.)
Licorice root

Jade Screen Powder was first recorded in 1481 AD. It has tonic properties and is used to build up body resistance in the prevention of the common cold and influenza. Due to its antivital as well as immunomodulating activities, it has drawn much attention in the past few years. So far, studies have demonstrated it to lower the incidence of cold and influenza, prevent the recurrence of chronic bronchitis, and enhance host immunity. After treatment with this prescription, patients' IgA, IgG, and rate of T-lymphocyte transformation and E-rosette formation are all markedly increased (Geng 1986, Li 1988, Liu 1987).

Honeysuckle Forsythia Powder was first recorded in 1798 AD. Currently it is probably the most widely used cold remedy in China and in overseas Chinese communities. It is used in treating the common cold, influenza, and other febrile viral infections. Its multiple pharmacological effects have been reported, which include antipyretic, anti-inflammatory, and anti-allergic (Deng et al. 1986).

Immunomodulating drugs. There are dozens of well-known Chinese medicinals with immunomodulating activities that have been traditionally used as tonics; some are now also used in cancer to counteract the toxic side effects of chemotherapy and radiotherapy. The following are a few examples of these medicinals (Chen 1985, Chinese 1985, Deng and Liao 1984, Du et al. 1986, Geng 1986, Li et al. 1986, Lin et al. 1985, Liu and Xu 1985, Wang 1987, Zang et al. 1985).

Tremella fuciformis Berk [fruiting body]—polysaccharides
Polyporus umbellatus (Pers.) Fries [sclerotium]—polysaccharides
Poria cocos [sclerotium]—polysaccharides
Lentinus edodes (Berk.) Sing. [fruiting body]—polysaccharides

Cordyceps sinensis (Berk) Sacc. [whole fungus plus host remains]—polysaccharides
Oriental ginseng polysaccharides
Astragalus polysaccharides

Others. I cannot leave this topic without mentioning another category of traditional drugs that are of keen interest not only to the Chinese but to Americans as well. These are the anti-aging medicinals. The newly published *Kang Shuai Lao Fangji Ci Dian* (*Encyclopedia of Anti-Aging Formulas*) records 1018 formulas, mostly selected from classic formularies, with only a few from modern sources. Over the past few years, I have seen a steady increase in reports on anti-aging research in the Chinese literature. Using modern criteria relating to aging such as immune functions, free radical formation, superoxide dismutase activity, monoamine oxidase activity, and blood lipid levels, many traditional tonics have been shown to have anti-aging effects. They include ginseng, Siberian ginseng [root/rhizome of *Acanthopanax senticosus* (Rupr. et Maxim.) Harms], *Schisandra chinensis* fruit, *lingzhi* (fruiting body of *Ganodertna* spp.), *fuzi* (processed lateral root of *Aconitum carmichaeli*), *Epimedium* herb, *heshouwu* (root of *Polygonum multiflorum*), *danggui* (root of *Angelica sinensis*), *baizhu* (rhizome of *Atractylodes macrocephala*), and *luobuma* (leaf of *Apocynum venetum* L.), among others (Jiangsu 1988, Li et al. 1986).

EXAMPLES OF COMMON CHINESE MEDICINALS

Mahuang

The most well-known Chinese medicinal that has been frequently quoted as a classic example of an herbal drug yielding a modern medicine (ephedrine) is *mahuang* (*Ephedra* spp.). It is the dried stems of one of three *Ephedra* species (*E. sinica* Stapf; *E. equisetina* Bunge; *E. intermedia* Schrenk et C.A. Mey) found in China, primarily in northem regions. It has been used in China as a diaphoretic, anti-asthmatic, and diuretic for at least 2000 years, with written records dating back to at least the *Shennong Herbal* (100 BC-200 AD.). Prescriptions based on *mahuang* for treating asthmatic conditions are countless, some of which date back to ancient formularies, such as the 3rd-century medical classic, the *Shang Han Lun* (*Theory on Febrile Diseases*). Other less known uses of *mahuang* include the treatment of influenza and rheumatism. In contrast to the diaphoretic properties of *mahuang* (stem), the root and rhizome of *Ephedra* species, known as *mahuanggen,* has antiperspirant properties. It is used to treat night sweat and spontaneous perspiration as well as excessive perspiration. For the latter, it is often used topically in the form of a powder for dusting or decoction for washing affected areas. Furthermore, recent studies have shown it to contain hypotensive flavonoids and alkaloids. The completely different medicinal properties of aboveground and underground parts of *Ephedra* species serve as another example to highlight the importance of specificity when evaluating and reporting on plant drugs.

Sour Date Kernel

One of the most commonly used sedative/hypnotic in Chinese prescriptions for treating insomnia and neurasthenia is *suanzaoren* (sour date kernel). It is the dried ripe kernels of *Ziziphus jujube* Mill. var. *spinosa* (Bunge) Hu ex H.F. Chow (syn. *Ziziphus spinosa* Hu). Although first recorded 3000 years ago, this medicinal has only recently been evaluated by modern scientific methods and found to indeed possess sedative and hypnotic effects in various experimental animals (Hong and Cao 1987). Spinosin, a flavonoid glycoside, is only partially responsible for these effects (Li and Zhang 1983, Yuan et al. 1987, Zeng et al. 1987). Other active components in this drug still await further investigations.

Sour date kernel is also traditionally known to "calm the heart." Recent studies have demonstrated it to have anti-arrhythmic and other cardiovascular activifies (Xu et al. 1987).

Qian Ceng Ta

Qian ceng ta is the whole plant of *Huperzia serrata* (Thunb.) Trev [syn. *Lycopodium serratum* Thunb.]. Although not as common as the previous two, it is traditionally used as a detoxicant to reduce swelling, break up blood stasis, and to stop bleeding. During its clinical use, patients were observed to exhibit cholinergic-type reactions in varying degrees. Subsequently, two new alkaloids, huperzine A and huperzine B, were isolated from it and shown to have strong and reversible anticholinesterase activity. The action of huperzine A against acetylcholinesterase was found to be three times stronger than that of physostigmine and thirty times that of galanthamine, with lower toxic side effects. Favorable results from a series of studies conducted in rats and mice plus a preliminary study on human subjects over the past two years indicate that these new alkaloids show promise in the treatment of Alzheimer's disease and related disorders (Liu et al. 1986, Wang et al. 1986, Wang et al. 1988, Tang et al. 1986, Xu and Tang 1987, Zhu and Tang

1987, Yan et al. 1987, Lu et al. 1988).

Detoxicants

"Detoxicant" is a rather vague term that can mean several things in traditional Chinese medicine. A detoxicant can be used to treat "toxic conditions" such as external sores and ulcers or internal conditions characterized by fevers or inflammations, results of viral or bacterial infections. Well-known Chinese medicinals used for such conditions include honeysuckle flower, *qingdai* (natural indigo), houttuynia herb [*Houttuynia cordata* Thunb.], forsythia fruit [*Forsythia suspensa,* and andrographis herb [*Andrographis paniculata* (Burm. f) Nees.]. Most of these have been extensively studied chemically and pharmacologically Modern drugs such as indirubin for leukemia and andrographolides for various bacterial infections have been the results of these studies.

Another type of detoxicants that so far have not been examined by modern technics include ginger, mung bean, soybean, and licorice that are routinely used in traditional Chinese medicine for treating drug or food poisoning as well as toxic side effects of cancer chemotherapy and heavy metal poisoning. There is no lack of clinical reports on these uses in the Chinese literature. However, reports on relevant chemical and pharmacological studies on these medicinals are lacking.

CONCLUSION

The Chinese people have been using their medicinals for several thousand years. Over this long period, they have accumulated a sizable pharmacopeia based on actual human trials, and have faithfully recorded their experience and knowledge of these medicines for posterity. Thus, compared to those of other countries, Chinese medicinals are unsurpassed in number, sophistication, and documentation.

Considering the billions of Chinese who have lived and died since ancient times, it is highly probable that for every disease known to mankind, there exists in the Chinese formularies and herbals an effective remedy to treat it. The disease may not bear the modern name familiar to us, but if one knows how and where to search one will most likely find the diseased condition and the drug or prescription for treating it. In fact the treasure house of Chinese medicinals can offer modern science sucha fertile field in which to look for leads to new drugs that we simply can no longer afford to ignore it. The data are there. But it will take industrial and/or government executives with foresight to initiate the efforts to make effective use of this information. Considering the poor results of conventional screening programs, obtaining new drug leads among Chinese medicinals may well be the most cost effective strategy and should be the concern of every executive who is interested in inexpensive and effective ways of developing new drug leads.

Since most Chinese medicinals have withstood centuries of safe use, new active principles isolated from them are viewed favorably by the Chinese who rarely hesitate to experiment with them directly on humans. They also continue to experiment with new herbal prescriptions and document them as they have for thousands of years, making the field of Chinese medicinals virtually a continuous massive clinical trial of which Western pharmaceutical and medical researchers should take advantage. With the huge sums of federal money now being spent in AIDS and cancer research, a minute fraction of it spent in tapping this Chinese resource would be most cost effective in obtaining leads to new drugs in these areas.

Lastly, many Chinese medicinals are derived from rather common plant sources. Some of these plants, such as *Pueraria lobata*, *Lonicera* spp., *Ailanthus altissima*, and *Polygonum cuspidatum*, have already been naturalized in America. They could be tumed into cash crops with minimal research should a medicinal market be developed.

Ng, T.J. 1993. New opportunities in the Cucurbitaceae. p. 538-546. In: J. Janick and J.E. Simon (eds.), New crops. Wiley, New York.

New Opportunities in the Cucurbitaceae*

Timothy J. Ng

The Cucurbitaceae consists of nearly 100 genera and over 750 species (Yamaguchi 1983). Although most have Old World origins (Whitaker and Davis 1962), many species originated in the New World and at least seven genera have origins in both hemispheres (Esquinas-Alcazar and Gulick 1983). There is tremendous genetic diversity within the family, and the range of adaptation for cucurbit species includes tropical and subtropical regions, arid deserts, and temperate locations. A few species are adaptable to production at elevations as high as 2000 m.

The genetic diversity in cucurbits extends to both vegetative and reproductive characteristics. There is considerable range in the monoploid (*x*) chromosome number (Jeffrey 1990), including 7 (*Cucumis sativus*), 11 (*Citrullus* spp., *Momordica* spp., *Lagenaria* spp., *Sechium* spp., and *Trichosanthes* spp.), 12 (*Benincasa hispida*, *Coccinia cordifolia*, *Cucumis* spp. other than *C. sativus*, and *Praecitrullus fistulosus*), 13 (*Luffa* spp.), and 20 (*Cucurbita* spp.).

Archaeological evidence has indicated that cucurbits were present in ancient and prehistoric cultures. *Lagenaria* was associated with man as early as 12,000 BC in Peru (Esquinas-Alcazar and Gulick 1983). Archaeological expeditions in the Oaxaca region of Mexico have reported Cucurbita pepo to be associated with man as early as 8500 BC and cultivated by 4050 BC (Esquinas-Alcazar and Gulick 1983). Written Chinese records describing the use of cultivated cucurbits have been found from as early as 685 BC (Herklots 1972). American Indians cultivated squash in pre-Columbian times (Whitaker and Davis 1962), and chayote was a common vegetable among the Aztecs prior to the Spanish conquest (Herklots 1972). Depending upon the species, virtually all parts of the plant can be used for food, including leaves, shoots, roots, flowers, seeds, and immature and mature fruits. Starch can be extracted from roots, and the seeds are a rich source of oils and proteins (Jacks et al. 1972). In addition, some cucurbits have been used for ornamental purposes (e.g., gourds), for utensils (e.g., bowls, ladles, sponges, boxes, birdhouses, musical instruments), and for fuel and pharmacological uses in certain areas of the world.

NEW OPPORTUNITIES WITH COMMONLY GROWN CUCURBITS

Cucurbit crops commonly grown in the United States include cucumber (*Cucumis sativus*), melon (*Cucumis melo*), watermelon (*Citrullus lanatus*), and squash and pumpkin (*Cucurbita* spp.). Due to intensive breeding efforts, particularly with cucumber and melon, numerous new cultivars have been developed, some of them quite different from the traditional forms for these crops.

Cucumbers have been traditionally grown for either pickling or slicing purposes. Newer forms which are increasing in importance include hothouse cucumbers, which are elongated, seedless, and "burpless" (putatively reducing eructation). Nerson et al. (1990) reported on the development of melofon, a genotype of *Cucumis melo* which is suitable for pickle production.

Until recently, melon production has been limited in most parts of the United States to the reticulated (netted), orange-fleshed muskmelon. However, the smooth-skinned, green-fleshed honeydews have increased in popularity over the past decade, and varied displays of casaba and canary (smooth-skinned with yellow or mottled rinds, white-fleshed), Persian (lightly-netted, pink-fleshed), and crenshaw (smooth-skinned, pale orange-fleshed) melons are becoming an increasingly common sight in major markets. The genetic diversity within the species for fruit characteristics has resulted in recent cultivar developments such as orange-fleshed honeydews and green-fleshed netted melons. Additionally, producers are showing interest in forms cultivated in other countries, including the smooth-skinned, delicately-fleshed "Charentais" types in Europe and the dark green smooth-skinned "hami gua" melons of Asia.

Watermelon types have traditionally been red-fleshed and seeded. There is genetic variation for flesh color in the species, however, and colors can range from white or yellow to orange, depending upon the genetic constitution. Yellow-fleshed cultivars are now available, and there may be a market for white-fleshed cultivars if quality could be assured, since consumers tend to associate white flesh with immaturity. A relatively recent development in watermelon breeding has been the use of ploidy manipulations to produce seedless triploid genotypes (Kihara 1951). A number of seedless cultivars have been developed, but they tend to be more susceptible to physiological problems such as poor seed germination and hollow heart. In northwest China, edible seed watermelons are an important crop (Zhang and Jiang 1990); these melons are small in size (2.5 to 3.5 kg) with low soluble solids content, but have a high ratio of seed to flesh in the fruits. The seeds are roasted before eating.

Squash, derived from Algonquin Indian "askoot asquash" which means "eaten green," is a generic term to describe cultivars of four *Cucurbita* species: *C. argyrosperma* (= *C. mixta*), *C. maxima*, *C.*

moschata, and *C. pepo*. These species are New World in origin, with all but *C. maxima* originating in central to southern Mexico (*C. maxima* originated in South America and was the only species not cultivated in the United States until post-Columbian times). Traditional forms of the *Cucurbita* spp. include summer squash, winter squash, pumpkins, and gourds. Production has recently increased with specialty forms such as spaghetti squash (*C. pepo*), whose internal flesh texture resembles strands of spaghetti following cooking. Another specialty crop is calabaza (*C. moschata*), a hard-shelled squash with bright orange, fine-grained flesh and excellent nutritive properties (Wessel-Beaver and Varela 1991). There has also been recent interest in edible pumpkin seed, particularly in genotypes with the hull-less trait (Loy 1990).

Although the new forms of these commonly grown cucurbits represent an increase of diversity within each commodity, they will probably not expand the market substantially (with the exception of niche markets) since consumers will probably elect to purchase them in place of the more traditional forms. Where the true opportunity for increased diversity and market growth exists is with cucurbit crops which are grown on an international scale, but are cultivated to only a limited extent in the United States.

CUCURBITS OF POTENTIAL ECONOMIC IMPORTANCE

Although by no means exhaustive, Table 1 lists cucurbit species which are cultivated to a significant extent in other parts of the world. Loosely grouped according to Old World and New World origins, Table 1 also lists the more frequently used common names for each of these species, along with growth habit and the parts of the plant which are used on an economic basis. Many of these species are described in detail by Chakravarty (1990), Herklots (1972), Tindall (1983), Whitaker (1990), Whitaker and Davis (1962), and Yamaguchi (1983).

Old World Cucurbits

Benincasa hispida. The winter melon has been reported to have been grown as a vegetable in China since 500 AD; even today, however, it is cultivated little outside of Asia. It was one of two cucurbit species identified by the National Academy of Sciences (1975) as being an underexploited tropical crop. Exhibiting relatively rapid growth, *B. hispida* grows best in temperate climates with adequate but not excessive rainfall. In Sri Lanka, the plant produces fruit from seed in two months during the rainy season. The distribution of staminate and pistillate flowers is influenced by temperature and daylength. Plants may be grown recumbent or trellised.

The mature fruit is the primary harvested plant part, although seeds are sometimes extracted, fried and eaten like pumpkin seeds. The fruit is covered by a white, chalky wax which deters microorganisms and helps impart an extraordinary longevity to the melon. Winter melon fruits can be stored for as long as a year without refrigeration. Fruits may weight up to 35 kg and consist of more than 96% water. They are usually sold whole in domestic markets, but are commonly displayed and sold by the slice in Asian markets. Somewhat bland in flavor when eaten fresh, the flesh is often used to make soup stock. Canned winter melon soup and dehydrated winter melon slices represent two of the processed products made from this species.

Citrullus colocynthis. A relative of watermelon, egusi is native to tropical Africa and highly drought tolerant. Productivity is enhanced during dry, sunny periods and reduced during periods of excessive rainfall and high humidity. It is suitable for production in "marginal growing areas." The fruits are extremely bitter, but the seeds are can be removed and roasted as an edible commodity (Soliman et al. 1985). The seeds are rich in oils, which can be extracted for cooking purposes, and the seeds can also be ground into a powder and used as a soup thickener or flavoring agent (Badifu and Ogunsua 1991).

Coccinia cordifolia. Ivy gourd is a semi-perennial which grows best under conditions of adequate rainfall and high humidity. One of the few dioecious cucurbits, with a hetermorphic (XY) chromosome pair determining sex, it produces best when a 1:10 ratio of male to females is used. Plants are commonly trellised. The leaves, shoots, and immature fruits are cooked and eaten; mature fruits are sometimes preserved.

Cucumis anguria. The West Indian gherkin grows and is used in a similar fashion as the cucumber. It was introduced into the United States in the early 1800s, but remains cultivated to only a limited extent. Oval in shape with a round cross-section, it has a highly warted skin, long spines and a large cavity with many seeds.

Lagenaria siceraria. The origin of the bottle gourd is acknowledged to be Africa, although archaeological evidence has placed it in Peru around 12000 BC, in Thailand about 8000 BC, and in Zambia around 2000 BC (Esquinas-Alcazar and Gulick 1983). It has traveled widely, perhaps because the hard, dry skin of the mature fruits is impervious to water; they are capable of floating on salt water for the better part of a year without any loss in seed viability (Herklots 1972; Tindall 1983). Tolerant to a wide range of rainfall, it may be grown either on the ground or trellised.

Young fruits are used as a cooked vegetable similar to zucchini. The flesh is white, firm, and has an excellent texture and a mild taste. Young shoots and leaves can be cooked, and seeds can be used in soups. Flesh of immature fruits can also be used in making icing for cakes, and the hard skin is sometimes sliced into thin, dry strips for cooking.

Some forms of *L. siceraria* are grown for non-food uses. Mature fruits, whose inside may be poisonous, contain an extremely hard and waterproof rind when dried. They can be used as multi-purpose containers (bowls, boxes, water jugs, cups, planters), utensils (ladles, pipes), musical instruments (e.g., sitars), floats for fishnets and rafts, or for ornamental purposes such as masks or native artifacts. Designs lightly scratched into the skin of developing fruit will develop into scars that remain intact in the mature fruits.

Luffa acutangula. The angled loofah is commonly grown in hot, humid tropical areas in Asia. Plants are generally grown on a trellis. Immature fruits, which are dark green with tender ridges, are used in soups and curries or as a cooked vegetable. They generally grow up to 0.6 m in length, and the flesh is spongy although the skin is coarse. The mature fruits are bitter and inedible, but the fibrous skeleton can be used as a sponge. However, the reticulated inner tissue is not as easily separated from the outer skin and inner flesh as *L. aegyptiaca* (= *L. cylindrica*).

Luffa aegyptiaca. Along with *Lagenaria siceraria*, *L. aegyptiaca* probably has the most diverse uses of any of the cultivated cucurbits. Immature fruits of the non-bitter genotypes are eaten fresh, cooked, or in soups, although they are inferior to immature *L. acutangula* fruits. The mature fruits are the source of the spongy reticulated material known as the domestic loofah. These loofahs are used for sponges and filters, and for stuffing pillows, saddles, and slippers. They can also be used for insulation and are attractive sources for packing materials because of their biodegradability. There is an increasing interest in domestic production (Davis 1991) since the United States is the major market and imports millions of loofahs from Asia each year.

Normally, mature fruits are left on vine to dry and the dry, thin outer skin is removed. The fruit is then soaked in running water for several days, after which the softer tissue is removed. After further soaking, then drying, the seeds are shaken out and the loofah is bleached either chemically or by the sun prior to marketing.

Momordica charantia. The bitter melon is adapted to a wide variation of climates, although production is best in hot, humid areas such as tropical Asia. The bitter immature fruits are usually soaked to remove some of the bitterness, then boiled or fried. Volatile components released during cooking enhance the flavor (Binder et al. 1989). Bitter melons can also be pickled or used in curries. Relative to other cucurbits, the fruit is highly nutritious due to the iron and ascorbic acid content. Plants are usually trellised, and fruits are protected from flies by tying a paper cylinder around the stalk. Some forms have bright red seeds due to a high lycopene content; Yen and Hwang (1985) have proposed using this pigment as an artificial food colorant.

Praecitrullus fistulosus. Primarily grown in India, the round melon was long considered to be *Citrullus lanatus* but was recently given its own taxonomic category due in part to its difference in monoploid chromosome number (Sujatha and Seshadri 1989). Growth conditions and requirements are similar to those of watermelon, but the entire immature fruit is used as a cooked vegetable. The seeds can also be removed and eaten.

Telfairia occidentalis. A dioecious perennial grown at elevations up to 2,000 m in West Africa, the fluted gourd is drought tolerant and is usually trellised. Shoots from the female plants can be cooked and eaten (Lucas 1988). The fruits are large (up to 13 kg) and inedible, but the seeds contain up to 30% protein and can be boiled and eaten, or ground into powder for soup. Seeds can also be fermented for several days and eaten as a slurry (Badifu and Ogunsua 1991).

Telfairia pedata. The oyster nut is a perennial grown in Central and East Africa. It is drought tolerant, can grow at elevations up to 2,000 m, requires 18 months to flowering, and is usually trellised. It produces very large, long, flat seeds which taste similar to almonds when roasted.

Trichosanthes cucumerina. The snake melon is an annual which requires high levels of soil moisture and trellising. A long growing season is necessary, and the flowers open late in the afternoon. Immature fruits are usually harvested when they are 0.3 to 0.4 m long; mature fruits can grow up to 1.5 m in length. Some of the fruits remain straight, while others may curl to resemble a snake. Immature fruits are boiled and eaten, while mature fruits are used in soups.

New World Cucurbits

Cucurbita ficifolia. The fig-leaved gourd grows in temperate highlands at elevations up to 2,000 m. One of the earliest cultivated plants in America, archaeological evidence indicates it was cultivated in Peru around 3000 BC (Herklots 1972). The immature fruits can be prepared and eaten similar to summer squash. Mature fruits can be preserved, and the black seeds are edible. In Latin

America, the flesh is impregnated with sugar to make a candy or it can be fermented to make beer (Whitaker 1990).

Cucurbita foetidissima. Identified as an underexploited tropical crop by the National Academy of Sciences (1975), the buffalo gourd has multiple food and non-food uses (Bemis et al. 1975; Gathman and Bemis 1990). It is a perennial and is found growing wild in marginal lands in the southwestern United States. Some plants have been reported to be over 40 years old. It has a very large, fleshy storage root which can grow to depths up to 5 m and weigh as much as 30 kg after two growing seasons. Roots of older plants can weigh over 100 kg. Buffalo gourd primarily reproduces by asexual reproduction, but also produces small yellow, hard shelled fruits which are considered inedible.

American Indians have used the ripe fruit as a soap substitute and as ceremonial rattles. The seeds, which contain an abundant quantity of polyunsaturated fats and protein, are edible. The large storage roots contain large amounts of starch (up to 56% of the dry weight), and can also be used as fuel. Air-dried roots burn with the heat equivalent of wood and are being tested in Afghanistan as an alternative fuel to decrease deforestation (Winrock International 1991).

Cyclanthera pedata. Korila is relatively cold tolerant and adapted to elevations up to 2,000 m, but is also easy to cultivate in the tropics and subtropics. It is currently cultivated in the Carribean and in Central and South America. The foliage is glabrous and odoriferous. Fruits are pale green, flattened, and mostly hollow. The seed cavity is spongy, and the seeds are attached to a single placenta. Seeds are usually removed and the fruits are eaten raw or cooked. They are often used stuffed with meat, fish or cheese, then baked and eaten similar to stuffed peppers. The shoots are also edible.

Sechium edule. Chayote was a common vegetable among the Aztecs prior to Spanish conquest of Mexico. It is still one of the most widely cultivated of the cucurbits in Costa Rica. It requires high levels of soil moisture and can grow at elevations up to 1,500 m. Unlike most cucurbits, it has a daylength requirement of 12 to 12.5 h for flowering. The plants grow best on hillsides and are usually trellised. Parthenocarpic fruit set can be induced by gibberellin.

Unlike other cucurbits, the fruit contain only a single, large seed. The immature fruits can be eaten raw in salads and provide a good source of vitamin C (Herklots 1972). They can also be boiled, fried, steamed, or stuffed and baked. Young leaves and tendrils are also eaten, and seeds can be sauteed in butter as a delicacy. The large storage roots represent a rich source of starch (Chakravarty 1990).

POTENTIAL BIOCHEMICAL AND MEDICINAL USES

Cucurbits are a well-recognized source of secondary metabolites. The cucurbitacins, tetracyclic triterpenoids which impart a bitter flavor to many cucurbits, have been well-studied as attractants of beetles such as *Diabrotica* (Whitaker and Davis 1962). Alkaloids have been reported in *Momordica*, and saponins have been found in *Cucurbita, Citrullus, Lagenaria,* and *Momordica* (Schultes 1990).

As biochemical isolation techniques become more sophisticated and refined, new compounds of interest are being isolated. For instance, Mukherjee et al. (1986) isolated amarinin from *Luffa amara*; amarinin inhibits plant cell growth in culture, and its action cannot be overcome with gibberellin.

Perhaps of greatest current interest are the compounds of potential medicinal interest present within cucurbits. Table 2 lists reported pharmacological properties of many cultivated cucurbits; similar properties have been ascribed to other cucurbit species not currently under cultivation (Schultes 1990). Putative properties include purgative actions and treatment for physical ailments, diseases, and infectious organisms. "Infusions" (minced tissue suitable for steeping) of selected cucurbits are sold in some markets and reported to be able to alleviate or cure certain human ailments.

Recently, abortifacient proteins with ribosome-inhibiting properties have been isolated from several cucurbit species (Ng et al. 1991). Some of these species have been used to induce second trimester abortions in China since the 1920s. The abortifacient proteins include momorcharin (from *Momordica charantia*), luffaculin (from *Luffa operculata*), trichosanthin (from *Trichosanthes kirilowii*), and beta-trichosanthin (from *Trichosanthes cucumeroides*). Trichosanthin is of particular interest because its ribosome-inhibiting properties have been shown to be effective in inhibiting the replication of human immunodeficiency virus (HIV) in infected lymphocyte and phagocyte cells, indicating potential as a therapeutic agent for AIDS (McGrath et al. 1989). These proteins vary in their level of action and effectiveness, and further germplasm evaluation of cultivated and wild species may identify related compounds with greater efficacy for ribosome inactivation.

GERMPLASM RESOURCES

Few of these Old World and New World species have been subjected to major, intensive breeding efforts. However, extensive germplasm collections are maintained by the USDA Plant Germplasm System at the Plant Introduction Station in Iowa (Clark et al. 1991) and by the Vavilov Institute in Leningrad, USSR (Robinson 1989). Another major germplasm repository is maintained by the Peoples' Republic of China (Robinson 1989), and smaller gene banks are located in Mexico, India, Spain, Nigeria, Costa Rica, and the Philippines (Esquinas-Alcazar and Gulick 1983). These germplasm collections represent a valuable resource for breeding adapted cultivars of these exotic cucurbits for domestic production.

*Scientific Article No. A6250, Contribution No. 8419 of the Maryland Agricultural Experiment Station.

Table 1. Old World and New World cucurbit species with potential for cultivation in the United States[z].

Species	Origin	Common names	Primary plant parts used	Other plant parts used	Growth habit
Old World					

Benincasa hispida (Thunb.) Cogn.	SE Asia & Indonesia	Winter melon, ash pumpkin, wax gourd, white gourd, dong gua, tallow gourd	Mature fruits	Young leaves, flower buds, seeds, immature fruits	Annual
Citrullus colocynthis (L.) Schrad.	Tropical Africa	Egusi	Seeds	Annual	
Coccinia cordifolia Cogn.	Trop. Asia & Africa	Ivy gourd, scarlet-fruited gourd	Leaves, shoots, immature fruits (preserved)	Mature fruits	Semi-perennial
Cucumis anguria L.	Tropical Africa	West Indian gherkin, bur gherkin, maroon cucumber	Immature fruits		Annual
Lagenaria siceraria (Mol.) Standl.	Tropical Africa	Bottle gourd, calabash gourd, white-flowered gourd, trumpet gourd, Zucca melon	Young fruits, mature fruits[y]	Young shoots, young leaves, seeds	Annual
Luffa acutangula (L.) Roxb.	India	Angled loofah, towel gourd, dish-cloth gourd, ridged gourd, silk gourd, long okra, ribbed loofah, ribbed gourd	Immature fruits, leaves		Annual
Luffa aegyptiaca Muell.	India	Smooth loofah, dish-cloth gourd, vegetable sponge, sponge gourd, rag gourd, hechima	Immature fruits, mature fruits[y]		Annual
Momordica charantia L.	Tropical Africa	Bitter melon, balsam pear, carilla fruit, carilla gourd, bitter gourd, alligator pear	Immature fruits young shoots	Young leaves,	Annual
Praecitrullus fistulosus (Stocks) Pang.	Tropical Africa	Round melon, squash melon	Mature fruit	Seeds	Annual
Telfairia occidentalis Hook. f.	Tropical Africa	Fluted gourd, fluted pumpkin	Female shoots, seeds		Perennial

Telfairia pedata (Sims) Hook.	Tropical Africa	Oyster nut, fluted pumpkin, Zanzibar oil vine	Seeds		Perennial
Trichosanthes cucumerina L.	India	Snake gourd, club gourd mature fruits	Immature fruits, young shoots	Young leaves,	Annual
New World					
Cucurbita ficifolia Bouche	Central Mexico	Fig-leaved gourd, Malabar gourd	Mature fruits, seeds	Immature fruits	Annual
Cucurbita foetidissima HBK	Mexico & Southern US	Buffalo gourd, mock orange, stinking wild gourd, chilicote	Mature fruits[y]	Roots[y], seeds	Perennial
Cyclanthera pedata Schrad.	South America	Korila, wild cucumber, caihua, achoccha	Immature fruits	Shoots	Annual
Sechium edule (Jacq.) Sw.	So. Mexico & Central America	Chayote, choyote, cho-cho,christophine, choke, choko, sou-sou, chaka plant, chayotl vegetable pear, mirliton	Immature fruits, tubers, seeds	Young leaves, young tendrils	Perennial

[z]Modified from Chakravarty 1990; Herklots 1972; Tindall 1983; Whitaker 1990; Whitaker and Davis 1962; and Yamaguchi 1983.

[y]Non-food uses such as soaps, fuels, sponges, utensils, containers, musical instruments.

Table 2. Putative medicinal and pharmacological properties of cultivated cucurbits[z].

		Therapeutic medications			
Species	Purgative	Physical ailments	Diseases	Infectious organisms	Other purported uses
Benincasa hispida	Diuretic, laxative	Dermatological, fever	Epilepsy, gonorrhea	Intestinal worms	Aphrodisiac
Citrulus colocynthis		Paralysis, muscle spasms			
Citrullus lanatus	Diuretic	Liver	Malaria		
Cucumis anguria		Stomach, edema, hemorrhoids		Ringworm	Freckle removal
Cucumis melo	Emetic			Intestinal worms	
Cucurbita maxima				Intestinal worms	

Cucurbita moschata & *Cucurbita pepo*	Diuretic	Ulcers, fever, jaundice	Measles, smallpox	Intestinal worms	
Lagenaria siceraria	Laxative	Kidney, flatulence, dermatological	Intestinal worms		
Luffa acutangula	Emetic	Stomach, fever		Intestinal worms	
Luffa cylindrica	Emetic, laxative	Asthma, sinusitis		Intestinal worms	Abortifacient
Momordica charantia	Laxative, emetic, emmenogogue	Colic, arthritis, hypertension, colds & fever, kidney & liver	Eczema, herpes, influenza, diabetes	Intestinal worms	Aphrodisiac
Sechium edule	Diuretic	Bladder, intestinal, hypertension, arteriosclerosis, dermatological

Dactylis glomerata L.

Poaceae

Orchardgrass, Cocksfootgrass

We have information from several sources:

Handbook of Energy Crops—James A. Duke. 1983. unpublished.

Cool-Season Grass Seed Production: Alternative Field Crops Manual, University of Wisconson Cooperative Extension Service, University of Minnesota Extension Service, Center for Alternative Plant & Animal Products

Magness, J.R., G.M. Markle, C.C. Compton. 1971. Food and feed crops of the United States.

Sea grape

Seaside grape, Uva de playa

Polygonaceae *Coccoloba uvifera* L.

Source: Magness et al. 1971

The sea grape is native to sandy shores of the American tropics. The plant is a small tree, sometimes reaching to 30 feet with stiff near-round leaves up to 8 inches across. Fruits are globose to pyroform, about 0.75 inch diameter and borne in clusters. The skin is pubescent, enclosing an edible pulp and single seed. The pulp is eaten directly and makes an excellent jelly. Ripening is mainly in midsummer. The sea grape appears not to be grown commercially, but some fruit from native plants is harvested.

Coffee

Cafe

Rubiaceae: *Coffea arabica* L.

***C. liberica* Bull ex Hiern**

Source: Magness et al. 1971

These two species constitute most of the coffee of commerce. The plants are woody, tropical, evergreen shrubs up to 15 feet in height. The leaves are elliptical, glossy, up to 6 inches long and 1/3 as wide. The fruit is a fleshy berry, in which 2 seeds are imbedded. Blossoming and fruit setting occur mainly 2 to 3 times per year. About 6 to 7 months are required to ripen the fruit, so fruits at various stages of maturity are on the plants at the same time. Ripe berries are picked at about 2-week intervals. The pulp is removed by machines. Seeds are dried in the sun or in dehydrators and roasted before being marketed. U.S. production was given as 5,000 tons, 1959 census (Hawaii only). Imports total about 1,450,000 tons annually.

Coix lacryma-jobi L.

Poaceae
Job's-tears, Adlay, Millet

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Weed to some, necklace to others, staff-of-life to others, job's tear is a very useful and productive grass increasingly viewed as a potential energy source. Before Zea became popular in South Asia, Coix was rather widely cultivated as a cereal in India. Still taken as a minor cereal, it is pounded, threshed and winnowed, as a cereal or breadstuff. The pounded flour is sometimes mixed with water like barley for barley water. The pounded kernel is also made into a sweet dish by frying and coating with sugar. It is also husked and eaten out of hand like a peanut. Beers and wines are made from the fermented grain. Chinese use the grain, like barley, in soups and broths.

Folk Medicine

According to Hartwell (1967-1971), the fruits are used in folk remedies for abdominal tumors, esophageal, gastrointestinal, and lung cancers, various tumors, as well as excrescences, warts, and whitlows. This folk reputation is all the more interesting when reading that coixenolide has antitumor activity (List and Horhammer, 1969-1979). Job's tear is also a folk remedy for abscess, anodyne, anthrax, appendicitis, arthritis, beriberi, bronchitis, catarrh, diabetes, dysentery, dysuria, edema, fever, gotter, halitosis, headache, hydrothorax, metroxenia, phthisis, pleurisy, pneumonia, puerperium, rheumatism, small-pox, splenitis, strangury, tenesmus, and worms (Duke and Wain, 1981). Walker (1971) cites other medicinal uses.

Chemistry

Per 100 g, the seed is reported to contain 380 calories, 11.2 g H_2O, 15.4 g protein, 6.2 g fat, 65.3 g total carbohydrate, 0.8 g fiber, 1.9 g ash, 25 mg Ca, 435 mg P, 5.0 mg Fe, 0 ug beta-carotene equivalent, 0.28 mg thiamine, 0.19 mg riboflavin, 4.3 mg niacin, and 0 mg ascorbic acid. According to Hager's Handbook (List and Horhammer, 1969-1979), there is 50-60% starch 18.7% protein (with glutamic-acid, leucine, tyrosine, arginine, histidine, and lysine) and 5-10% fatty oil with glycerides of myristic- and palmitic-acids.

Description

Annual (in the temperate zone) but perennial where frost is absent or mild, freely branching upright or ascending herb 1-2 m tall, the cordate clasping leaf blades 20-50 cm long, 1-5 cm broad. Spikelets terminal, and in the upper axils, unisexual, staminate spikelets two-flowered, in twos or threes on the continuous rachis; pistillate spikelets three together, one fertile, and two sterile; glumes of the fertile spikelet several-nerved, all enclosed finally in a bony beadlike involucre, the grain, white to bluish white, or black, globular orvoid, 6-12 mm long.

Germplasm

Reported from the Indochina-Indonesia Center of Diversity, Job's Tears or cvs thereof is reported to tolerate laterite, low pH, photoperiodic latitude, poor soil, slope, virus, and waterlogging. ($2n$ = 10, 20) (Duke, 1978)

Distribution

Native perhaps to southeast Asia, but now rather pantropical as cultigen and weed. Listed as a serious weed in Polynesia, a principle weed in Italy and Korea, a common weed in Hawaii, Iran, Japan, Micronesia, and Puerto Rico, also in Australia, Borneo, Burma, Cambodia, China, Congo, Colombia, Costa Rica, Dominican Republic, Fiji, Ghana, Guatemala, Honduras, Hong Kong, India, Iraq, Melanesia, Nepal, Pakistan, Peru, Philippines, Rhodesia, Senegal, South Africa, Sudan, Thailand, United States, and Venezuela (Holm et al, 1979).

Ecology

Ranging from Cool Temperate Moist to Wet through Tropical Very Dry to Wet Forest Life Zones, Job's Tears is reported to tolerate annual precipitation of 6.1 to 42.9 dm (mean of 31 cases = 17.9) annual temperature of 9.6 to 27.8°C (mean of 31 cases = 21.5) and pH of 4.5 to 8.4 (mean of 23 cases = 6.2). (Duke, 1978, 1979)

Cultivation

Propagation by seeds, sown during monsoon (in India) at rate of 6-10 kg/ha. Seed dibbled 2.5 cm deep, at spacing of 60 x 60 cm. One intercultivation, before the plants tiller, and shade on ground may be necessary. Sufficient rains in early stage of growth and a dry period when grain is setting are necessary for good yields. Plants respond well to liberal applications of organic manure.

Harvesting

Crop harvested in 4-5 months after sowing. Plants are cut off at base and grain separated by threshing. Seeds are dried in sun prior to milling. Adlay flour milled and used with wheat flour for baking purposes.

Yields and Economics

Yields vary as to strains cultivated in different countries: yield of unhusked grains in Philippine Islands is about 3.5 T/ha; in Sri Lanka, 2.1 T/ha. In some areas 40-75 bu/acre is considered good under average conditions. Loss in hulling is about 30-40% in Philippine Islands and 70% in Sri Lanka. Adlay is extensively cultivated in Philippine Islands, Indochina, Thailand, Burma, and Sri Lanka, and is used as an auxiliary food crop, especially as a substitute for rice. It does not enter international trade, although it is used locally in large quantities.

Energy

According to the phytomass files (Duke, 1981b), annual productivity ranges around 5 MT/ha, but few data are available. Duke's field observations in Panama suggest that in Tropical Fresh Water Swamp situations, standing biomass visually suggests closer to 10 20 MT/ha. In Mali, it provides only 45-53 MT fresh fodder/ha. If perennial in the tropics, there is the good possibility that 2 MT grain and 10 MT biomass could be harvested renewably, with proper soil management.

Biotic Factors

Following fungi attack adlay: *Cladosporium herbarum, Curvularia coicis, Diplodia coicis, Epicoccum hyalopes, Fusarium equiseti, F. graminearum, F. moniliforme, F. semitectum, Helminthosporium coicis, Ophiobolus graffianus, Phyllachora coicis, Phyllosticta coixicola, Ph. coix-lacrimae, Puccinia operta, Nigrospora sphaerica, Trilletia okudaire, T. taiana, Uredo operta, Ustilago coicis, U. lachrymae-jobi.* Leaf-gall virus and the nematode *Meloidogyne incognita acrita* also attack this plant. Most losses are due to rats and parrots.

Cola

Kola

Sterculiaceae *Cola acuntinata* (Beauv.) Schott & Endl.

***C. nitida* (Vent.) Schott & Endl.**

Source: Magness et al. 1971

The cola seeds of commerce are from medium size spreading trees, up to 40 feet, native to tropical Africa, but now cultivated in the West Indies and other tropical countries. The seeds or nuts are borne in leathery or woody oblong capsules, about 6 inches long. Seeds are near globose, about an inch in diameter. They, or preparations from them, are widely used in tropical countries as a stimulant and appetizer. Preparations from the seeds are widely used for flavoring the cola drinks, very popular in the U.S. and other countries.

Coltsfoot

Tussilago farfara L.

Figure 41.—Coltsfoot (*Tussilago farfara*)

Other common names.—Coughwort, assfoot, horsefoot, foalfoot, bull's-foot, horsehoof, colt-herb, clayweed, cleats, dove-dock, dummyweed, ginger, gingerroot, hoofs, sowfoot, British tobacco, gowan.

Habitat and range.—Coltsfoot is found along brooks and in wet places and moist clayey soil along roadsides from eastern Quebec to Pennsylvania, Ohio, and Minnesota.

Description.—The white woolly, scaly flowering stalks of this plant with their yellow blossoms appear in the spring before the leaves. There are several stalks, from 3 to 18 inches in height, arising directly from the rootstock and each one bearing at the top a single yellow flower head having in the center numerous tubular disk flowers which are surrounded by ray flowers. The flowers open only in sunny weather. The ripe seed head looks somewhat like that of a dandelion. Some time after the flowers appear the leaves are produced on long erect stalks directly from the rootstock. They are from 3 to 7 inches wide and in shape resemble a horse's hoof. The lower surface is white with densely matted woolly hairs.

Part used.—The leaves and roots, the former collected when they are nearly full size.

Scientific Name: *Commelina benghalensis* Linn.
Family: Commelinaceae
English Name: Day Flower, Dew Flower.
Hindi Name: Kanchara, Kaua-kaini, Kanuraka.

General Description: It grows as common weed in crop fields particularly in rice fields in India. It is popularly used as folk medicine.

Botanical differences among the major *Commelina* species.

Characters	*C. benghalensis*	*C. albescens*	*C. diffusa*	*C. forskalae*	*C. paludosa*	*C. erecta*
Plant	A large, straggling annual, rooting at basal nodes and covered on all parts with a colourless pubescens	A perennial diffuse or suberect herb from a woody, knotted rhizomotous stock	A variable, straggling annual with glabrous, arching internodes, rooting at lower nodes	A much branched, diffuse annual, rooting at lower nodes	A. scadent, perennial herb	A perennial much branched, decumbent or ascending herb

Stem	branches many, some of them growing under ground and bearing reduced leaves and spathes with apetalous closed flowers and capsules	Annual, much branched, clothed below with many, white, membranous sheaths with or without whittering leaves		Branches slender, glabrous or puberulent	Stem stout, branched from the base, rooting at basal nodes, glabrous	
Leaves	Ovate-elliptic or oblong, shortly triangular or subobtuse apex.	Linear-lanceolate, broadest a little above base, gradually tapering to an acute apex	Broadly lanceolate or ovate-lanceolate, abruptly acuminate	Narrowly oblong or scarcely elliptic, obtuse or subacute at apex	Subsessile, elliptic-lanceolate or oblong-lanceolate, some what oblique at base, glabrous	Lanceolate, entire, somewhat pubescent above, glabrous and greyish-green below, acute or acuminate
Flowers	Bluish-violet, cyme branches 1 or 2, one often suppressed, when 2, inner bearing one male flower, outer bearing 2-3 perfect flowers	Pale blue	Deep cobalt-blue		White, in simple or branched cymes.	
Fruit	Capsule broadly ovoid-oblong	Capsule 5mm long	Capsule elongate, 7 mm long	Capsule sub-cubic, buff coloured.		Capsules oblong
Seeds	Ovoid	Obliquely ovoid	Ovoid elongate			Black with membranous margin. One in each cell

Useful Parts: Whole herb.

Traditional Medicinal Uses: According to Ayurveda, it is bitter and useful in treatment of leprosy, and nervous system related disorders.

Sweetfern

Comptonia peregrina (L.) Coulter.

Synonyms.—*Comptonia asplenifolia* Gaertn.; *Myrica asplenifolia* L.

Figure 104.—Sweetfern (*Comptonia peregrina*)

Other common names.—Ferngale, fern bush, meadow fern, shrubby fern, Canada sweetgale, spleenwort bush, sweet bush, sweet ferry.

Habitat and range.—Sweetfern is usually found on hillsides, in dry soil, from Canada to North Carolina and west to Indiana and Saskatchewan.

Description.—Sweetfern is a shrub from 1 to 3 feet high with slender, erect, or spreading branches and reddish-brown bark. The thin, narrow leaves are from 3 to 6 inches long, from one-fourth to one-half an inch wide, deeply divided into many lobes and in general resembling the leaves of a fern. Both male and female flowers are produced. The former are borne in cylindrical catkins in clusters at the ends of the branches and the latter in egg-shaped catkins. The whole plant has a spicy, aromatic odor, which is more pronounced when the leaves are bruised.

Part used.—The entire plant, especially the leaves and tops.

Poison Hemlock

Conium maculatum L.

Figure 85.—Poison hemlock (*Conium maculatum*)

Other common names.—Spotted parsley, spotted cowbane, poison parsley, St.-Bennet's-herb, bad-man's-oatmeal, wode-whistle, cashes, bunk, heck-how, poison root, spotted hemlock, spotted conium, poison snakeweed, beaver poison.

Habitat and range.—This poisonous weed is occasional in waste places and along roadsides, principally in the Eastern States.

Description.—Poison hemlock is a very dangerous weed, the close resemblance of the leaves to those of parsley often causing it to be mistaken for the latter with fatal results, all parts of the plant being extremely poisonous. It has a smooth, hollow, purple-spotted stem about 2 to 6 feet in height with muchbranched, and large, parsleylike leaves. In June or July it produces showy, flat-topped clusters of small white flowers. The fruit, which ripens in August and September, is grayish green and about an eighth of an inch m length The entire plant has a disagreeable, mouselike odor which is especially noticeable when the plant is bruised.

Part used.—The fruit, collected when fully developed but still green, carefully dried and stored in tight containers to protect it from air and light. It is of no value after it has been kept more than two years. The leaves are also used to some extent.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Eucalyptus microtheca F. Muell.

Myrtaceae
Flooded box, Coolibah

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

This tall tree, featured in the song, "Waltzing Matilda", produces one of the hardest and strongest timbers in the world. The wood is, however, difficult to work because of the interlocking grain. Unsuitable for construction, it makes durable poles and fence posts. Little (1983) suggests that the wood is suitable for bearings, bushings, bolts, shafts, frames, and wheel parts for heavy vehicles. The tree is esteemed for erosion control, shade and soil conservation in hot arid climates. Aborigines obtained water from the superficial roots, by cutting forearm-sized root segments, then holding them vertically, after debarking. Sometimes they blew into the distal portion to enhance the flow. Aborigines use the branch and leaf as a fish poison (Watt and Breyer-Brandwijk, 1962).

Folk Medicine

Reported to be antiseptic and disinfectant, the inner bark is a folk remedy poulticed onto snakebite.

Chemistry

Leaves contain 0.49% essential oil with cineol, phallandrene, and pinene. The bark contains ca 6% tannin (Watt and Breyer Brandwijk, 1962).

Description

Evergreen tree 6–20 m high, usually crooked or irregular, 30–100 cm in diameter. Bark gray or brackish, thick, fibrous, rough, not shedding. Leaves alternate, narrowly lanceolate, 6–20 cm long, 1–3 cm wide, acuminate apically, basally acute, not entire, glabrous, slightly thick, leathery, dull green, slightly paler underneath. Panicles mostly near ends of twigs, short, branched with slightly angled slender stalks ending in umbels of 3–7 short stalked fragrant flowers. Flowers very small, the bud 4–6 mm long. Stamens many, spreading, white, short, 3–4 mm long, anthers rounded with small round gland. Pistil with inferior 3–4-celled ovary and stout style. Capsules short-stalked, hemiglobose or turbinate, very small, 3–4.5 mm long and wide. Seeds many, tiny, 2 mm long, blackish (Little, 1983).

Germplasm

Reported from the Australian Center of Diversity, coolibah, or cvs thereof, is reported to tolerate alkalinity, clay, drought, fungus, heat, heavy soil, high pH, insect, savanna, waterlogging, and wind (NAS, 1980a; Little, 1983). Trees will not tolerate fires, especially when young.

Distribution

Widely distributed in Australia (except Victoria and Tasmania) in open woodlands, floodplains, seasonally flooded areas, and the edges of swamps, coolibah has been successfully introduced to Egypt, Iran, Iraq, Nigeria, Pakistan, Sudan, and Tanzania.

Ecology

Estimated to range from Tropical Thorn to Tropical Very Dry (Little also suggests Tropical Moist) through Warm Temperate Thorn to Dry Forest Life Zones, coolibah is estimated to tolerate annual precipitation of 2 to 12 dm, annual temperature of 17 to 25°C, and pH of 6.0 to 8.2. Mean maximum temperatures in the hottest months are 35–38°C; mean minimum in the coolest, ca 5°C. It can withstand a few light frosts. In its native range it grows between 80–700 m elev. on clays or silty clay loams, often alkaline.

Cultivation

Easily propagated by seeds, seedlings are outplanted at ca 6 mos. when they are ca 4 dm tall. Seeds must be exposed to light during germination. Trees must be carefully weeded until they are well established.

Harvesting

The tree coppices well. In the Gezira, the seedling crop is harvested in 8 years, then harvested on a 6-year coppice rotation.

Yields and Economics

The tree may grow 3 m a year (in height). Wood yield of 5 to m^3/ha/yr are reported (Webb et al., 1980).

Energy

Making an excellent firewood, coolibah is cultivated as such in the Sudan, for example. It makes a fairly good charcoal with a relatively high ash content (2–6%).

Copaifera langsdorfii Desf.

Caesalpiniaceae
Diesel tree

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

That the oleoresin called copaiba could be obtained by incising the trunk was first reported in England in 1625, in a work published by Purchas, "...a single tree is said to yield about 40 litres." (Grieve, 1931, reprinted 1974). Quoting nobel-laureate Calvin, Maugh says (1979), "Natives ... drill a 5 centimeter hole into the 1-meter thick trunk and put a bung into it. Every 6 months or so, they remove the bung and collect 15 to 20 liters of the hydrocarbon. Since there are few Rabbit diesels in the jungle, the natives use the hydrocarbon as an emollient and for other nonenergy-related purposes. But tests have shown, he says, that the liquid can be placed directly in the fuel tank of a diesel-powered car." (Maugh, 1976). The copal is used in lacquers, massage preparations, medicines, and paints. Wood and resin can be used for fuel. The wood is used in carpentry (Burkart, 1943).

Folk Medicine

According to Hartwell (1967-1971), balsam of one species is used in folk remedies as a fomentation, for tumors of the prostate gland. Grieve (1931) describes the balsam as stimulant, diuretic, carminative, laxative; in large doses purgative, causing nausea, vomiting, strangury, bloody urine, and fever. A good remedy for chronic catarrh and bronchitis, as it assists expectoration and is antiseptic; given with advantage in leucorrhoea, chronic cystitis, diarrhea, and hemorrhoids. It is chiefly used in gonorrhea (though not advocated for chronic cases), often combined with cubebs and sandal. It has also been recommended externally for chilblains. Both the volatile oil and resin are greatly altered when expelled in the urine, and when precipitated by nitric acid might be mistaken for albumen; it is considered a valuable hydragogue diuretic in obstinate dropsy. It creates an irritant action the whole mucous membrane, imparts a peculiar odor to the urine and breath, causes an eruption resembling measles attended with irritation and tingling; it is the resin, not the oleoresin, that is used as diuretic. Duke and Wain (1981) note that this species is a folk remedy for dermatosis, eczema, and gonorrhea. In Panama, Yaviza negros mix cabismo resin with honey and give it to the newborne, to impart knowledge and ward off hexes. The gum is also used for treating venereal diseases, for massage, and for hair oil (Duke, 1972, under "cabismo").

Chemistry

In what could as well apply to other species, Hager's Handbuch lists delta-elemene, copaene, alpha- and beta-cubebene, cyperene, alpha-bergamoten, beta- and gamma-elemene, beta-farnesene, alloaromadendrene, alpha- and beta-humulene, beta-bisabolene, alpha- and beta-selinene, delta- and gamma-cadinene, ar-curcumene, calamenene. From the wood, Langenheim (1981) reports the following diterpenoids: polyalthic acid; (-)-jkaur-16-en-19-oic acid, (-) 16 betakauren- 19-oic acid and eperu-8(20)-en-15,18-dioic acid. In 1980, Calvin published the chromatogram of products obtained from Copaiba oil.

Langenheim (1981) compares the sesquiterpenes of *Hymenaea*, shall we call it the "kerosene tree," and *Copaifera*, Calvin's "diesel tree."

Sesquiterpene Hydrocarbons	*Hymenaea*	*Copaifera*
Allo-arodendrene	--	wood
alpha-Bergamotene	--	wood
beta-Bisabolene	wood	wood
delta-Cadinene	leaf-pod-stem cortex	wood, leaf
gamma-Cadinene	leaf-stem cortex	leaf
Calamenene	--	wood
Calarene	pod	--
Caryophyllene	leaf, pod-stem cortex	wood, leaf
alpha-Copaene	leaf-stem cortex	wood, leaf

beta-Copaene	leaf-stem cortex	wood*, leaf*
alpha-Cubebene	leaf-stem cortex	wood, leaf*
beta-Cubebene	--	wood

Selina-4(14), 7-diene	pod	--

*probably present Langenheim (1981)

Description

Evergreen tree to 35 m tall, to 1 m in diameter, otherwise rather resembling *Copaifera officinalis*, which see. In Argentina (Territorio de Misiones) it is 6-12 m tall, with paripinnate glabrous, subcoriaceous leaves 5-10 cm long; leaflets 2-4 pairs, opposite or semialternate petiolulate, elliptic ovoid, 2-6 cm long, 1.2-2.5 cm broad with finely pinnate reticulate nervation, glandular-punctate. Flowers in terminal racemes to compound panicles with numerous, subsessile whitish flowers. Sepals 4 lanceolate, concave, firm, glabrous outside, pubescent inside. Petals absent. Stamens free, (8-)10, the anthers elliptic, versatile. Ovary hirsute; briefly stipitate; fruit ovoid, compressed, ca 2 x 3 cm, coriaceous, with one large seed partially covered with a thick aril (Burkart, 1943). There is some question about the distinctness of the species. This species, called "Copaiba" in Brazil, is called "Cabismo" in Venezuela, a name applied in Darien Panama to what was identified by Duke (1972) as *Copaifera officinalis*, but has since been relegated to another species. Duke describes "cabismo" as one of the finest timbers in Darien. Calvin (1980) mentions another similar species, *Copaifera multijuga*.

Germplasm

Reported from the Middle and/or South America Center of Diversity, the diesel tree, or cvs thereof, is reported to tolerate some waterlogging. Seedlings germinate well in dense shade. In his lecture at Beltsville, Calvin states that he has obtained somatic fusion of *Copaifera* and *Euphorbia*. Perhaps he has changed his mind since then. ($2n = 2$)

Distribution

Because of the taxonomic obscurity of the species, I cite only northern and Amazonian South America.

Ecology

Probably ranging from Subtropical Dry to Wet through Tropical Dry to Wet Forest Life Zones, this copaiba probably tolerates annual precipitation of 10 to 40 dm, annual temperature of 20 to 27°C (with no frost), and pH of 4.5 to 7.5. Early USDA publications suggest that most copaiba comes from regions with annual precipitation of 3500 mm or more and annual temperature ca 27°C.

Harvesting

A cross section of the trunk shows that the hydrocarbons collect in thin capillaries that may extend the full 30-meter height of the tree. A holedrilled into the tree probably collects hydrocarbons from capillaries ruptured by the drilling, Calvin speculates, so that it may be possible to increase the yield by drilling additional holes. An acre of 100 mature trees might thus be able to produce 25 barrels of fuel per year. Unfortunately, in the United States the tree would probably grow only in Southern Florida. The Brazilian government has already established experimental plantations. Calvin concedes that copaifera will probably never represent a significant source of diesel fuel for the U.S. It is of interest chiefly as an example of the great diversity of materials produced by plants (Maugh, 1979). Old USDA information summaries give a slightly different harvesting story. "The wood of the tree is honeycombed with a network of connected cavities in which the oleoresin forms. To tap the tree, a drainage reservoir is hollowed out near its base by cutting inward and downward into the center of the trunk. The cavities containing the oleoresin gradually drain into these hollowed-out wells. This process is repeated several times during the season. When first obtained, copaiba is thin and clear but on aging becomes thicker and acquires a yellowish tinge."

Yields and Economics

USDA once reported per tree yields as high as 53 liters (14 gallons). A tree yields 53 liters of "diesel" and diesel sells for $1.00 per liter, it would pay the natives to gather the material. Apparently this is not happening to any great extent. Back in 1938, the U.S. imported from Brazil nearly 100 tons worth only ca $30,000 then, 106 tons worth ca $34,000 in 1939, and 102 tons worth ca $36,000 in 1940.

Energy

Although not specifically recommended as a firewood, the balsamiferouswood, with density of 700-900 kg/m^3, should burn readily, perhaps even when green. Calvin (1980) reports yields of 40 liters of hydrocarbon per tree per year, which can be "used directly by a diesel-powered car." Calvin sent a sample to Mobil Corporation to obtain a cracking pattern. "It produces the same kind of mixture in general as the oil from the *E. lathyris* [mostly aromatics (50%), LPG (25%), and low-molecular-weight fuel gas (3 to 4%) and coke]." (Calvin, 1980). In his seminar at Beltsville, Calvin (1982) seems to favor the terpenes of *Copaifera* to those of *Euphorbia* and hopes, by somatic hybridization to develop a *Euphorbia*, suitable for our climates, which will produce the sesquiterpenes. Apparently N-fixation has not been reported for this species.

Biotic Factors

No data available.

Goldthread

Coptis trifolia (L.) Salisb.

Other common names.—Coptis, cankerroot, mouth root, yellowroot.

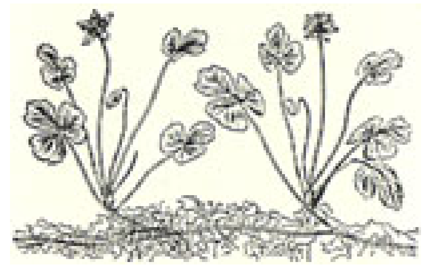

Figure 57.—Goldthread (*Coptis trifolia*)

Habitat and range.—Goldthread is found in damp, mossy woods and bogs from Canada and Alaska south to Maryland and Minnesota. It is most common in the New England States, northern New York and Michigan, and in Canada, where it frequents the dark sphagnum swamps, cold bogs, and the shade of dense forests of cedars, pines, and other evergreens.

Description.—This plant, which in its general appearance somewhat resembles the strawberry plant, is of low growth, being only 3 to 6 inches in height. Its shiny, evergreen leaves, which are divided into three parts, grow directly from the base of the plant. A single small, white, star-shaped flower, which appears from May to August, is borne at the end of each flowering stalk. The plant is appropriately named after the long, slender, creeping, much-branched and frequently matted, bright golden-yellow root.

Part used.—The root, collected in autumn.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Erythrina berteroana Urb.

Fabaceae
Coralbean, Macrette

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Cultivated here and there as an ornamental, as a living fence post, as fuelwood species, and cork substitute (Duke, 1972). Resides living fenceposts and hedges, the trees have been grown as support in vanilla plantations. According to Little and Wadsworth, it is seldom used for anything but fuel in Puerto Rico. The wood is whitish, soft, lightweight (specific gravity 0.3) and has been used for carving toys and figurines. Cattle and rabbits graze the young shoots and leaves. In Guatemala, flower buds, young leaves, and young twigs are eaten like stringbeans though deemed potentially harmful (Little and Wadsworth, 1964). Poisonous seeds have been strung into bracelets, necklaces, and novelties. Bark yields a yellow dye. Crushed branches are used to intoxicate fish. Corollas of this and other species, placed in hollow leaf stalks, serve as a children's whistle.

Folk Medicine

Reported to be narcotic, piscicidal, poisonous, and soporific, coralbean is a folk remedy for dysmenorrhea and other female ailments (Duke and Wain, 1981). According to Morton (1981), the sedative flower decoction is used for dysentery, hemorrhages and nervousness. Guatemalans believe that tucking the flowers and leaves under ones pillow will make one sleep well. Recently we acquired large quantities for further research in the now-defunct cancer-screening program. Bayano Cuna of Panama use the plant for female ailments (Duke, 1972).

Chemistry

Per 100 g, the leaves and young buds are reported to contain 48 calories, 84.2 g H_2O, 4.4 g protein, 0.2 g fat, 10.0 g total carbohydrate, 2.4 g fiber, 1.2 g ash, 108 mg Ca, 80 mg P, 2.2 mg Fe, 220 ug beta-carotene equivalent, 0.19 mg thiamine, 0.19 mg riboflavin, 1.2 mg niacin, and 37 mg ascorbic acid. (Duke and Atchley, 1984). On a zero-moisture basis, leaves contain 304 calories, 27.8 g protein, 1.3 g fat, 63.3 g total carbohydrate, 15.2 g fiber, 7.6 g ash, 684 mg Ca, 216 mg P, 9.7 mg Fe, 12,433 ug beta-carotene equivalent, 1.3 mg thiamine, 0.92 mg riboflavin, 25.43 mg niacin, and 16 mg ascorbic acid (Duke, 1981b). Seeds contain erysodine, erysoline, erysopine, erysothiopine, erysothiovine, erysovine, alpha- and beta-erythroidine (also in the wood), and hypaphorine. Hypaphorine, the betaine of tryptophane is a curare-like convulsive poison. Chawla et al., (1982) report one new alkaloid in the seed extract, 8-oxo-alpha-erythroidine, and 8-oxo-beta-erythroidine in the leaf extract.

Description

Armed tree to 10 m tall, the leaves alternate, trifoliate, 10-35 cm long, the leaflets ovate or deltoid, 5-12.5 cm long, 4-12.5 cm wide, entire shortly acute or acuminate at the apex. Flowers pinkish to red, appearing with the leaves, in terminal racemes, each flower ca 5-10 cm long, embracing 10 stamens, the anthers protruding. Ovary stalked, pubescent. Pod dark brown, curved, moniliform, 10-30 cm long, 1-1.5 cm broad, the beak 2-4 cm long, the several seeds oblongoid, bright orange red, with a conspicuous black hilum (Morton, 1981; Little and Wadsworth, 1964).

Germplasm

Reported from the Central American (and possibly West Indian) Center of Diversity. ($2n = 42$)

Distribution

According to Krukoff (1970) *E. berteroana* is by far the most common species in Central America. It is the common lowland species ascending to nearly 1500 m in drier regions, like the Oriente of Guatemala. Morton (1981) extends the range to 2000 m and to Colombia, noting that it is wild or naturalized in Cuba and Hispaniola, cultivated and naturalized in Panama.

Ecology

Estimated to range from Tropical Dry to Wet through Subtropical Dry to Wet Forest Life Zones, this coralbean is estimated to tolerate annual precipitation of 10 to 40 dm, annual temperature of 20 to 28°C, and pH of 6 to 8.

Cultivation

According to Martin and Ruberte (1975), this is one of the easiest species of *Erythrina* to grow. Like most *Erythrinas*, this probably roots readily from large fence-post sized cuttings. Seeds germinate rather rapidly.

Harvesting

For those risking them as vegetables, the young buds and leaves are probably at their tenderest when leafing out, often in tandem with the commencement of the rainy season.

Yields and Economics

No data available.

Energy

With no hard data available to me, I have no reason to suspect that this species would be any less productive than *E. poeppigiana*, which probably returns ca 25 MT/ha/yr in monoculture, 10 MT/ha in intercropping.scenarios. Nitrogen fixing nodules are reported in Hawaii (Allen and Allen, 1981).

Biotic Factors

No data available.

Introduction and Domestication of Rare and Wild Fruit and Nut Trees for Desert Areas*

Avinoam Nerd, James A. Aronson, and Yosef Mizrahi

INTRODUCTION

The range of crops that can be grown commercially in hot desert regions is very limited. This is specially true for orchard crops. The purpose of our research program is to develop new crops for hot desert area's through introduction and domestication. Our approach is based on perennial plants from two sources: wild plant species from arid and semiarid areas, yielding nutritious fruits or nuts eaten by the local people (Wehymeyer 1966, Felger and Moser 1976, Biesele et al. 1979, Felger 1980, Fox and Norwood-Young 1982, Taylor 1986); and rare fruits that can be obtained in local markets or from growers of rare fruits. Israel's Negev desert, with its broad spectrum of climatic conditions and types of soil and water, is an appropriate site for such a project. We have set out to exploit the Negev's variation to test the suitability of a number of plant candidates for introduction and domestication in desert areas. This is our first report on the project, and summarizes four years of work starting from 1984. We will describe our activities in general and give some details regarding six of our plant candidates.

METHODOLOGY

Suitable plant candidates, i.e., wild or semi-domesticated perennials yielding tasty, nutritious fruits or nuts as well as fruit trees not commonly cultivated in developed countries, were selected on the basis of information collected from rare fruit growers and investigators. The common and botanical names and families of the plant candidates are listed in Table 1. With the exception of *Opuntia ficus-indica* and *Ziziphus mauritiana*, which were introduced as cuttings and grafted plants, respectively, all the plant material was obtained from seeds collected in the wild or obtained from growers of rare fruits.

Seeds were germinated and plants established under quarantine conditions, then transferred to a nursery. Introduction orchards were established throughout the Negev desert (Fig. 1). Each of the introduction orchards has distinct climate and water quality characteristics (Table 2, 3, 4). To eliminate the effect of random local conditions each species was planted in three separate blocks at each site. Five to ten plants were used for each species per block.

All orchards are equipped with drip irrigation systems. Each tree is supplied with a 2-liter/hour dripper. When the canopy has developed either the dripper is replaced with one of larger capacity or additional drippers are added. Fertilization with NPK is given via the irrigation system. Sequestrene 134 is applied to correct iron deficiency symptoms. All irrigation and fertilization regimes were adapted from the recommendations of the Extension Service for mango trees grown in the Negev area (Frenkel and Zohar 1987). The following operations relevant for plant establishment are being carried out at all locations: growth measurements; phenological observations; climate, soil, water, and mineral analyses.

At the next stage, fruit and nut yields and quality will be determined, followed by clonal propagation of the selected clones and rootstocks.

This research was partially supported by the following agencies: US-AID CDR; GIARA-Germany-Israel Agriculture Research Agreement; PEF-Israel Endowment Fund; New-jersey Freedom From Hunger Campaign (Headed by Mr. Brach); and the Israeli Ministry of Agriculture.

PROMISING SPECIES

Cordeauxia edulis

Yehib is an evergreen shrub native to and zones on the borders of Somalia and Ethiopia. The plant produces pods usually containing a single seed weighing 2-3 g and rich in starch and sugars. The seed is tasty and is used by nomads as a staple food. It is also sold in local markets. The yehib has been described as a drought tolerant plant and is an endangered species (Miege and Miege 1979, National Research Council 1979).

Seeds germinated well, and seedlings grew under quarantine conditions and then in the nursery. Upon transfer to the various locations growth was inhibited, followed in many cases by death. With the exception of a few survivors at Qetura, the yehib plants did not become established in most of the orchards. Growth of the survivors occurred from May until October but was very slow both in the nursery and in the orchard (Fig. 2 and 3). Yellowing of leaves was common in many plants, generally followed by death. The survivors also showed some yellowing of leaves; this phenomenon was particularly marked in mid-summer, when temperatures can reach up to 48°C, but it was also observed in winter.

Ricinodendron rautanenii

Mongongo is a large, dioecious, deciduous tree which grows in the wild on sandy soils between latitudes 15 and 21° S in southern Africa. The fruit of the tree has a thin edible flesh and a pleasant-tasting kernel contained in a hard-walled stone. The kernel weighing about 1.2 g is rich in fats (~40%) and proteins (~38%) and plays a central role in the diet of the Kung San food gathering and hunting people of the Kalahari desert (Biesele et al. 1979, Fox and Norwood-Young 1982). The mongongo fruits abscise green when mature, and start ripening (skin color change to brown, flesh softening and taste development) a few days later.

Seeds germinated after treatment with (2-chloroethyl) phosphonic acid (ethephon) (Keegan and Van Staden 1981). Seedlings were transplanted successfully in all orchards. At Neot Hakikar after a brief growth spurt in June the plants turned yellow, showed the typical leaf bum symptoms of NaCl damage, and subsequently died. At Qetura the main growth period occurred during the spring; in mid-summer growth slowed down. At the Besor location winter dormancy broke very late (in June), and growth continued until November (Fig. 4, 5). This location is much cooler than Qetura (Table 2). In all locations some of the trees showed signs of leaf yellowing, which was diagnosed as iron deficiency and corrected by applications of iron. The healthiest looking trees are those growing at the Besor plot (Fig. 5).

Sclerocarya birrea subsp. *caffra*

Marula is a large, dioecious, deciduous tree which grows wild in northern South Africa and parts of eastern Botswana. The flesh of its fruit is very juicy and aromatic and is eaten fresh or processed, yielding quality jams, juices and alcoholic beverages. Inside the stone is a very small tasty nut. The fruit serves as an important source of vitamin C for the rural people (Shone 1979, Taylor 1986). When mature, the green fruit abscise followed by a skin color change to yellow, flesh softening and aroma development. These changes occur 7-10 days after abscission. Recently Prof. Holtzhausen (pers. commun.) of the University of Pretoria selected improved clones producing large fruits up to 100 g in weight and with a variety of skin colors.

Seeds germinated after the operculum had been opened (Teichman et al. 1985). All plants were transferred successfully to the orchards. Breaking of winter dormancy occurred at Qetura first, then at Besor and Neot Hakikar. The slowest growth rate was recorded at Neot Hakikar. While growth was steady at Besor, at Qetura, rapid growth occurred from June to August followed by slower growth in September and October (Fig. 6, 7). Neot Hakikar is characterized by high salinity due mainly to NaCl, and many plant species failed to survive there. Marula did not show any signs of salinity leaf burns. At Qetura three-year-old male and female trees started to flower and fruit developed.

Stenocereus gummosus

Pitahaya agria, a columnar cactus which grows wild in the Sonora and Baja California deserts of Mexico, produces variously colored edible fruits resembling those of prickly pear. In many cases the thorns of the fruits abscise upon ripening. The seeds are small and can be eaten without difficulty, unlike those of the prickly pear (Felger and Moser 1976).

The seeds germinated rapidly; however, first development was very slow, and it took two years for seedlings to reach a size suitable for transplanting (a height of ca. 10-15 cm). The slowest growth rate was at Neot Hakikar. Cessation of growth occurred only during the mid-winter months (December, January, and February). At Qetura three-year-old plants reached a total shoot length of 160 cm (Fig. 8, 9).

Casimiroa edulis

White sapota is a medium-sized evergreen tree from central America which can be found in backyard gardens. Growers of rare fruits in California and Florida have selected a number of high-yielding cultivars with improved fruits. The fruits are medium to large with a thin green-yellow skin and cream-white sweet flesh (Batten, 1984). Our seeds were obtained from the collection of Mr. and Mrs. Chambers of Fallbrook, California and from trees growing in Israel.

The seeds germinated easily and seedlings transplanted well at all locations. At Neot Hakikar the plants turned yellow with severe symptoms of NaCl leaf burn; they survived for a while and then died. Fig. 10 shows plant growth at Besor and Qetura. At Qetura growth started in March/April and slowed down in the hottest months, namely July and August. At this time the leaves showed some symptoms of yellowing and tip burns, which vanished in the autumn. Despite these difficulties, development at Qetura is satisfactory (Fig. 11). At Besor the fastest growth occurred in May-August, and damage to leaves was not observed.

Ziziphus mauritiana

Ber is a medium-sized evergreen thorny tree believed to be of African origin. Ber is grown commercially on a wide scale in the hotter areas of India, and is reported to be salt- and drought-tolerant (Alexander 1984). The fruits can reach the size of a plum and when ripe develop a thin, yellow-brown skin enclosing a tasty, white, sweet flesh.

Many cultivars are known in India of which two, 'Gola' and 'Seb', were introduced by us to Israel. They were grafted onto *Z. spina-cristi* (native to our region) and onto *Z. abysscinica*. Development at the various sites on each of the two rootstocks is successful; a one-year-old plant at Qetura is shown in Fig. 12.

PROBLEMS

The first problem one faces when seeds are collected from the wild is that they often fail to germinate or that the germination rate is low. In the wild it is sufficient for some seeds to germinate every few years to ensure a steady population. Indeed, one of the mechanisms by which a population maintains itself under drought conditions is by staggering germination over a long period of time (Koller 1972). This is the case for the mongongo and marula which we collected from Botswana. Some work has already been done by various authors for both species. Mongongo can germinate efficiently if the exocarp is removed and the seed treated with either ethylene or ethephon (Keegan and Van Staden 1981). Marula can be forced to germinate by opening the operculum found in the very hard and thick exocarp (Teichman et al. 1985). Using these techniques we obtained over 80% germination for mongongo and 100% for marula. All other species germinated without special difficulty. The next stage after establishment in the nursery is planting the seedlings at the various locations. Among the species studied, yehib showed a very high mortality rate. While the reason has not yet been established, we speculate that damage to the very long roots in the shallow nursery containers may have been partially responsible. We found that growth rate of the roots was 15 times faster that of the shoots. It appears that Besor is too cold for yehib, since during two consecutive years it died in the spring after a spell of low temperatures. In any case, this shrub grows very slowly. Despite these difficulties, several yehib plants at Qetura are now three years old and are continuing to grow. Vegetative propagation will be considered in the future. In addition, as soon as seeds become available from these plants we will try to sow seeds directly in the field in order to avoid damage to the root system.

There is no way of predicting the success of the various species at each locations. Both marula and mongongo were introduced from Botswana (a semiarid zone), yet there are considerable differences in performance between the two species. Mongongo failed at Neot Hakikar, probably due to NaCl salinity. Marula is growing well in all locations despite some inhibition of growth at Neot Hakikar. In the latter orchard only a few species have survived and are still growing. These include ber (which was introduced from India) and various cacti including pitahaya agria but excluding *Hylocereus* species, which suffered both from the extreme light and from the extreme salinity. Ciruelo is also growing very well at this location. The sulfate salinity at Qetura is less harmful to the new plant introductions than the NaCl salinity characteristic of Neot Hakikar. Mango *and pummelo* on a proper rootstock (13-1 and sour orange, respectively) are grown commercially at Qetura, but are unable to survive at Neot Hakikar. White sapota grows well at Besor. It seems to tolerate cold weather but not very high temperatures. Given special care and proper selection of rootstocks and cultivars, the plant might also be grown at Qetura. To draw definite conclusions about the performance of a species at a particular location it is obligatory to test in situ. Aside from simple survival, successful economic performance, which depends on yields and product quality, requires evaluation.

Selection of rootstocks and scion cultivars will have to be performed for promising species in the future. Correspondingly, proper vegetative techniques will have to be developed for each of the plant species that grows successfully. These rare and wild fruit trees deserve much more attention from the scientific community than they have so far received.

Ti Palm

Liliaceae *Cordyline terminalis* (L.) Kunth

Source: Magness et al. 1971

The plant is low, slender and palm-like, to 6 feet, with leaves up to 30 inches long and 5 inches wide, native in the East Indies. There it is cultivated for the large, tuberous roots, up to 14 pounds, which contain much sugar. Roots are usually baked or roasted. Baked, macerated roots are also fermented in water and an intoxicating liquor is obtained by distillation. So far as known, Ti Palm is not grown in the U.S. outside of Hawaii.

New Crops News, Spring 1994, vol. 4 no. 1

Productive Shelterbelts

Decorative branches from woody perennial shrubs are becoming extremely popular for use by the florist industry in floral arrangements. Trends in floral design have increased the demand for branches from a number of shrubs with decorative flowers and fruits, as well as branch form and color. A study is underway under the leadership of Bruno Moser, head of Purdue's Department of Horticulture, to develop a sustainable system to produce economic shoots of a number of plant species including the *Salix caprea* (pussy willow) and *S. matsujdana tortuosa* (corkscrew willow).

Pussy willow is a large (8-12' high), multistemmed perennial woody shrub with attractive flowers in early spring. It has been used in landscapes for years, and its branches are often found in floral arrangements during the months of March through May as a signal of the spring season. Popularity of the pussy willow has outstripped supply, and the availability of high quality branches is limited.

Large scale growing of this new crop has been shown to be feasible on marginal wet areas. The crop becomes an economically viable filter strip between agronomic crops and waterways and streams running through farmland. Plants are grown 6' apart in rows with rows 10' apart to facilitate access by equipment. The filter strip approach utilizes three rows of plants occupying a 50-60' wide strip of land parallel to watercourses. The result is an environmentally sound planting on marginal land which absorbs runoff from adjacent agricultural fields and limits contamination of surface watercourses from soil and agricultural chemicals.

Branches are harvested in February when most farmers would have time to devote to this new crop. Shrubs are pruned to within 18" of the ground. The harvested branches are trimmed, graded into appropriate lengths, and tied in bundles of 50 each. Markets are primarily wholesale florists, but limited sales can be made directly to individual retail florists in a grower's area. Results indicate that each plant will produce between 60 to 80 branches per plant each year (about 50,000 shoots per acre). Research efforts are now being directed towards forcing systems for branches and other postharvest techniques to broaden the market window and provide added value in the form of longer shelf life. Decorative branches for the florist trade offer new entrepreneurial opportunities for those with marketing skills who are looking for a niche crop in which most of the work is done during the winter and early spring.

Corn Salad

Lambs lettuce, Fetticus

Valerianaceae *Valerianella olitoria* (L.) Pohl

Italian Corn Salad

***V. eriocarpa* Desv.**

Source: Magness et al. 1971

Corn salad is extensively grown in Europe as a salad vegetable, but little grown in the U.S. The plant is a biennial, forming a rosette of leaves the first year, and a seed stalk the second. Leaves are spoon shaped to round, up to 6 inches long. Exposure of leaves is comparable to that of spinach. Leaves are used both as raw salad and as pot herbs.

Italian corn salad is similar in growth and use. Leaves are slightly smaller, somewhat pubescent and toothed near the base. The plant is more southern in adaptation than corn salad.

Season, seeding to usable leaves: 2 to 3 months.

Production in U.S.: No data. Very limited.

Use: Salad, pot herb.

Part of plant consumed: Leaves.

Flowering Dogwood

Cornus florida L.

Other common names.—Cornus, American dogwood, Virginia dogwood, Florida dogwood, American cornelian tree, flowering corner, Florida cornel, white cornel, Indian arrowwood, nature's-mistake.

Figure 50.—Flowering dogwood (*Cornus florida*)

Habitat and range.—Dogwood occurs in woods from southern Maine and southern Ontario to Florida, Texas, and Missouri, but grows most abundantly in the Middle Atlantic States.

Description. The dogwood sometimes grows to a height of 40 feet, but more frequently is a shrub. In the early spring the naked, leafless branches support numerous large, showy white flowers, so-called. The four showy parts of these "flowers" are petallike bracts which surround the true flowers, which are small, greenish-yellow, and inconspicuous. The leaves, which develop after the flowers have disappeared, turn a bright red in autumn, and this with the scarlet fruit makes the tree very attractive at that time of the year.

Part used.—The bark of the root, collected in autumn.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Keukand (*Costus speciosus* Koen ex. Retz.) Sm.

Contributor: Pankaj Oudhia

Copyright (c) 2002. All Rights Reserved. Quotation from this document should cite and acknowledge the contributor.

Common (Indian) Name
Hindi: Keukand, Keu, Kust
Gujrati: Pakarmula
Canarese: Changalkashta, Chikke,Karikattu,
Marathi: Penva, Pinga, Pushkarmula
Sanskrit: Kustha, Kashmira, Kemuka, Shura, Pushkarmula
Malyalam: Narum canna, Cannakkuvva, Cannukkilannu
Tamil: Kostam
Telugu: Cengalva Kostu

Family: Zingiberaceae

Botany: An erect plant, up to 2.7 meters high; root stock tuberous; stem sub-woody at the base; Leaves 15–30 × 5.7–7.5 cm sub sessile, oblong, spirally arranged, silky-pubescent beneath; sheaths coriaceous; flowers in very dense spikes, many; bracts ovate, mucronate, bright red; corrolla tube short, lobes ovate-oblong subequal; lip white with yellow center, crisped, concave; disk with a tuft of hair at the base. Fruits capsule, globosely trigonus, red; seeds black with white aril. Flowering time in Indian condition is August to October.

Useful parts: Roots

Medicinal Properties: According to Ayurveda the rhizomes are bitter, astringent, acrid, cooling, aphrodisiac, purgative, anthelmintic, depurative, febrifuge, expectorant and tonic and useful in burning sensation, constipation, lepsory, worm infection, skin diseases, fever, asthma, bronchitis, inflammatians and anaemia.

Chemical Constituents: Tigogenin and diosgenin from rhizomes (2.6% diosgenin) and stems have been isolated. α-amyrin stearate, β-amyrin and lupeol. Palmitates from leaves have been isolated.

Cultivation: Costus is under cultivation in isolated patches in different parts of India. It is cultivated as rainy season (Kharif) crop. About 15–20 quintal rhizomes are used for sowing per hectare. Standard cultivation practices of Costus have yet not been developed.

Cotton seed oil

Malvaceae *Gossypium* sp.

Source: Magness et al. 1971

Cotton is grown primarily for the fibers or lint, but the oil containing seeds are highly important. World production of cotton seed oil averaged 2,673,000 tons, 1964-66. The cotton plant is a stiff growing herbaceous annual outside the tropics, with fairly large, lobed leaves. The fruits are capsules which dehisce as they ripen. Each capsule contains up to 40 or 50 obovate, rounded or angular seeds, to which are attached the fibers or lint. The lint and seeds are harvested from the dehiseed bolls, partly by hand but now largely by machine in the U.S. The longer lint is removed from the seeds mechanically at cotton gins, then baled. The seeds of most varieties are still covered with short fibers or linters after the ginning. The seeds consist about half of hull and half of kernel. The kernels contain 28 to 40 percent oil. In extracting the oil the seeds are cleaned, delinted, and pressed or put through expellers either whole or after dehulling. A ton of seeds yields around 300 pounds of oil. The meal or press cake is a valuable high-protein livestock feed and the cotton fields, after the harvest, may be used for livestock pasturage. The oil is used mainly for shortenings. Smaller quantities are used for cooking and salad oils, margarines, and soap manufacture.

Hymenaea courbaril L.

Caesalpiniaceae
Coubaril, Kerosene tree, West Indian locust

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Important timber tree, used for furniture, (sometimes compared with mahogany), carpentry, general construction, wheels and cogs, dugouts, shipbuilding, crossties, posts, looms, cartwheels, etc. The wood should be attractive for cabinet work, interior trim, plywood, turnery, and veneer. Indians made canoes from the smooth, hard, thick bark by stripping in one piece the bark of a large tree, sewing the ends together, waterproofing the seams with gum or resin, and inserting wooden crosspieces. The roots and trunk yield a pale yellow or reddish resinlike gum known commercially as South American copal. The gum exudes and forms hard lumps which become buried in the soil at the base of a tree. Sometimes as much as a barrel of gum has been found around the roots of a large tree or at the site of a former tree. The gum is used mainly in varnish but also for incense and local medicines (Little and Wadsworth, 1964). The copal is also used for patent leather and in stains for tin ware (Uphof, 1968).

Folk Medicine

Reported to be anodyne, antiseptic, astringent, expectorant, laxative, pectoral, purgative, sedative, stomachic, stimulant, tonic, and vermifuge, coubaril is a folk remedy for arthritis, asthma, beriberi, blenorrhagia, bronchitis, bruises, catarrh, cystitis, diarrhea, dyspepsia, emphysema, fractures., headache, laryngitis, lungs, malaria, nephritis, rheumatism, sore, spasms, stomatitis, ulcers, and venereal disease (Duke and Wain, 1981). According to Ayensu (1981), the bark infusion is used as a depurative stomachic in exanthema; smoke from rosin used for headaches and rheumatism.

Chemistry

Per 100 g, the dry fruit pulp is reported to contain 309 calories, 14.6 g H_2O, 5.9 g protein, 2.2 g fat, 75.3 g total carbohydrate, 13.4 g fiber, 2.0 g ash, 28 mg Ca, 143 mg P, 3.2 mg Fe, trace of β-carotene equivalent, 0.23 mg thiamine, 0.14 mg riboflavin, 4.1 mg niacin, and 11 mg ascorbic acid. Langenheim (1981) compares the sesquiterpenes of *Hymenaea* the tongue-in-cheek "kerosene tree" and *Copaifera*, Calvin's "diesel tree".

Wood contains the diterpene copalic acid. The wood and copal may cause dermatitis.

Description

Tree to 20 (30) m tall and 50 (200) cm DBH; outer bark brown, closely lenticellate, bitter tasting; wood reddish-brown, hard. Leaves bifoliolate; petioles 1–2 cm long; leaflets narrowly oblong to elliptic-lanceolate, asymmetri- cal, short-acuminate, unequally rounded at base, 4–10 cm long, 2–5 cm wide, coriaceous, punctate, the midrib conspicuous below. Inflorscences terminal, sub-corymbose, to ca 8 (12) cm long, the branches puberulent, jointed and articulate;flowers white or purplish, soon falling, probably opening at night; bracts caducous; pedicels thick, ca 7 mm long; calyx tube ca 8 mm long, 4-lobed, the lobes ovate to oblong, expanding to ca 15 mm long, coriaceous, densely tomentose inside, easily caducous; petals 5, white, sometimes tinged with purple, rounded, 1.5–2 cm long, ca 9 mm wide, clawed below, the claw ca 1.5 mm long; stamens 10, alternately short and long, the long ones to 2 cm long; style attached laterally at apex of ovary, directed somewhat to one side of the flower; stigma held above the lower anthers and at some distance from the divergent longer set. Legumes oblong, flattened, to 17 cm long and 6.5 cm wide, turgid, hard, reddish-brown; seeds (2) 4–6, embedded in sticky pulp (Croat, 1978).

Germplasm

Reported from the South American (Amazonian) Center of Diversity, the courbaril, or cvs thereof, is reported to tolerate shade and slope (Duke, 1978). ($2n = 24$)

Distribution

Throughout West Indies from Cuba and Jamaica to Trinidad and Tobago. Also from central Mexico to Peru, Bolivia, Brazil, and French Guiana. Rarely planted in southern Florida (Little and Wadsworth, 1964).

Ecology

Ranging from Tropical Dry to Wet through Subtropical Dry to Wet Forest Life Zones (Duke, 1978). Coubaril is estimated to tolerate annual precipitation of 6–42 dm, annual temperature of 22 to 28°C, and pH of 5.5–7.5. Rare in the young forest. Flowers during the dry season and the early rainy season (December to May) in Panama. The fruits mature chiefly during the rainy season, especially late in the rainy season (Croat, 1978).

Cultivation

Shade is required at first if the tree is to produce a straight trunk.

Harvesting

No data available.

Yields and Economics

Trees underplanted in a forest near Rio Piedras, Puerto Rico attained heights ranging up to 6.5 m in 13 years. Plantings in the open, for shade and ornamental purposes, pruduce attractive and spreading trees more rapidly.

Energy

I presume the wood can be used as firewood (density 750–1050 kg/m^3) the pods for alcohol generation, but there is some question as to whether this is an important nitrogen-fixing tree. Isolated from nodules on a large Hawaiian specimen reacted like a typical cowpea rhizobium. Large rough-surfaced nodules were observed on 10 of 15 Philippine specimens. In Trinidad, nodulated specimens were not found (Allen and Allen, 1981). I am surprised this has not yet been labelled the "kerosene tree." According to Pereira (1929), this species, closely related to the "diesel tree" *Copaifera,* contains a medicinal oil (the resin) which burns like kerosene. I doubt that it would produce significantly more or less resin than the *Copaifera,* but would not write either of them off without an examination of the facts.

Biotic Factors

Flowers are believed to be bat pollinated. Browne (1968) lists: Isoptera. *Coptotermes curvignathus.*

Mucuna pruriens Bak., Leguminosae, is one of the popular medicinals of India. and is constituent of more than 200 indigenous drug formulations It is widespread over most of the subcontinent and is found in bushes and hedges and dry-deciduous, low forests throughout the plains of India. (Sister and Kavathekar 1990; Agharkar 1991; Singh et al. 1996). All parts of *Mucuna* posses valuable medicinal properties (Pandey 1998; Pandey 1999; Caius 1989) and there is a heavy demand of *Mucuna* in Indian drug markets. After the discovery that *Mucuna* seeds contain L-dopa, an anti-parkinson's disease drug, its demand in international market has increased many fold (Farooqi 1999) and demand has motivated Indian farmers to start commercial cultivation.

Botany

Mucuna is an annual twinning plant.. Leaves are trifoliate, gray-silky beneath; petioles are long and silky, 6.3–11.3 cm. Leaflets are membranous, terminal leaflets are smaller, lateral very unequal sided. Dark purple flowers (6 to 30) occur in drooping racemes. Fruits are curved, 4–6 seeded. The longitudinally ribbed pod, is densely covered with persistent pale-brown or grey trichomes that cause irritating blisters. Seeds are black ovoid and 12 mm long (Sastry and Kavathekar 1990; Agharkar 1991; Verma et al. 1993).

Uses

Roots, according to the *Ayurveda*, are bitter, thermogenic, anthelmintic, diuretic, emollient, stimulant, aphrodisiac, purgative, febrifuge, tonic. It is considered useful to relieve constipation, nephropathy, strangury, dysmenorrhoea, amenorrhoea, elephantiasis, dropsy, neuropathy, consumption, ulcers, helminthiasis, fever, and delirum (Lindley 1985; Ramnath 1992; Warrier

1995; Shalini 1997; Upadhyay 2000).

Leaves are popular potherbs and are used as a fodder crop. Leaves are useful in ulcers, inflammation, cephalagia and general debility.

The trichomes of pods contain mucunain and serotonin and as a result pod causes itching, blisters, and dermatitis. Pods are also used as vegetable. Pod hairs (trichomes) are used as anthelmintic. Hairs mixed with honey have been used as vermifuge. As ointment prepared with hairs act as a local stimulant and mild vesicant. (Shastry and Kavathekar 1990; Chandra 1993; Shastry 1995) Beside medicinal properties, *Mucuna* fixes nitrogen and is as a green manure and covercrop.

Seeds contain L-DoPA (4-3,4-dihydroxy phenylalanine), glutathione, lecithin, gallic acid, glycosides, nicotine, prurenine, prurenidine, dark brown viscous oil. It is a source of minerals (Rastogi and Mehrotra 1991a,b; Singh et al. 1995). According to *Ayurveda*, seeds are astringent, laxative, anthelmintic, aphrodisiac, alexipharmic and tonic.

Cultivation

Mucuna is a popular kharif crop in India. Seeds are sown at rate of 50 kg/ha between 15 June to 15th July with plant spacing of 60 × 60 cm. Delayed sowing may result in infestation of aphids (*Aphis craccivora*) (Oudhia 2001a). Although, no named cultivar of *Mucuna* is available, locally available seeds possess good viability and higher germination (Oudhia 2001b). Plant support increases yield 25% and reduces pest infestation. Normally flowering begins 45–50 days after sowing. (Oudhia and Tripathi 2001). Yields of 5000 kg/ha have been recorded from well managed irrigated crop having supports. (Singh et al. 1995; Farooqi et al. 1999)

Crabapple

Rosaceae *Pyrus* sp.

Source: Magness et al. 1971

The term crabapple is applied to native species of apple like fruits, as well as to hybrids of these with the larger fruited apples. Bailey lists 27 species of apple type fruits, 10 of which are native in some part of the U.S. Some American and Asiatic species are beautiful ornamentals, and fruit from these or native trees may be used in homes for jellies. The crabapples of commerce are probably all hybrids of native species with apples. These are fruits 1 to 2 inches in diameter, which in culture and general exposure are in all respects similar to apples, which see. In general, the trees are hardier than most apple varieties.

Season, bloom to harvest: About 4 months.

Production in the U.S.: No separate data; 1000-2000 tons.

Use: Mainly jelly or pickling.

Part consumed: Whole fruit; for jelly, whole fruit cooked - with core tissue and peel sieved out.

Sonneratia caseolaris (L.) Engl.

Sonneratiaceae

Crabapple Mangrove

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

The heavy wood (800 kg/m^3) is used for boatbuilding, construction, piles, and posts. Sour young fruits, used in or for vinegar, are widely used in Oriental chutnies and curries. Ripe fruits, said to taste like cheese, are eaten raw or cooked. A clear jelly can be prepared from the pectinaceous fruits. Pneumatophores cut up and used as corks or floats for fishing nets. The pulp is suitable for kraft paper production. Flowers, in anthesis, contain abundant honey (Backer and van Steenis, 1951).

Folk Medicine

Reported to be hemostat, crabapple mangrove is a folk remedy for sprains, swellings, and worms (Duke and Wain, 1981). Burmese use the fruits for poultices, Indochinese poultice crushed leaves with salt onto cuts and bruises. Malayans use old fruit walls for worms, half-ripe fruits for coughs, and pounded leaves for hematuria and smallpox (Perry, 1980).

Chemistry

Fruits yield 11% pectin (ZMB). Wood yields 52.7% brown pulp (8.5% lignin, 17.6% pentosan). Emodin and chrysophanic acid may be the coloring matter in the crude drug (Perry, 1980). Bark from Africa assayed at 17.1% tannin, of the pyrogallol class. Indian stem bark assayed 9–17%, twig bark 11-12%. Wood yields two coloring principles, archin ($C_{15}H_{10}O_5$) and archinin ($C_{15}H_{14}O_{12}$) (C.S.I.R., 1948–1976).

Description

Evergreen tree 5–15(–20) m high without buttresses or stilt roots, with rather open spreading crown, glabrous throughout. Pneumatophores 50–90 cm high, to 7 cm in diameter. Bark gray, coarsely flaky. Leaves opposite, without stipules, nearly sessile, elliptical, oblong or ovate, 5–13 cm long, 2–5 cm wide, with broad or tapering base and blunt or rounded tip, entire, with 8–12 widely spreading fine side veins on each side, leathery. Flowers 1–3 at end of drooping twigs malodorous, nocturnal. Hypanthium with 6–8 calyx lobes; petals 6–8, 2–3.5 cm long, 1.5–3.5 mm wide, dark or blood-red, stamens numerous, with threadlike filaments 2.5–3.5 cm long, pistil with 16–21-celled ovary with many ovules; style long, stout (Little, 1983).

Germplasm

Reported from the Australia, Indonesia-Indochina, and Hindustani Centers of Diversity, crabapple mangrove, or cvs thereof, is reported to tolerate coral, disease, insects pests, salt, and waterlogging (NAS, 1980; Little, 1983). ($2n$ = 24 in other *Sonneratia*).

Distribution

Sri Lanka to Malay Peninsula and northern Australia. Also Sumatra, Java, Borneo, Celebes, Philippines, Moluccas, Timor, New Guinea, Solomon Islands, New Hebrides. Not widely introduced (Little, 1983).

Ecology

Estimated to range from Tropical Moist to Rain through Subtropical Moist to Rain Forest Life Zones, crabapple mangrove is estimated to tolerate annual precipitation of 10 to 80 dm, annual temperature of 20 to 27°C, and pH of 6.0 to 6.5. Usually on the less salty parts of mangrove forests on a deep muddy soil, never on coral banks, often along tidal creeks with slow moving water, ascending these as far as the flood mounts (Backer and van Steenis, 1951).

Cultivation

According to the NAS (1980), planting is usually not needed because natural regeneration is so successful. In *Avicennia* and *Rhizophora*, direct seeding results in ca 90% survival.

Harvesting

Harvested as needed from wild stand. Trees recover rapidly after branches are lopped off for fuel. Since this mangrove can regrow rapidly from buds beneath the bark along the trunk and branches, it is said to suffer little from removal of much of the branchwood (NAS, 1980).

Yields and Economics

Cannell (1982) cites data on a mangrove forest dominated by *Rhizophora*, *Ceriops*, and *Sonneratia*, averaging 11 m tall, with an LAI (leaf area Index) of 3.7–4.2.The stemwood and bark on a DM basis weighed 74.4 MT/ha, the prop roots 61.2 MT/ha, the branches 15.8, the foliage 7.4, the fruits 0.3, for a total standing aerial biomass of 157 MT/ha. The CAI (current annual increment) of stem wood, bark, and branches was 20 MT/ha/yr, foliage 6.7, fruits 0.3. These data, taken from a mangrove on Phuket Island, Thailand, regenerated following clear felling, suggest annual productivity may attain 20 MT/ha/yr in Asian mangroves.

Energy

Although the calorific value of the wood is above average, it is inferior to true mangrove, and has a high ash and salt content.

Biotic Factors

Heartwood is said to be very resistant to teredos.

Cranberry

Ericaceae *Vaccinium macrocarpon* Ait.

Source: Magness et al. 1971

This native American fruit grows on a prostrate evergreen "vine" though not a climber. The stems are actually rather tender to cold, but stand winter covering with water well. Thus in commercial culture where most are grown (Mass., Wisc., NJ) they are planted on peat bogs prepared so they can be covered with water in winter. The berries are borne on short uprights 6 to 8 inches in length, rising from the dense mass of stems prostrate on the soil surface. Fruit has a smooth skin, is generally round, eliptical, or bell shaped and about 0.33 inch in diameter and 0.5 to 1 inch long. Inconspicuous seeds are attached at the center of the fruit and surrounded by the tart pulp. Plantings persist for many years if properly managed. Weed control is a major problem.

Season, bloom to harvest: 100 to 130 days.

Production in U.S.: About 70,000 tons.

Use: Fresh, canned, frozen, juice, jellied.

Part of fruit consumed: Whole fruit or interior pulp and juice. Skins and seeds are screened out in juice and jelled products, after heating.

Mayhaw: A New Fruit Crop for the South*

Jerry A. Payne and Gerard W. Krewer

INTRODUCTION

The mayhaw, an edible early ripening hawthorn, is a relatively unexplored and underutilized indigenous fruit tree of the lower southern states. Mayhaws (*Crataegus aestivalis* [Walter] Torrey & Gray *C. opaca* Hook. & Arn., *C. rufula* Sarg.) are members of the Rosaceae, subfamily Maloideae, tribe Crataegeae. This arborescent shrub or round-topped small tree (8-10 m) has outstanding ornamental characteristics (attractive foliage, showy blossoms, clusters of brilliantly colored fruits) and is often armed with thorns. Mayhaws are locally abundant in low, wet areas in the alluvial acid soils of rivers, streams and swamps from North Carolina to Florida and west to Arkansas and Texas, (Fig. 1) (Clewell 1985, Coker and Totten 1945, Correll and Correll 1975, Correll and Johnston 1970, Godfrey and Wooten 1981, Kurz and Godfrey 1962, Mohr 1969, Phipps 1988, Radford et al. 1974, Sargent 1965, Small 1913, West and Arnold 1952). Hawthorns are easily recognized as a group, but species are extremely difficult to distinguish due to polyploidy and apomixis (Cronquist 1981, Phipps 1983). Over 800 species have been described from North America (Bailey 1960, Render 1960) but only those early ripening edible southern U.S. *Crataegus*, series *Aestivales*, are considered mayhaws.

Mayhaw trees flower profusely and early (late February to mid-March in southern Georgia, Zone 9A) and the fruit ripens mostly in early May, hence the name mayhaw. Some clones (selections) ripen through June. The fruit is a small pome (8-19 mm diameter), yellow to bright red, fragrant, acid and juicy, resembling cranberries in appearance and crabapples in taste (Fig. 2). Until recently the fruit has only been used locally in marmalades, butters, preserves, jellies, condiments, syrups, wines, desserts and as food for wildlife (Elliot 1971, Gibbons 1974, Halls 1977, Hedrick 1919, Morton 1963, Reynolds and Ybarra 1984, Wood 1864). However, during the last 5-10 years mayhaws have begun to receive attention as a possible source of income for cottage industries. Fruit sells for $2.75-$4.40/kg ($5-$8/gallon) and jelly for $18-00/liter ($8.50/pint). Because demand exceeds supply, many farmers and entrepreneurs are showing interest in the culture and utilization of this crop.

HORTICULTURE

Propagation

Under natural conditions seed do not germinate until overwintered (Hartmann and Kester 1983). *Crataegus* species have embryo dormancy and require treatment in a moist medium at low temperature before germination will occur (Schopmeyer 1974). Seeds may be an easy way to propagate clones since nucellar seedlings, which produce fruit like the mother tree, are common in mayhaws (Wayne Sherman pers. commun.).

Mayhaw softwood stem cuttings can also be rooted under intermittent mist or in a humidity chamber during the summer. Dipping the cuttings in a root promoting hormone (8000 ppm K-IBA + 2000 ppm K-NAA) has promoted rooting success of 36.4% for 'Super Spur': and 34.4% for 'T.O. Super Berry' (G.W. Krewer, and J. Gibson, unpubl.). Propagation from hardwood and root cuttings have also been reported by nurserymen, however, no details were revealed.

Mayhaws are easily grafted during dormancy (late winter). A whip and tongue or simple whip graft can be used. Cleft grafting can be used on larger trees.

Rootstocks

Mayhaw appears to be initially compatible with any hawthorn species. In Mississippi the parsley haw (*C. marshallii* Eggl.) is considered an excellent rootstock for *C. opaca*. Good results have been reported using cockspur (*C. crusgalli* L.) and Washington hawthorn (*C. phaenopyrum* [L.f.] Med.) rootstock in Texas for *C. opaca*. Trials in Louisiana, however, have produced variable results with Washington hawthorn. In Georgia, the hoghaw (*C. flava* Aiton) which grows on our sand ridges can be used but due to its slow growth rate the mayhaw scions may overgrow the hoghaw rootstock. *C. aestivalis* can also be grafted onto commercially available Washington hawthorn seedlings, but it is not known how they will perform at maturity Mayhaw seedlings are probably the best choice as a rootstock in damp soils.

Cultivars

About a dozen mayhaw selections have been collected from the wilds (river bottoms, lime sinks, swamps, sloughs) of Georgia, Mississippi, Louisiana and Texas with attention given to size of fruit, harvest or ripening period and yield (Table 1), but information from field trials is very limited. Most ripen over a 30-day harvest period, but 'Lori' may have 80% of the fruit ripe at one time. Little comparative cultivar information is available at this time, 'Super Spur' appears to be the best from a yield and tree form standpoint. Yields of 30 kg/tree have been reported for 30-40 year old wild mayhaws in Georgia and 60 kg for a 15-year-old 'Super Spur' in Louisiana. Preliminary reports indicate that selected mayhaw clones are adaptable to USDA zones 8 and 9. Although some cultivars have a low chilling requirement and bloom early, other cultivars should be adapted to the piedmont of the southeast. *C. aestivalis* cultivars may bloom a few days later than *C. opaca* cultivars and may be better choices further north. Bloom occurs over an extended period of time and the fruit are reported to be fairly frost hardy once past the bloom period. Winter hardiness may be good. There are reports of mayhaws fruiting after -25°C (-13°F) (1981) and two year old trees survived -32°C (-25°F) (1985) without damage (Akin 1985).

Orchards

Although tolerant of wet, very acid soils, better growth has been observed when mayhaws are planted on well drained, slightly acid soils. Mayhaw trees are long-lived and may have a 9m canopy diameter after 20 years. Therefore current suggested tree spacing for a permanent orchard is 4.6-6.1 m (15-20 ft) in the row and 5.5-6.1 m (18-20 ft) between rows giving (270-400 trees/ha or 109-161 trees/A). Row spacing must be adjusted to fit the equipment if mechanical harvesting of mayhaw is desired. Mayhaws should be trained to a single trunk at the base with the first branches at 45 cm or higher so orchard equipment can be operated under the tree. Yearly pruning to open up the tree canopy for greater light penetration may be necessary with most cultivars. Central leader and modified central leader training systems like those used on apples are suggested.

Pest Problems

There is limited information on the pest management of mayhaws; however, it is known that they are susceptible to many of the insects and diseases that attack other pome fruits (Crops Res. Div. 1960, Forest Service 1985). Several insects including plum curculio, hawthorn lace bug, flower thrips, roundheaded appletree borer, whitefringed beetle, leafminers, scales and mealybugs feed on the foliage, flower, fruit and wood of mayhaw. The plum curculio in particular has caused extensive damage to fruit in some locations and will probably need to be controlled in future commercial orchards.

There are numerous diseases known to occur on various hawthorn species but little information is available on diseases of mayhaws. Quince rust, (*Gymnosporangium clavipes* Cke. & Pk.), has been quite severe on some southern Georgia native mayhaws and several *C. aestivalis and C. opaca* cultivars since 1983. Presently no rust control recommendations are available except the planting of rust-free selections. At this time only two natural pesticides, insecticidal soap and rotenone/pyrethrin, can be utilized for pest control on mayhaws destined for food use.

PROSPECTS

Although mayhaw appears to be initially compatible on most *Crataegus* rootstocks, our knowledge of mayhaw rootstocks is rudimentary at best. There is little published information available on the productivity and long term compatibility since mayhaw orchard plantings have existed for less than 5 years. Existing information on methods of propagation is also very limited. Cultivar evaluations have not been conducted in replicated orchard plantings and low-chilling requirements of many cultivars may limit their commercial adaptability to zone 9A or 9B.

While only the jelly manufacturing has been investigated by university or industry personnel, there are many other products made from mayhaws such as juices, jellies, preserves, candies, pastries and wine that could have commercial potential. Thus, the opportunity exists for a greatly expanded market based upon a consistent supply of fruit. If the industry is to seriously develop, cultivars adapted to mechanical harvesting will be needed. Unless problems associated with production are solved, supplies will be too short to allow for alternate product development.

SAFFRON

Family: Iridaceae, *Crocus sativus* L.

Source: Simon, J.E., A.F. Chadwick and L.E. Craker. 1984. Herbs: An Indexed Bibliography. 1971-1980. The Scientific Literature on Selected Herbs, and Aromatic and Medicinal Plants of the Temperate Zone. Archon Books, 770 pp., Hamden, CT.

Saffron, *Crocus sativus* L. is a perennial herb known ,only in cultivation. The plant has been prized since antiquity for the yellow-colored dyestuff that comes from the flower stigmas. Also known as saffron crocus, the species is principally grown in Spain, but is also cultivated in Greece, Turkey, India, France, Italy, and the People's Republic of China. The low-growing, cormous plant, whose linear upright leaves reach heights of 0.15 to 0.3 meters, has fragrant flowers.

The reported life zone of saffron is 6 to 19 degrees centigrade with an annual precipitation of 0.1 to 1.1 meter and a soil pH of 5.8 to 7.8 (4.1-31). The crop grows best in well-drained soils of medium fertility (14.1-31). Planted from early spring to autumn from corms, the plants can remain undisturbed for three to five years before they need to be divided. Blossoming lasts only a few weeks, and flowers must be collected daily as they open in order to remove the stigmas. Approximately 210,000 dried stigmas from 70,000 flowers make one pound of true saffron (11.1-128).

Saffron contains a volatile oil, picrococin, crocin, a fixed oil, and wax (1.1-275, 14.1-35). The volatile oil consists of safranal, oxysafranal, pinene, 1,8-cineole isophorone, napthalene and other compounds (1.1-275). Extracted saffron is a red-orange color, and has an aromatic odor and a bitter taste. Principal coloring pigments of saffron include crocin, crocetin, carotene, lycopene, zeaxanthin, and picrocrocin (11.1-126).

Saffron, available commercially as individual stigmas, ground, or crushed, is used in cookery as a spice, in flavoring aperitif beverages, and to color such foods as butter, cheese, rice, sauces, and soups (11.1-75). The high cost of saffron production encourages the use of turmeric and the synthetic colorant tartrazine as alternatives to saffron (11.1-75).

As a medicinal plant, saffron has traditionally been considered an anodyne, antispasmodic, aphrodisiac, diaphoretic, emmenagogue, expectorant, and sedative (11.1-101). The plant has been used as a folk remedy against scarlet fever, smallpox, colds, insomnia, asthma, tumors, and cancer (14.1-16). Saffron is reported to contain a poison of the central nervous system and kidneys that can prove fatal (11.1-136, 11.1-101).

Autumn or meadow crocus, *Colchicum autumnale* L., is a poisonous plant not related to saffron. Fake or American saffron actually refers to safflower, *Carthamus tinctorius* L., whose flower heads yield a dye used as an adulterant to true saffron.

Saffron is generally recognized as safe as a natural seasoning or flavoring and plant extract (21 CFR sections 182.10, 182.20 [1982]).

Crotalaria

Leguminosae *Crotalaria* sp.

Striped crotalaria *C. mucronata* Desv.

Showy crotalaria *C. spectabilis* Roth

Slenderleaf crotalaria *C. intermedia* Kotschy

Lanceleaf crotalaria *C. lanceolata* E. Mey.

Source: Magness et al. 1971

All are upright growing summer annuals. Stems are coarse and well branched except in thick stands. Leaves are trifoliate, the leaflets varying in shape from linear to ovate. Crotalarias are adapted only to warm climates with a long growing season. They are resistant to the rootknot nematode and are valuable to reduce the nematode population in infested soils. They do well on soils of low fertility and are most used to turn into the soil for soil improvement. *C. spectabilis* contains an alkaloid poisonous to livestock. The other three species can be used for pasture or silage though palatability is low. According to the 1960 census, seed was harvested in 1959 from 2,657 acres in this country, and sufficient seed was produced to plant around 35,000 acres.

Croton tiglium L.

Euphorbiaceae
Purging croton, Physic-nut, Croton-oil plant

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Studying insecticidal activity of 20 plants to adult females of *Uroleuron cathami*, Deshmukn and Borle (1975) reported the petroleum ether extracts of purging croton seeds to be most effective (0.125% as toxic as nicotine sulfate). Hager's Handbuch (List and Horhammer, 1969-1979) says it is more effective than Derris extract. Himalaya tribes use the bark in arrow poisons. Bark has been used as a tannin source. Mashiguchi et al. (1977) report on the molluscididal activity of the seed against *Oncomelania quadrasi*. It is also used to poison fish. When Croton oil was evaluated for possible effects on the P-388 lymphocytic leukemia in mice, significant inhibitory activity was noted. Fractionation of the oil led to characterization of the major component, the phorbol diester, phorbol 12-tiglate 13-decanoate which exhibits significant inhibitory activity at dosages of 60-250 ug per kg body weight against P-388. There is a paradoxical similarity in structure between the cocarcinogenic and antileukemic principles of the Euphorbiaceae and the Thymelaeaceae (Kupchan et al., 1976). Croton oil, a fixed oil expressed from seeds by methods similar to those used to obtain castor oil, is used in human and veterinary medicine as a cathartic, irritant, and rubefacient. Internally, it is a drastic, very rapid purgative or cathartic; applied externally to the skin, it is a powerful local irritant, causing pustular eruptions. When diluted, oil is used as a counter-irritant, and is usually administered with sugar and bread crumbs. In Malaysia, the oil is used more for illumination and soapmaking than for medicine. According to the Wealth of India (C.S.I.R. 1948-1976), "Croton oil appears no longer any place in medical practice." Crushed seeds and leaves, pulverized and put in sacks, are placed in ponds and rivers to stupefy fish.

Folk Medicine

According to Hartwell (1967-1971), the seed oil and bark are used in folk remedies for cancerous sores and tumors. Reported to be cathartic, diaphoretic, ecbolic, emetic, emmenagogue, purgative, rubefacient, and vesicant, purging croton is a folk remedy for apoplexy, cancer, carbuncles, colds, dysentery, fever, flux, paralysis, ranula, scabies, schistosomiasis, skin, snakebite, sore, throat, and toothache (Duke and Wain, 1981). Leaf poulticed onto snakebite in Sumatra. Seed, POISONOUS, employed as purgative in lead colic and cancer; recommended as a revulsive in colds and fever for obstinate diarrhea and dysentery, delayed menstruation, edema, ranula, apoplexy, paralysis, scabies, throat afflictions, toothache. Seed oil recently used in schistosomiasis. Bruised root applied to cancerous sores and carbuncles. Seeds contain one of the most purgative substances known; also quite vesicant; once used as emmenagogue. Homeopathically used for gastroenteritis, pustulose eczema, conjunctivitis, and mastitis. Here the reader should be warned that homeopathic practitioners use some very poisonous plants in very dilute concentrations. Like so many plants, this contains both cancer-causing and cancer correcting compounds. According to Pettit (1977), phorbol is the cocarcinogenic substance of *Croton tiglium*. For a man, about four seeds, for a horse, about 15 seeds represent a lethal dose. On the other hand, Pettit and Cragg (1978) list Phorbol 12-tiglate 13-decanoate as active at doses of 60-250 ug/kg against the PS-tumor system (Duke and Ayensu, 1984). In Malaya a single kernel is eaten as a purgative; when purging has gone far enough, coconut milk is drunk to stop it.

Chemistry

C.S.I.R. reports that the oil contains 3.4% toxic resin. Of the acids, 37.0% is oleic, 19.0% linoleic, 1.5% arachidic, 0.3% stearic, 0.9% palmitic, 7.5% myristic, 0.6% acetic, 0.8% formic, with traces of lauric, tiglic, valeric, and butyric, plus some unidentified.

Description

Small shrub or tree up to 12 m tall, evergreen; leaves alternate, membranous, ovate with broadly rounded, sometimes slightly decurrent base, acuminate, acute or blunt, very shallowly serrate, glabrous above, with few stellate hairs beneath, 7.5-17 cm long, 4-9.5 cm broad, metallic green to bronze or orange; petiole slender, about 4 cm long; stipules caducous, subulate, 1.5- 3.5 mm long; axis of inflorescence glabrous; flowers small, inconspicuous; male flowers stellately hairy with narrowly oblong petals and 15-20 stamens; female flowers apetalous; capsule scabrid with stellate hairs, triangular, 15-20 mm long, 10-15 mm broad, oblong or ellipsoid, 3-lobed; seeds 3 per fruit, oblong-ovoid, orange, about 12 mm long, smooth, about 4160/kg. Fl. summer; fr. Nov.-Dec.

Germplasm

Reported from the Hindustani Center of Diversity, purging croton or cvs thereof is reported to tolerate drought, insects, and poor soil. (Duke, 1978). In Java, two forms are distinguished: var. *tiglium*, with ovary and fruit trigonous, and petals of female flower consisting of a glabrous stalked bud, found in West Java; and var. *globosus*, with ovary subglobose, subtrigonous, with petals linear and hairy at apex, found in East Java. (2*n* = 10)

Distribution

Native to tropical Asia from India to New Guinea and Java, north into Indonesia and China. Wild throughout the Philippine Islands, where it is also cultivated to a limited extent; often becoming naturalized after cultivation. Grown in southern California and elsewhere as an ornamental and curious plant.

Ecology

Ranging from Subtropical Moist to Tropical Very Dry throught Wet Forest Life Zones, purging croton is reported to tolerate annual precipitation of 7.0 to 42.9 dm (mean of 8 cases = 20.6), annual temperature of 21.0 to 27.5°C (mean of 8 cases = 25.3), and pH of 4 5 to 7.5 (mean of 6 cases = 6.1). (Duke, 1978, 1979) A dry land plant, adaptable to most tropical climates, up to 1,500 m elevations, not particular as to soil type or texture. Often grown in mixed forests, and commonly planted in and about towns.

Cultivation

Propagated from seed, the seed sown directly in the forest, or in seedbeds and the young plants planted in desired places. It may be cultivated as a pure crop or as an intercrop with cacao or coffee, providing some shade (Reed, 1976).

Harvesting

Plants begin bearing seed in 3 years after planting, and are full-bearing in 6 years. Seeds ripen in November and December, and should be collected before capsules open.

Yields and Economics

Yields in the third year may be 200-750 kg seed/ha, but at full bearing 750-2,000 kg/ha, assuming the cwt/ha in our reference is a metric quintal rather than 100 pounds. Otherwise, the yield reported by Duke (1978) may be the high report at 900 kg seed/ha. Croton oil is produced in India and Europe, with most of the commercial supply of seed being obtained from Sri Lanka and India. Market value of seeds fluctuates considerably depending on demand. United States imports ca 1.5

MT/a oil from Germany and United Kingdom. Export of seeds from Sri Lanka in 1933 was 73,150 cwt.

Energy

If seed yields of 900 kg/ha are all that can be expected, this does not seem a promising energy species, especially if it can only be used outdoors. According to Burkill, "the fumes of burning oil indoors are intolerable."

Biotic Factors

Plants are attacked by the following fungi: *Cercospora tiglii*, *Fomes lignosus, Macrophomina phaseoli*, *Placosphaeria tiglii*, and *Polyporus hirsutus*. They are also attacked by root knot nematodes: *Meloidogyne acronea, M. arenaria thamesi, M. hapla, M. incognita acrita,* and *M. javanica.* Trees sometimes attacked by caterpillar, *Amyna punctum.*

Yamaguchi, M. 1990. Asian vegetables. p. 387-390. In: J. Janick and J.E. Simon (eds.), Advances in new crops. Timber Press, Portland, OR.

Asian Vegetables

Mas Yamaguchi

INTRODUCTION

Recent Asian immigrants have brought about dramatic changes in the kinds of vegetables consumed in the United States, especially in localities where these peoples are concentrated. Thirty-seven years ago, Porterfield (1951) described vegetables in New York City's Chinatown and 15 years ago Yamaguchi (1973) reported on the production of oriental vegetables in the United States. At present, these vegetables as well as new ones, especially those originating from Southeast Asia, are finding a home as new crops in the United States. In this paper, I will present some of the more interesting of these "new crops" and some which I think have potentials as new exotic vegetables in western culinary recipes. Nutritional values of some of the vegetables are presented in Table 1.

ASIAN VEGETABLES

Note on US import restrictions

Zizania latifolia Turcz. (*Z. aquatica* L.). [Common names: water bamboo, Manchurian wild rice; coba, kuw-sun, kwo-bai, jiao-bai (China, Taiwan); makomo dake (Japan)]. Water bamboo belongs to the Poaceae (-Gramineae), the same family as the common bamboo (*Phyllostachys* spp.) and is closely related to wild rice (*Zizania aquatica* L.) of North America. Grown since ancient times, this aquatic plant is cultivated in all parts of Asia from Manchuria in the north through eastern China to Indo-China on the south and east to Japan and Taiwan. A perennial water bamboo can be grown in stagnant ponds and in poorly drained soils. Plants grow from 1.2 to 2.4 m in height and the fully elongated leaves measure from 30 to 60 cm in length. Enlarged stems are harvested, the upper leaves cut off and only the stem with husk-like wrapper leaves sent to market. The edible portion is the succulent stem after the husks are removed.

There are three types of water bamboo in China:
Green stem-a small plant with fine leaves, early maturing.
White stem-large plant, mid to late season.
Pink or red stem-large plant, mid to late season.

Water bamboo is propagated by tillers. The most vigorous plants with short stout stems, large abundant leaves and no signs of floral initiation are selected for propagation. Tillers are planted in a nursery and allowed to grow for a year before transplanting to the field. Also, clumps of 4 to 5 tillers may be transplanted directly into the field. Tops are trimmed to about 40 cm height before planting.

Preparation of the field is sin-similar to that for paddy rice. Clay type soil, high in organic matter and pH range of 5.5 to 6.0 is preferred. Transplants are put into the mud about 6 cm deep at 30 to 40 cm spacing and in rows 90 to 100 cm apart. After planting the water is raised to a depth of 10 to 15 cm. Fifteen cm water depth is optimum, but in hot weather, the level is raised to 20 cm.

Field plantings in the sub-tropics are made in January through March and in the temperate regions, in March through April. If plantings are made late, the growing season is shortened so yields are reduced. High light intensity is desirable and mean temperatures of 25°C is optimal. At 20°C, the plant grows poorly and the harvested stems are not tender. The crop is fertilized with nitrogen four times during the season, twice with phosphorus and once early with potassium containing fertilizer.

Stem enlargement occurs after about 4 months growth. Harvest is made in about 150 days from planting with the green type and about 170 days with the white and pink types. Stem enlargement is due to the fungus, *Ustilago esculenta* P. Henn. Evidently, the fungus prevents floral initiation but allows the stem to elongate and enlarge. Harvest must be made before the fungus goes into the reproductive phase when the black smut (spores) is produced. With time there appears black longitudinal streaks in the swollen stem and eventually the entire stem turns black, very much like the corn ear smut. Because water bamboo is a perennial and asexually propagated, the fungal organism is apparently transferred from mother plant to the daughter tillers.

In Taiwan, the harvested swollen stems with leaves trimmed off are placed in large vats filled with water. This is done to keep the temperature down and keep the stalks moist in order to retard the formation of black streaks. Lack of nutrients in the plant or low water level in the field causes the fungus to go into the reproductive phase much earlier reducing quality and yield. In Beijing in Northern China, transplants are brought from the southern province near Guangzhou (Canton) every 2 or 3 years because production declines. Plants can survive the freezing temperatures of December and January in Beijing.

Water bamboo is a very popular vegetable in China. The swollen stem is sliced and eaten raw or cooked. Although water bamboo has a much softer texture than regular bamboo, the tissues remain crisp when stir-fried.

If water bamboo is brought into the United States, would the fungus which is necessary to cause the stem to swell, infect the wild rice and reduce production? Tests need to be made to determine whether infection can take place. I think that water bamboo would do well in the swampy regions of the Southern United States and in areas where paddy rice is produced.

Nelumbo nucifera Gaertn. (*Nelumbium nelumbo* Druce). [Common names: Lotus root (rhizome), East Indian lotus, Egyptian lotus; lian, lin ngau (China, Taiwan); hasu (Japan for the plant), renkon (Japan for the edible storage rhizome)]. A perennial aquatic plant of East Indian origin and belonging to the Nymphaceae, the lotus was brought to China and Egypt thousands of years ago. From China it was taken to other parts of Asia including Japan and northern Australia.

The plant, long known for its beautiful flowers, is mainly grown for the edible storage rhizomes (60 to 120 cm long and 6 to 9 cm in diameter). The storage rhizomes appear segmented because the diameter at the node is from 1/3 to 1/2 the diameter of the internode. The proximal segment (internode) is long and somewhat tapered, the diameter at the distal end being larger than the proximal end. Lengths of the segments decrease with increasing distance from the origin. The number of segments vary from 2 to 6.

Longitudinal circular passages are present in each segment. There is one central passage surrounded by 7 larger diameter and 2 medium diameter passages at about middistance from the center to the epidermis. Alternately to 7 large passages are small diameter passages near the outer perimeter of the rhizome. These passages probably function as ducts for gaseous exchange to the atmosphere.

Although seeds are very long lived, (there are reports of germination after 500 years in the soil) propagation is usually from recently harvested or stored rhizomes. Rhizomes are planted in paddies similar to that for rice. In Taiwan, rhizomes with at least 3 segments are planted 9 cm deep into the mud at an angle of about 20° to 30°C with the proximal end above water level. At planting time water level is kept at 6 cm depth. With growth the water level is gradually raised to about 30 cm and is maintained at this level. With the first two leaves that emerge, the blades float on the surface of the water. Petioles of subsequent leaves subtend above the surface and the blades unfurl in the air. The leaves are peltate and the blades are 30 to 90 cm in diameter on long slender tubular petioles.

The first growth is vegetative. The stem diameter is small and the internodes long so that the rhizomes do not appear segmented. From each vegetative node a leaf is produced, each petiole taller than the previous one. However, the last leaf that emerges before the onset of storage rhizome formation, is shorter than the previous one. The rhizomes grow in about 30 cm deep in the mud. Flower stalks emerge in July from the vegetative nodes.

The segmented storage rhizomes begin to form about the beginning of August. Large healthy leaves produce many segments; small or diseased leaves produce few segments. No leaves are produced from these. By late September the storage rhizomes are fully developed.

Storage rhizomes can be harvested after 120 days in warm climates and after 150 to 180 days or after the leaves die in cold weather in cool climates. At harvest, the water is drained and the fragile rhizomes are dug carefully. In some farms in Japan, high pressure water stream is used to wash away the mud and expose the storage rhizomes. Yields vary from 3.5 to 4.5 metric tons per ha. Higher yields can be obtained if flowers are removed.

Lotus rhizome retain their crisp texture even when cooked. Thread-like mucilaginous strands exude from cut or broken surfaces when the pieces are pulled apart. Starch obtained from the storage rhizome has properties similar to that from arrowroot. Immature leaves including the petioles are used as greens. Mature seeds and carpets are eaten, both are reported by the Chinese to have medicinal qualities.

Lotus has been grown in the Imperial Valley of California and I believe it can be successfully grown in the southeastern United States.

Note on US import restrictions

Ipomoea aquatic Forsk (*I. reptans* Poir.). [Common names: Water convulvulus, water spinach, swamp cabbage; ung tsoi, weng kai (China, Taiwan); kang kong (S.E. Asia); asagao na, yu sai (Japan)]. Water convulvulus belongs to the Convulvulaceae (morning glory family) and the same genus as the sweet potato (*Ipomoea batatas* L.) Probably of Chinese origin, cultivation dates back to at least 300 AD It is a very important green vegetable in Southeast Asia, because it is easy to grow, high yielding, and very nutritious.

The plant is herbaceous, an aquatic or semi-aquatic annual with hollow stems and ovate to elliptic shaped leaves. It has a creeping growth habit but may grow erect in water.

There are two main cultivars, the white flowered green stemmed type used in dry land (moist soil) culture and the pink colored purple centered flowers with white stems which are planted in flooded lands.

The green stem type is usually propagated by sowing seeds directly in the bed. Plants are spaced 12 cm apart and fertilized heavily with organic materials. When rainfall is not adequate, the crop is irrigated. Harvest of the entire plant can be made 50 to 60 days after planting.

Propagation is by stem cuttings for the white stem cultivar. Cuttings about 30 cm long with 7 to 8 nodes are obtained from the existing crop or from a nursery. The field is prepared as for paddy rice. Cuttings are planted 3 to 5 cm deep into the mud at about 40 cm spacing. Water is allowed to flow into the field as the crop grows, the depth is gradually increased to 15 to 20 cm. High rates of fertilizer are applied throughout growth; the water drained before application and flooded again a day afterwards. First harvest can be made a month after planting. Shoots are cut at about water level and bunched. After the first cutting, harvests can be made every 7 to 10 days. Annual yield of 90 metric tons per ha can be made from wet culture plantings.

Vigna sesquipedalis (L.) Fruw. (*V. unguiculata* (L.) Walp. sub spec. *sesquipedalis* (L) Verd.). [Common names: Yard long bean, asparagus bean; chang jiang dou, cheung kung tau (China, Taiwan); sitao (Philippines); zuyu roku sasage (Japan)]. Possibly of tropical African origin, the yard long bean (Fabaceae-Leguminosae), is a close relative of the cowpea. The crop is an annual trailing vine usually grown on poles or interplanted with corn for support of vines. Long slender immature pods which grow from 30 to 90 cm in length and about 0.9 to 1.0 cm in thickness are harvested.

There are two cultivars, a long white podded type which is harvested in the spring and the green podded type which is harvested from spring through fall in Southeast Asia. The crop is tolerant to high temperature and acid soils common in the tropics. It is intolerant to cold temperatures and under low soil moisture the pods are short and fibrous. Yard long beans can best be tried in regions where high temperatures prevent flower set of the common snap bean.

Cryptotaenia japonica Hassk. (*C. canadensis* D.C. var. *japonica* Makino). [Common names:

Mitsuba, Japanese honeworts.] Probably of Japanese origin, n-mitsuba, meaning 3 leaflets is cultivated in Japan, Korea, and China. It is a member of the carrot family (Apiaceae-Umbelliferae). Like celery but a much smaller plant, it is grown for its long slender petioles and leaflets. The petioles are 10 to 15 cm long and 2 to 4 mm in thickness. When blanched or grown under crowded conditions, the petioles elongate to 30 cm or more in length.

In Japan, mitsuba is grown all year round in plastic houses, with the main production from fall through winter. Some growers culture the crop on polyfoam blocks which are floated on nutrient solution. Mitsuba is grown commercially near Los Angeles, California, in plastic houses for the oriental people in that area.

Mitsuba has a very distinct flavor; it is eaten raw in salads or as garnish and is used as flavoring in soups or cooked as greens.

Raphanus sativas L., cultivar 'Sing li mei'. [Common name: red fleshed radish]. In 1979, while visiting an agricultural experiment station in Japan, I saw some red flesh winter radish grown from seed brought from mainland China. While in China this summer, I saw this radish again. It was developed by a breeder at the Beijing Vegetable Research Center. The cultivar is named 'Sing li mei', meaning "the heart is beautiful" in Chinese. The roots I saw were grown the previous fall and put into storage and kept until mid June. The pigment is probably an anthocyanin.

The radishes are eaten raw as a snack food; they are crisp and sweeten somewhat during storage. This radish cultivar should prove popular in the western world in adding color to salads and for vegetable hors d'oeuvres.

[y]Howard, F.D. et al. (1962).

The fungus *Ustilago esculenta*, which causes stem enlargement of Manchurian wild rice, *Zizania latifolia* is a regulated organism. Bringing infected *Z. latifolia* into the United States is a violation of the Federal Plant Pest Act regulations. The fungus poses a threat to native species of wild rice. One illegal planting of Manchurian wild rice was eradicated in California in 1991. Infected wild rice has been detected in Louisiana and authorities are developing recommendations to address the issue.

Ipomoea aquatica is a federal noxious weed. Under authority of the Federal Noxious Weed Act, the Animal and Plant Health Inspection Service prohibits the importation and interstate movement of this species, except under USDA-issued noxious weed permit. Although *I. aquatica* is prized as a vegetable, it is also an agricultural and environmental pest, reducing yields of rice and sugarcane in other parts of the world, and affecting aquatic ecosystems, irrigation systems, reservoirs, and navigation and recreation on fresh waterways.

APHIS (Animal and Plant Health Inspection Service) encourages importers to be aware of import restrictions meant to protect American agriculture and natural areas. Please refer to the APHIS web site for more information: http://www.aphis.usda.gov/ppq/permits/

Cucurbitaceae *Cucumis melo* L. (Flexuosus group)

Source: Magness et al. 1971

The plant on which this melon or cucumber is grown is closely related and similar to muskmelon. Fruits are very long and slender, up to 36 inches long and 3 inches in diameter. They are grown mainly as curiosities, but are used to some extent for preserves.

Season, seeding to harvest: 4 or more months.

Production in U.S.: No data. Limited.

Use: Preserves.

Part of plant consumed: Whole fruit.

Ramcharan, C. 1999. Culantro: A much utilized, little understood herb. p. 506–509. In: J. Janick (ed.), Perspectives on new crops and new uses. ASHS Press, Alexandria, VA.

Culantro: A Much Utilized, Little Understood Herb

Christopher Ramcharan

Culantro (*Eryngium foetidum* L., Apiaceae) is a biennial herb indigenous to continental Tropical America and the West Indies. Although widely used in dishes throughout the Caribbean, Latin America, and the Far East, culantro is relatively unknown in the United States and many other parts of the world and is often mistaken and misnamed for its close relative cilantro or coriander (*Coriandrum sativum* L.). Some of its common names descriptive of the plant include: spiny or serrated coriander, *shado beni* and *bhandhania* (Trinidad and Tobago), *chadron benee* (Dominica), *coulante* (Haiti), *recao* (Puerto Rico), and fit weed (Guyana).

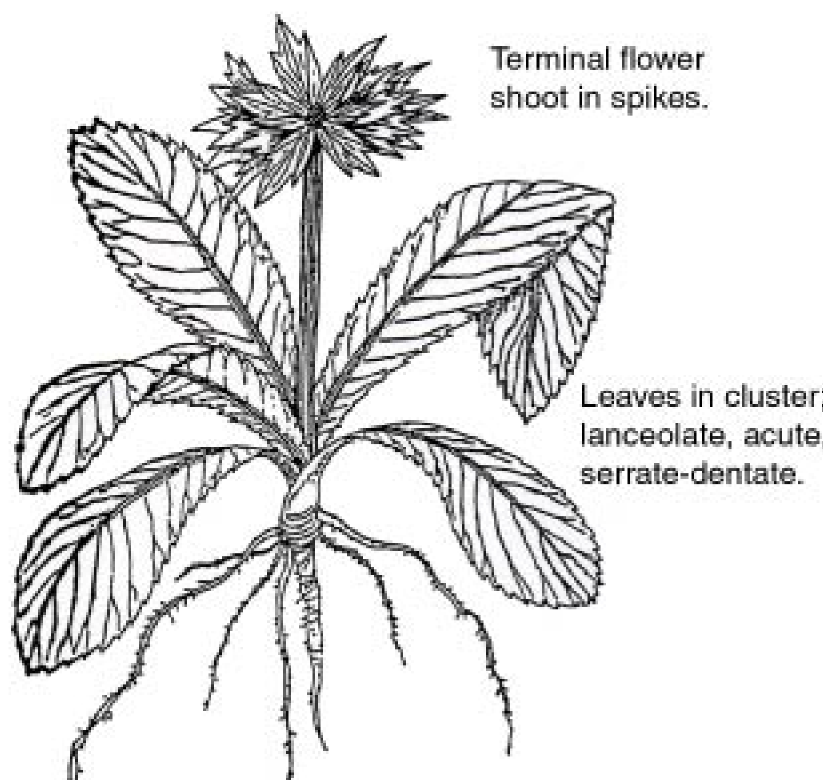
Culantro grows naturally in shaded moist heavy soils near cultivated areas. Under cultivation, the plant thrives best under well irrigated shaded conditions. Like its close relative cilantro, culantro tends to bolt and flower profusely under hot high-light long days of summer months. Recent research at UVIAES has demonstrated that it can be kept in a vegetative mode through summer when treated with GA_3 sprays.

The plant is reportedly rich in calcium, iron, carotene, and riboflavin and its harvested leaves are widely used as a food flavoring and seasoning herb for meat and many other foods. Its medicinal value include its use as a tea for flu, diabetes, constipation, and fevers. One of its most popular use is in chutneys as an appetite stimulant. The name fitweed is derived from its supposedly anti-convulsant property. The presence of increasingly large West Indian, Latin American, and Asian immigrant communities in metropolises of the US, Canada and the UK. creates a large market for culantro and large quantities are exported from Puerto Rico and Trinidad to these areas.

Culantro is increasingly becoming a crop of international trade mainly to meet the demands of ethnic populations in the developed countries of the West. Large immigrant communities in London, New York, and Toronto represents a vast potential market for the herb. One exporter from Trinidad alone packages and air freights up to 2.4 t of fresh culantro weekly to the US. In 1988, Puerto Rico reportedly produced 165,000 kg of culantro for a value of $201,000 (Dept. of Agriculture 1988). The herb is used extensively in the Caribbean and in Asia particularly in India and Korea. It is used mainly as a seasoning in the preparation of a range of foods, including vegetable and meat dishes, chutneys, preserves, sauces, and snacks. Although used in small quantities, its pungent unique aroma gives the characteristic flavor to the dishes in which it is incorporated and this is responsible for its increasing demand among ethnic populations. Culantro is also widely used in herbal medicines and reportedly beneficial in the treatment of a number of ailments (Wong 1976).

NOMENCLATURE

The derivation of culantro and recao, by which the plant is commonly known in Central America, is unknown but many of its names outside its natural habitat compare it to the common coriander or cilantro, e.g. Hindi bhandhanya, broad dhanya, or coriander, and Thai pak chi farang "foreign coriander." The botanical genus name *Eryngium* is derived from the Greek sea holly, *Eryngium vulgare*, and its specific name comes from the Latin *foetidum* meaning stink or bad odor; its smell is sometimes equated to a crushed bedbug. Some of the common names of culantro in the Caribbean area are: *shado beni* (Trinidad), *chadron benee* (Dominica), fitweed (Guyana), *coulante* or *culantro* (Haiti), *recao* (Puerto Rico) (Seaforth et al. 1983; Morean 1988; Seaforth 1988). Names in different languages include: *langer koriander* (German); *ketumbar java* (Malay); *pak chi farang* (Thai); *ngo gai* (Vietnamese); *culantro, racao, recao* (Spanish); *bhandhanya* (Hindi), and long leaf or spiny coriander (English).



Eryngium comprises over 200 tropical and temperate species (Willis 1960). Most are spiny ornamental herbs with thick roots and fleshy waxy leaves with blue flowers in cymose heads. *Eryngium foetidum* is a tap-rooted biennial herb with long, evenly branched roots (Fig. 1). The oblanceolate leaves, arranged spirally around the short thick stem, form a basal rosette and are as much as 30 cm long and 4 cm broad. The leaf margin is serrated, each tooth of the margin containing a small yellow spine. The plant produces a well-branched cluster of flower heads in spikes forming the characteristic umbel inflorescence on a long stalk arising from the center of the leaf rosette (Morton 1981; Moran 1988). The calyx is green while the corolla is creamy white in color.

Fig. 1. The culantro plant, *Eryngium foetidum*.

ECOLOGY AND CULTURE

Culantro is native to continental tropical America and the West Indies (Adams 1971). It grows naturally throughout many Caribbean islands including Trinidad and Tobago, where it is abundant in forests particularly in disturbed areas as in slash and burn sites. The herb is also commonly found along moist or shaded pathways and near cultivated areas where heavy soils predominate (Seaforth et al. 1983; Morean 1988). Although the plant grows well in full sun most commercial plantings occur in partially shaded moist locations. Shaded areas produce plants with larger and greener leaves that are more marketable because of their better appearance and higher pungent aroma. In a study on the effects of light intensity on growth and flowering of culantro, a significant delay in flowering and increased fresh weight of leaves were found in plants grown under 63% to 73% shade (Santiago–Santos and Cedeno–Maldonado 1991). Shaded plants also had fewer inflorescences with lower fresh weight. Although culantro grows in a wide variety of soils, it does best in moist well drained sandy loams high in organic matter particularly under full light. Precise fertilizer recommendations have not been made but high nitrogen fertilizers or manures promote leaf growth. Plants are usually started from seed which germinate in about 30 days, and for home or backyard gardens can be cultivated in containers or wooden boxes. For such cultivation, a slow release fertilizer such as Osmocote (14–14–14) can be incorporated in the soil mix at the rate of 1.8 kg/m^3.

Like many of its relatives, culantro tends to bolt and flower profusely under long day conditions resulting in reduced leaf growth and market value, and increasing costs for flower pruning. In a study to reduce bolting and increase leaf:flower size, ProGibb (PG) 4% a vegetative growth promoter was applied in increasing concentrations as a foliar spray to 1-month old culantro plants grown under 54% shade in a poly greenhouse (Ramcharan 1998). While leaf length increased with increasing levels of PG, leaf dry weight increased up to the 150 ppm PG level but was reduced at 200 ppm. Concomitantly, both fresh and dry weights of inflorescences were reduced by increasing levels of PG. Flowers produced in treated plants were less woody and spiny and leaf-like in appearance, making them easier for pruning. Pro Gibb 4% at 100 ppm concentration was therefore found to be optimum for maximizing leaf production and minimizing flower growth in culantro.

Culantro is relatively pest- and disease-free but the author has seen root knot nematodes on plants that have been grown for 2–3 years in box containers. A leaf spot problem which appears to be bacterial black rot (*Xanthomonas* sp.) has also been observed on such long-lived plants. Anecdotal reports mention that the flower heads are attractive to ladybugs, green lacewings, and other beneficial insects. Plants around the garden have also reportedly provided excellent defense against aphids.

While there are few reports on cultivation and fertilizer requirements for culantro, there has been considerable research on postharvest techniques for the herb. In a refrigerated storage trial, Sankat and Maharaj (1991) found that unpackaged culantro became unmarketable within 4 days of storage regardless of temperature. Storage at 10°C extended shelf life up to 2 weeks and chilling injury was observed at 3°C after 8 days in storage. In another postharvest study, the combination of polyethylene packaging, gibberellic acid (GA_3) in a 200 ppm dip treatment and reduced storage temperature (20°–22°C) extended the shelf-life of culantro up to 22 days (Mohammed and Wickham 1995). Freeze drying of harvested leaves is another alternative being considered to extend postharvest life.

CULINARY USES AND NUTRITIONAL VALUE

The appearance of culantro and cilantro are different but the leaf aromas are similar, although culantro is more pungent. Because of this aroma similarity the leaves are used interchangeably in many food preparations and is the major reason for the misnaming of one herb for the other. While relatively new to American cuisine, culantro has long been used in the Far East, Latin America, and the Caribbean. In Asia, culantro is most popular in Thailand, Malaysia, and Singapore where it is commonly used with or in lieu of cilantro and topped over soups, noodle dishes, and curries. In Latin America, culantro is mostly associated with the cooking style of Puerto Rico, where recipes common to all Latin countries are enhanced with culantro. The most popular and ubiquitous example is *salsa*, a spicy sauce prepared from tomatoes, garlic, onion, lemon juice, with liberal amounts of chiles. These constituents are fried and simmered together, mixed to a smooth paste and spiced with fresh herbs including culantro. Salsa is usually consumed with tortilla chips as an appetizer. Equally popular is *sofrito* or *recaito*, the name given to the mixture of seasonings containing culantro and widely used in rice, stews, and soups (Wilson 1991). There are reportedly as many variations of the recipe as there are cooks in Puerto Rico but basically sofrito consists of garlic, onion, green pepper, small mild peppers, and both cilantro and culantro leaves. Ingredients are blended and can then be refrigerated for months. Sofrito is itself the major ingredient in a host of other recipes including eggplant pasta sauce, cilantro garlic butter, cilantro pesto, pineapple salsa, and gazpacho with herb yogurt.

Culantro is reported to be rich in calcium, iron, carotene, and riboflavin. Fresh leaves are 86–88% moisture, 3.3% protein, 0.6% fat, 6.5% carbohydrate, 1.7% ash, 0.06% phosphorus, and 0.02% iron. Leaves are an excellent source of vitamin A (10,460 I.U./100 g), B_2 (60 mg %), B_1 (0.8 mg %), and C (150–200 mg %) (Bautista et al. 1988). On a dry weight basis, leaves consist of 0.1–0.95% volatile oil, 27.7% crude fiber, 1.23% calcium, and 25 ppm boron.

MEDICINAL USES

The plant is used in traditional medicines for fevers and chills, vomiting, diarrhea, and in Jamaica for colds and convulsions in children (Honeychurch 1980). The leaves and roots are boiled and the water drunk for pneumonia, flu, diabetes, constipation, and malaria fever. The root can be eaten raw for scorpion stings and in India the root is reportedly used to alleviate stomach pains. The leaves themselves can be eaten in the form of a chutney as an appetite stimulant (Mahabir 1991).

CONCLUSION

Although used widely throughout the Caribbean, Latin America, and the Far East, culantro is still mistaken for and erroneously called cilantro. The herb is rapidly becoming an important import item into the US mainly due to the increasing ethnic immigrant populations who utilize it in their many varied dishes from around the world. It is closely related botanically to cilantro but has a distinctly different appearance and a much more potent volatile leaf oil. Recent research to prevent bolting and early flowering will increase its leaf yields and consequently its demand. Successes in prolonging its postharvest life and storage under refrigeration will undoubtedly increase its export potential and ultimately its popularity among the commonly used culinary herbs.

Culvers-Physic

Veronica virginica L.

Figure 45.—Culvers-physic (*Veronica virginica*)

Synonym.—*Leptandra virginica* (L.) Nutt.

Other common names.—Culvers-root, blackroot, bowmansroot, beaumont root, Brinton root, tall speedwell, tall veronica, physic-root, whorlywort.

Habitat and range.—This common native herb is found abundantly in moist rich woods, mountain valleys, meadows, and thickets from Nova Scotia to British Columbia and south to Alabama, Missouri, and Nebraska.

Description.—Culvers-physic is a tall, slender-stemmed herb from 3 to 7 feet in height. The long, narrow, pointed leaves, which are arranged around the stem at intervals, in groups of from three to nine, are 3 to 6 inches in length and 1 inch or less in width. The tube-shaped flowers, produced from June to September, are borne in several densely crowded, slender, terminal, spikelike heads from 3 to 9 inches long. The flowers are usually white, but at times are pink to bluish or purple.

Part used.—The rootstock and roots, collected in the fall of the second year.

Prosopis chilensis (Molina) Stuntz

Mimosaceae
Cupesi, White algarobo

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

White algarobo used for shade, timber, fuel, and concentrated forage or food (sweet, pulpy fruits). Pods eaten as sweets "patay" or drunk as "aloja". A staple food for cattle in arid regions. Sometimes cultivated in Argentina and Chile; promising reforestation species (Burkart, 1976). South Africans believe the ripe pod makes excellent fodder but the green pod is bitter and valueless. Reddish mesquite gum may be used as a substitute for gum arabic as an adhesive and in the manufacture of gumdrops (Watt and Breyer-Brandwijk, 1962). Wood is said to have good acoustical properties (Allen and Allen, 1981).

Folk Medicine

A ten percent infusion of the leaves shows some antibiotic activity.

Chemistry

Like *P. alba* this species contains apigenin 8-glucoside, apigenin 6-glucoside, quercitin 3-glucoside, quercitin 3-rhamnoside, quercitin 3-rutinoside, and traces of myricetin 3-rhamnoside, luteolin, kaempferol-3-OMe quercetin, and quercitin 3-OMe (Simpson, 1977). Pipecolic and 4-hydroxy pipecolic acid also occur in both, but varying concentrations of pipecolic acid and proline are interpreted as reflecting a plastic response to changing environmental conditions. The consistent patterns of flavonoid distributions in several species groups, on the other hand, apparently reflects genetic fixation independent of known environmental factors (Simpson, 1977). Patay (ground beans filtered to remove the endocarp, and made into flour for breadstuffs) contains 10–12% water, 4–6% fiber, 0.8–4.3% protein, and 55–65% carbohydrates (44% sugar, 11% starch, plus cellulose) and is relatively high in calcium. Fresh pods, but not dry pods, are said to be harmful to horses. Seeds contain small quantities of saponins. Bark and root contain tannin. Young leaves contain 1.8% alkaloids, intermediate leaves, 1.7%, and mature leaves, 0.9% (Simpson, 1977).

Source: Gohl, B. 1981.

Description

Tree, becoming large in age, with short trunk, 3–10 m tall, treetop rounded; branchlets flexuous, knotty, partly spinous; spines on strong shoots, axillary, geminate, uninodal, hard, conic-subulate, up to 6 cm long. Leaves deciduous, glabrous, uni- to bi- or trijugate, elongate, but giving only slight shade, mostly fascicled; petiole (rachis when extant included) 1.5–12 cm long; pinnae 8–24.5 cm long; leaflets 10 to 29 pairs per pinna, long-linear and distant on the rachis (4–12 mm apart), glabrous throughout or with some cilias on the margins at base, 1.1–5.4 cm long x 1.1–3 mm broad, pale green, nearly enervate or only the costa prominent, but not of a different color. Racemes spiciform, densiflorous, ca 7–12 cm long; flowers greenish-white to yellowish, ca 250 per raceme; calyx 1 mm; petals 3 mm long, villous within; stamens 5–6 mm long; ovary pubescent. Legume linear, compressed, with parallel margens, strawyellow, stipitate and acuminate, nearly straight, thick; mesocarp sugary, edible; endocarp segments transverse-rectangular, broader than long, subcoriaceous, easy to open numbering 20 to 32; seeds ovoid, compressed, brown, 6–7 mm long (Burkart, 1976).

Germplasm

Reported from the South American Center of Diversity, cupesi, or cvs thereof, is reported to tolerate drought. Simpson (1977) reports self–incompatibility. ($2n$ = 28, 56).

Distribution

Extending from Peru and Bolivia to central Chile and northwestern Argentina. In southern Peru it is found at elevations of up to 2900 m (Burkart, 1976).

Ecology

Our computer entries for *Prosopis* spp. are unreliable, partly due to past taxonomic confusion. I estimate this species ranges from Tropical Thorn to Moist through Subtropical Thorn to Moist Forest Life Zones. At the Bolson de Pipanaco, elevation ca 1072 m, annual precipitation ca 3 dm, annual temperature ca 18.6°C, *Prosopis chilensis* often forms dense stands along the broad washes. Associated species are mentioned in Simpson (1977). In Argentina, the species leafs out in spring (September) with mean temperature ca 16°C staying in leaf until fall (April). Blooms in October in Andalgala for about two weeks.

Cultivation

Felker et al. (1981) reported water requirements of 535.3 cm^3 per g of dry matter making this one of the more water efficient species of *Prosopis*.

Harvesting

Commonly cut for fuel as needed.

Yields and Economics

According to Simpson (1977) a mature tree produces ca 10,000 inflorescenses per year, each with about 279 flowers, but setting only 1.65 fruits per inflorescence. Each inflorescence is estimated to produce 12.89 mg sugar or ca 13 g from all 10,000; and 26.50 mg pollen (26 g in all per tree). At Riverside, #0009 *P. chilensis* average measured (not projected from regression equations) oven dry biomass corresponded to a 41 MT/ha 3-season yield or a 13.7 MT/ha/yr. This yield was obtained with total irrigation plus rainfall of 1,390 mm or a seasonal average of 460 mm. Others showed an average annual production of 14.5 MT/ha in the Imperial Valley, but the total DM production for all 55 accessions tested averaged an annual increment of 8.2 MT/ha. Under similar conditions, Felker et al. (1981) report:

	UCR biomass tree (kg)	Imp. vall. biomass/ tree (kg)	Pods (g)	Pods/ tree(s)	Coppice (%)	Salinity	Na/hr?

Energy

Felker et al (1981) report that small plots with 1.5 x 1.5 m spacing yielded 11.7 MT/ha the first year, 16.9 MT/ha the second year.

Biotic Factors

Some specialists (*Brachyphatnus* sp. and *Noctuid* sp.) and some generalists (*Melipotis bisinuata, Oiketicus geyeri, Semiothisa* sp.) are reported to "graze" the species in Argentina. The major *Prosopis* bee visitors are *Bicolletes* sp., *Centris brethesi, Collates* spp., *Eremapis pravula, Exomalopsis* sp., *Liopoeum argentina, Megachile* spp., *Oediscelis, Svastrides zebra,* and *Xylocopa splendidula* (Simpson, 1977). Among bruchids, *Rhipibruchus picturatus, R. prosopis,* and *Scutobruchus ceratioborus* are reported. Bruchids may destroy 90% of the seed. *Phoradendron hieronymi, P. liga, P. pruinosum, Prosopanche americana, Psittacanthus cuneifolius,* and *Tapinanthus* sp., possibly even *Ximenia americana* are hemiparasitic or parasitic flowering plants on the algarrobo. The desert cavy eats leaves and pods and may strip bark from small tender branches. Many other *Prosopis* eaters are listed and discussed in Simpson (1977). Golden (p.c. 1984) lists the nematode *Rotylenchus reniformis.* Felker et al (1981) review the pest infestations of their *Prosopis* plantings with suggestions for their control.

Turmeric, Tumeric

Tumerico

Zingiberaceae *Curcuma longa* L.

Source: Magness et al. 1971

The plant is a large-leaved herb, closely related to ginger. It is cultivated in tropical countries for the thick, rounded, underground stems or rhizomes, which constitute the spice, turmeric. Turmeric contains an oil, which consists in part of curcumin, which on oxidation is changed into vanillin, the active principle in vanilla. The rootstocks of turmeric, both fresh and dried, are also used as flavoring in curries and other cookery.

Cultural Studies in Ornamental Ginger

Jeff S. Kuehny, Mauricio J. Sarmiento, and Patricia C. Branch

INTRODUCTION

Hedychium species (butterfly ginger) and *Alpinia zerumbet* (shell ginger) have been grown in the Southern United States since at least the turn of the century (Burch 1998). *Curcuma* and *Kaempferia* are two other genera in the Zingiberaceae family that have recently gained much notoriety. *Kaempferia* species have unique foliage and *Curcuma* species colorful, long-lasting inflorescences, both with a 90- to 100-day production cycle and few pest problems. These gingers have great potential for use as flowering pot plants, both indoors and as patio and landscape plants. They are herbaceous perennials with short fleshy rhizomes and tuberous roots, often with a dormancy period (Burch et al. 1987). Inflorescence stalks arise either from a short pseudostem or independently from buds on the rhizome. The inflorescence of *Curcuma* species are a compressed spike of colorful long lasting bracts subtending 2 to 7 true flowers (Luc-Cayo and Fereol 1997). *Kaempferia* species, however, have short lived flowers with attractive, colored/patterned leaves that vary in size and shape. Burch (1998) reported that between 150,000 to 250,000 rhizomes of ginger would be sold in 1998. Because of the new genera of ginger continuing to enter the market, the value of ornamental ginger has not been well documented. The number of rhizomes sold has probably doubled (E. Welch, pers. commun.) since 1998 and this does not account for number of plants sold from tissue culture.

There is little information on the optimum production environment, postproduction longevity, and landscape survivability of commercially available gingers. The objectives of this research were to determine the effects of light intensity, photoperiod, and plant growth regulator application on various cultures of *Curcuma* and *Kaempferia* species (Fig. 1–5).

Fig. 1. *Curcuma alismatifolia* ‘Chiang Mai Pink’.

Fig. 4. *Curcuma petiolata*.

Fig. 5. *Kaempferia* spp. ‘Grande’.

METHODOLOGY

All plants were grown in the greenhouse using a medium consisting of 1/2 peat moss, 1/3 pine bark, and 1/6 perlite, amended with dolomite limestone (5.1 kg/m^3) and superphosphate 0–18–0 (2.7 kg/m^3). Immediately after planting containers were drenched with a tank mix of metalaxyl (Subdue 2E, Novartis, Greensboro, North Carolina) at 15.6 ml/100 L and PCNB quintozene (Terraclor 75% WP, Uniroyal Chemical, Middlebury, Connecticut). Plants were spaced on 21 × 21 cm centers and fertigated with 24N–3.5P–13.3K (Peters 24–8–16 Tropical Foliage, Scotts-Sierra, Marysville, Ohio) at 150 ppm N as needed.

Data was analyzed using PROC GLM. Comparisons between means was conducted by Tukey’s studentized range test.

Light Levels and Plant Growth Retardants

Curcuma spp. ‘Precious Petuma’, *C. parviflora* ‘White Angel’, and *C. alismatifolia* ‘Chiang Mai Pink’ rhizomes were planted one per 14 cm container on 4 April 2000. Plants were grown in a greenhouse at temperature setpoints of 27°/21°C day/night. When shoot height was 10 cm, the plants were drenched with 118 ml of paclobutrazol or uniconazole at 0, 10 or 20 mg a.i. per container and grown under a 0% (1,860 µmol/s/m^2), 30% (922 µmol/s/m^2) or 60% (352 µmol/s/m^2) shade. Average daily temperatures for the three light levels were 30°C. Days to emergence, days to bloom, number of flowers, height of the flowering stalk, and days to anthesis (postproduction longevity) were determined for all plants.

There was no significant effect of shade level on days to emergence or days from emergence to first flower for *Curcuma* spp. ‘Precious Petuma’. Flower height was 22% taller for those plants grown under both shade levels. Application of paclobutrazol and uniconazole at 20 mg a.i./pot reduced the flower height of ‘Precious Petuma’ by 27% and 54% respectively. Because flower height was acceptable (approximately 25 cm) at all shade levels, the use of a growth retardant is not recommended. Shade level had no affect on flower longevity, with an average 29 day postproduction longevity. The number of days from first flower to second flower were extended by approximately 12 days when plants were grown under 60% shade.

Days from emergence to first flower of *C. parviflora* ‘White Angel’ was significantly extended by approximately 13 days when grown under 60% shade. Flower height was 23% taller at 30% shade; however, due to the short stem of this flower, this height was still acceptable (less than 25 cm). Thus, the use of a growth retardant is unnecessary. Shade level did not affect flower longevity or days to second flower. Flower longevity was favorable at approximately 30 days and days to second flower was approximately 40 days for all treatments.

Days from planting to emergence and emergence to first flower of *C. alismatifolia* ‘Chiang Mai Pink’ were unaffected by shade level or rate of growth retardant. Days from first flower to second flower was significantly extended by both shade levels with no second flower produced at 60% shade. Thus, these plants must be grown under full sun for best quality. When grown at 30% or 60% shade, flower height was significantly taller by 9 and 13 cm respectively. The flower height of these plants, regardless of shade treatment, was not of marketable quality. The results from this study indicate that for production of a marketable flowering ‘Chiang Mai Pink’ ginger, application of uniconazole at 10 mg a.i./pot and a rate greater than 20 mg a.i./pot of paclobutrazol is recommended. Postproduction longevity of this ginger is approximately 40 days.

Gibberellic Acid

Curcuma alismatifolia 'Chiang Mai Pink', *C. gracillima* 'Violet', and *C. thorelii* one cm rhizomes were planted one per 14 cm container on 17 April 1999. Prior to planting, rhizomes were soaked for 10 min in a solution containing 2% GA_{4+7} (Provide, Abbot Labs, North Chicago, Illinois) at 0, 200, 400, or 600 mg/L, 10% Physan 20 (10% dimethyl benzyl ammonium chloride, 10% dimethyl ethyl ammonium chloride, 80% inert, Maril Products, Tustin, California) and distilled water. Rhizomes were dried and planted in a greenhouse with average minimum and maximum temperatures of 23° and 30°C night/day. Treatments were arranged in a complete randomized design.

Plants were harvested once a week when they reached a stage characterized by the opening of the last bract and one flower (marketable stage). Days to bloom, number of flowers, and height of the flowering stalk were recorded for all plants.

GA at 200, 400, and 600 ppm delayed shoot emergence of *C. alismatifolia* 'Chiang Mai Pink' (Table 1). GA at 400 ppm delayed flowering but did not increase the number of inflorescences. All plants had one inflorescence per container. Application of GA at 600 ppm reduced flower height (data not shown). GA concentrations of 600 ppm delayed shoot emergence of *C. gracillima* 'Violet' and *C. thorelii* (Table 1). Days to bloom and flower height was unaffected for either *Curcuma*, and plants developed no more than one flowering stem.

Table 1. Effect of gibberellic acid (GA) on days to emergence and days to bloom of *Curcuma alismatifolia* 'Chiang Mai Pink', *C. gracillima* 'Violet', and *C. thorelii*.

Photoperiod

Tissue culture plants of *Curcuma petiolata* 'Emperor', *C. thorelii*, and *Kaempferia* sp. 'Grande' were planted one per 15 cm container in the greenhouse on 16 Aug. 1999. Tissue culture plants of *C. cordata* were planted two per 15 cm container on 9 Sept. 1999. Rhizomes of *C. alismatifolia* 'Siam Tulip White' were planted one per 12.5 cm container on 27 Aug. 1999. All ginger species were arranged in a complete randomized design under each photoperiod treatment.

Photoperiod treatments were initiated 17 d after transplanting for *C. alismatifolia C. petiolata*, *C. thorelii*, and *Kaempferia* sp. 'Grande' and 18 d after transplanting for *C. cordata*. On 2 Sept. 1999 photoperiod treatments of 8, 12, 16, and 20 hr were initiated. Plants received 8 hr of natural light from 0900 to 1700 hr. Zero, four, eight, and twelve hours of supplemental light were provided for the 8, 12, 16, and 20 hr photoperiod, respectively. Light source was 100 watt incandescent light bulbs at an irradiance of 11 $\mu mol/s/m^2$ (14 to 50 foot candles). Average minimum and maximum temperatures were 18° and 26.5°C. *Curcuma petiolata*, *C. thorelii*, 'Emperor', and *Kaempferia* sp. 'Grande' completed 21 weeks in the photoperiod treatment, *C. cordata* was 19 weeks and *C. alismatifolia* 18 weeks.

Each week, the number of newly unfolded leaves was counted as a measurement of plant growth. On 1 Dec. 1999, the height of the plants was measured from the medium surface to the tip of the longest leaf. On 1 Feb. 2000, the photoperiod treatment ended. Plants which did not go dormant during the course of the experiment were forced to dormancy by terminating irrigation. After all plants were dormant, the number of rhizomes and t-roots was counted for each treatment.

Dormancy was induced on all ginger grown under an 8 hr photoperiod. The number of weeks required for plants to go dormant under an 8 hr photoperiod was 9.0±0.17 weeks for *C. cordata*, 15±0 weeks for *C. petiolata*, 11.6±1.2 weeks for *C. thorelii*, and 12±0 weeks for *Kaempferia*.

Plant height of *C. alismatifolia* increased as length of photoperiod increased to 20 h (Table 2). *Curcuma* cordata plants grown at 20 and 16 hr were significantly taller than plants grown at 12 hr. Plants grown at 8 hr became dormant. *Curcuma* petiolata plants grown under 8 and 12 hr were significantly shorter than plants under 20 and 16 hr. *Curcuma* thorelii plants grown under 16 and 20 hr were significantly taller than plants at 12 hr. There were no significant differences in height between 12, 16, and 20 hr treatments for *Kaempferia*.

Table 2. Effect of photoperiod on plant height for *Curcuma alismatifolia* 'Chiang Mai White', *C. cordata, C. petiolata* 'Emperor', *C. thorelii*, and *Kaempferia* sp. 'Grande'.

Photoperiod (hr)	Plant height (cm)				
	Curcuma alismatifolia	*Curcuma cordata*	*Curcuma petiolata*	*Curcuma thorelii*	*Kaempferia 'Grande'*
8	20.7 a[z]	dormant[y]	35.6 a	dormant	dormant
12	30.0 b	42.7 a	41.6 a	32.0 a	31.6 a
16	38.8 c	50.2 b	65.3 b	37.3 b	46.6 a
20	35.6 bc	49.0 b	70.3 b	38.0 b	46.6 a

[z]Mean separation of photoperiods by HSD test, P=0.05. Means within columns with different letters are significantly different.
[y]Plants were dormant prior to measurement.

The number of leaves unfolded increased during the 16 and 20 hr photoperiod for *C. alismatifolia* (Table 3). *Curcuma cordata* plants under 16 and 20 hr photoperiods produced more new leaves than 8 and 12 hr photoperiods. *Curcuma petiolata* 'Emperor' plants grown at 16 and 20 hr produced more new leaves than plants grown at 8 and 12 hr (Table 3). Photoperiod did not significantly affect the number of new leaves *C. thorelii* produced. *Kaempferia* sp. 'Grande' plants in the 16 and 20 hr photoperiod produced more new leaves than those in 8 hr.

Table 3. Effect of photoperiod on total number of new leaves unfolded *Curcuma alismatifolia* 'Chiang Mai White', *C. cordata, C. petiolata* 'Emperor', *C. thorelii*, and *Kaempferia* sp. 'Grande'.

Photoperiod (hr)	Number of leaves unfolded				
	Curcuma alismatifolia	*Curcuma cordata*	*Curcuma petiolata*	*Curcuma thorelii*	*Kaempferia 'Grande'*

[z]Mean separation of photoperiods by HSD test, P=0.05. Means within columns with different letters are significantly different.

Curcuma alismatifolia, *C. cordata*, and *C. petiolata* plants grown under 16 and 20 hr produced a greater number of rhizomes than those plants grown under 8 and 12 hr (Table 4). Photoperiod did not affect the number of rhizomes produced by *C. thorelii* or *Kaempferia*. *Curcuma alismatifolia* grown under a photoperiod of 16 hr or less produced approximately two t-roots per plant and approximately one t-root at 20 hr (Table 5). *Curcuma cordata, C. petiolata*, and *Kaempferia* produced approximately 5 t-roots or more when grown at a photoperiod of 12 and 8 hr, and almost no t-roots at 16 and 20 hr. *Curcuma thorelii* responded to changes in photoperiod by producing a large number of t-roots for all treatments, producing the greatest number of t-roots at 16 hr.

Table 4. Effect of photoperiod on number of rhizomes of underground organs for *Curcuma alismatifolia* 'Chaing Mia White', *C. cordata, C. petiolata* 'Emperor', *C. thorelii*, and *Kaempferia* sp. 'Grande'.

COLCLUSIONS

Curcuma spp. 'Precious Petuma', *C. parviflora* 'White Angel', and *C. alismatifolia* 'Chiang Mai Pink' produce marketable flowering pot plants requiring no application of shade. 'Precious Petuma' and 'White Angel' can be grown under shade levels of up to 60% without use of growth retardant and no deleterious affect on plant quality. 'Chiang Mai Pink' should be grown in full sun and an application of either 10 mg a.i./pot of uniconazole or over 20 mg a.i./pot of paclobutrazol for production of a quality flowering pot plant. These ornamental gingers have an excellent postproduction longevity of up to 40 days.

GA did not increase the number of inflorescences of *Curcuma* alismatifolia but did delay shoot emergence and flowering. GA applied (as a spray) at concentrations of 1.44 and 2.88 mm suppressed shoot emergence of field grown edible ginger (*Zingiber officinale* Roscoe) (Furutani and Nagao 1986). GA usually stimulates stem lengthening however, GA at 600 ppm significantly reduced flower height of *C. alismatifolia*. Soaking rhizomes in GA at 200, 300, 400, and 600 ppm did not inhibit shoot sprouting but delayed it. GA has been recommended for extending dormancy, thereby inhibiting sprouting in storage of yams (*Dioscorea cayenensis rotundata* Lam. and *D. alata* L.), an edible tuber (Girardin et al. 1998). Thus, GA could be used to prolong storage of ornamental ginger rhizomes prior to planting. It should not be used to promote or increase flowering.

Photoperiod affected height of all species of ginger evaluated. The plants grown under 20 or 16 hr photoperiods were taller than those grown under 12 or 8 hr photoperiods. Photoperiod affected the number of unfolded leaves of all plants except for *C. thorelii*. The 16 and 20 hr photoperiods increased number of leaves unfolded compared to 12 and 8 hr. Effect of photoperiod on number of rhizomes and number of t-roots was dependent upon the species of ginger. *Kaempferia* sp. 'Grande', *C. petiolata*, *C. cordata*, and *C. alismatifolia* 'Siam Tulip White' produced more t-roots when grown under 8 or 12 hr than 20 or 16 hr photoperiods. The exception was *C. thorelii*, where more t-roots where produced on the plants growing at 20 or 16 hr photoperiod than in 12 or 8 hr. *Siphonichilus decora* did not produce t-roots under any of the 4 photoperiods. *Curcuma petiolata*, *C. cordata*, and *C. alismatifolia* 'Siam Tulip White' produced more rhizomes under the long day photoperiods (20 and 16 hr) than under 12 or 8 hr.

Ginger shoot and rhizome growth were optimized when plants were grown under 16 or 20 hr photoperiods, whereas an 8 hr photoperiod promoted dormancy. The best production strategy for growers of gingers as flowering potted plants is to plant in the spring (April) and grow the plants throughout the summer, finishing production in the fall. If production in the winter is desired, 16 hr photoperiod must be used.

Curly mesquite

Gramineae *Hilaria belangeri* (Steud.) Nash

Source: Magness et al. 1971

This is a warm climate grass native from Central Texas and Arizona south throughout Mexico. It is stolon forming and grows on dry soils that may range in texture from clay to gravelly. The plant grows in tufts, new tufts developing at the nodes of the stolons. Stems are slender, up to a foot tall, with short narrow leaves. It is highly drought resistant, palatable both green and when dry, thus is a valuable range grass for warm dry areas.

Palaniswamy, U.R., J.D. Stuart, and C.A. Caporuscio. 2002. Effect of storage temperature on the nutritional value of curry leaf. p. 567–569. In: J. Janick and A. Whipkey (eds.), Trends in new crops and new uses. ASHS Press, Alexandria, VA.

Effect of Storage Temperature on the Nutritional Value of Curry Leaf

Usha R. Palaniswamy, James D. Stuart, and Christian A. Caporuscio

INTRODUCTION

Curry leaf (*Murraya koenigii* Spreng., Rutaceae), is a popular leafy-spice used in Asian-Indian cuisine for its characterizing authentic flavor and distinct aroma (Fig. 1). The curry leaf is used by Asian Americans originating from South Asia almost daily in its fresh form when available and is preserved as dried or frozen for long-term storage. Interest in greater use of curry leaf has been stimulated since its high antioxidant and anticarcinogenic potential were reported (Khan et al. 1997; Khanum et al. 2000), as well as the changing demographics nationwide that have created a ready market and greater demand for this spice (Palaniswamy 2001). Curry leaf is used in very small quantities for its distinct aroma due to the presence of volatile oils and as a result most studies report on the concentrations of volatile oils and not on the nutritional value and functional properties attributed to antioxidant vitamins and plant pigments. The objective of this study was to evaluate the locally available curry leaves as a source of α-tochopherol, β-carotene, and lutein and study the effect of storage temperature on the concentrations of these vitamins and plant pigments.

Fig. 1. Curry leaf.

METHODOLOGY

Postharvest Treatments for Study

Curry leaf was purchased from local Asian grocery stores, pooled, divided into four lots, and sampled as (1) freshly bought, (2) oven-dried at 60°C for 1 day, (3) air-dried for 10 days spread on a table at 22°C, and (4) sealed in polythene bags and frozen at –15°C for 10 days. The freshly bought leaf was analyzed the same day of purchase, while the other samples were analyzed ten days after purchase when all the treatments were completed. The air-dried and the oven-dried samples were put in glass bottles when completely dried to imitate the traditional method of home storage for culinary use.

Leaf Vitamin Extraction and Sample Preparation

The vitamins were extracted form the leaf tissue as given by Sommerburg et al. (1998). Leaf tissue (1 g) was homogenized for 3 min in 20 mL sodium phosphate (10 mm) containing 0.15 N sodium chloride (pH 4.7); 2 mL of methanol containing 0.5 mg/mL butylated hydroxytoluene and 10 mL internal standard (1 mg/mL) in hexane were added, vortexed for 5 min, and centrifuged for 10 min. The upper layer was collected and stored. The remaining extract was vortexed again for 2 min and centrifuged for 5 min. The upper layer was collected and combined with the first extract. The combined extracts were passed through sodium sulfate to remove moisture. All extracts were transferred and stored in 4 mL amber vials, sealed, and refrigerated.

Chlorophyll Measurement

At the time of chemical analysis, the fresh curry leaves as well as the leaf samples that received the different postharvest and storage treatments were extracted with N, N-dimethylformamide and the chlorophyll content was determined by the method of Inskeep and Bloom (1985).

High Performance Liquid Chromatography

A Restek reversed phase Ultra C18 column (150 mm, 4.6 mm i.d., 5 mm particle size; Restek Corporation, Bellefonte, Pennsylvania) with a 20% carbon load, along with a Ultra C18 Guard column (10 mm, 4 mm i.d, 5 mm packing) and 50 mL injection loop (Rheodyne Inc, Cotati, California) were used with a HPLC (Perkin Elmer Binary LC Pump Model 250, PE Biosystems, Norwalk, Connecticut) fitted with a Perkin Elmer Diode Array Detector Model 235, set at the wavelengths of 270 nm for β-carotene and lutein, and 290 nm for α-tocopherol and α-tocopherol acetate as internal standard with an attenuation of 0.2 absorbance units. Monitoring at higher wavelengths caused detector saturation. The column was placed in a Perkin Elmer Oven Model 101 set at 35°C, and the data collected on a computer (PE Nelson Model 1022 LC computer). Two solvents were prepared for the mobile phase. A rapid 20 min gradient of 90% solvent mixture A: 85% acetonitrile, 2.5% hexane, 2.5% methylene chloride, and 10% methanol followed by 20 minutes of 100% solvent B: 50% acetonitrile, 20% hexane, 20% methylene chloride, and 10%

methanol at a flow rate of 1 mL min^{-1} was used. The column was allowed to equilibrate prior to the next injection with a 25-min gradient of 90% solvent A.

Prior to injection into the HPLC, the extract was filtered through a 4 mm, 0.2 mm nylon syringe filter (Alltech, Deerfield, Illinois). After filtering 200 mL extract was injected into the HPLC. The detector was optimized at 270 nm for β-carotene and lutein, and 290 nm for α-tocopherol. The peaks were identified with standards lutein (X6250), β-carotene (C4582), α-tocopherol (T3251), and α-tocopherol acetate (T3376) purchased from Sigma Chemical Co. (St. Louis, Missouri) and confirmed by LC/MS.

Mass Spectrometry

Mass spectra were monitored in the mass range m/z 300–700 on a Quattro II mass spectrometer equipped with an atmospheric pressure chemical ionization (APCI) interface (Micromass, Beverly, Massachusettes). The capillary temperature was set to 150°C, the APCI vaporizer temperature was set to 450°C. The corona discharge voltage was optimized at 3 kV. The same column and LC conditions used in the HPLC-UV diode array experiments were also used for the LC-MS experiments, however the flow rate was reduced to 0.3 mL min^{-1}.

RESULTS

Lutein

The fresh curry leaves had the highest concentration of lutein and the frozen leaves had the lowest concentration of lutein (Table 1). Frozen curry leaves contained 70% less lutein than fresh leaves. Curry leaves subjected to oven-drying and air-drying contained 60% less lutein compared to fresh leaves.

Table 1. Anti-oxidant vitamin contents in curry leaves and post harvest storage temperature and treatment (mean concentration per gram dry weight±SD).

Post harvest storage temperature and treatment	Lutein (µg/g)	α-tocopherol (ng/g)	β-carotene (ng/g)	Chlorophyll (mg/g)
Fresh	27±2.8	592±10.1	511±10.5	27.8±1.2
Oven-dried (60°C)	11±1.9	296±8.2	148±1.2	9.9±1.2
Air-dried (22°C)	10±2.1	515±8.5	357±1.3	18.9±1.1
Frozen (-15°C)	8±2.5	589±11.2	398±1.5	26.9±1.1

α-Tocopherol

The α-tocopherol concentrations of the fresh leaves were unaffected by freezing at –15°C (Table 1). Air-drying at 22°C resulted in a lower loss of α-tocopherol (13%) compared to oven-drying where 50% of α-tocopherol was lost.

β-Carotene

The β-carotene concentration was highest in fresh leaves and lowest in the oven-dried leaves (Table 1). The loss of β-carotene were 22% in frozen, 30% in air-dried, and 71% in oven-dried samples.

Chlorophyll

The fresh and the frozen curry leaves had similar chlorophyll concentrations (Table 1). Oven-drying resulted in a greater loss (~64%) of chlorophyll compared to air-drying (~32%).

DISCUSSION

Our results report a lower loss of β-carotene and apparently no loss of α-tocopherol and chlorophyll concentration in curry leaf frozen at –15°C compared to air-drying or oven-drying. However, the loss of lutein in the frozen samples was higher perhaps due to destruction of lutein during the freezing process. The loss of β-carotene, α-tocopherol, and chlorophyll when air-dried or oven-dried may be attributed to loss of these compounds due to oxidation. Our results identify freezing at –15°C as an acceptable practical way of storing curry leaves. Air-drying resulted in higher retention of vitamins β-carotene and α-tocopherol compared to oven-drying.

LEMONGRASS

Family: Poaceae (Gramineae), *Cymbopogon* species

Source: Simon, J.E., A.F. Chadwick and L.E. Craker. 1984. Herbs: An Indexed Bibliography. 1971-1980. The Scientific Literature on Selected Herbs, and Aromatic and Medicinal Plants of the Temperate Zone. Archon Books, 770 pp., Hamden, CT.

Lemongrass, a perennial herb widely cultivated in the tropics and subtropics, designates two different species, East Indian, *Cymbopogon flexuosus* (DC.) Stapf., and West Indian, *Cymbopogon citratus* (DC. ex Nees) Stapf. East Indian lemongrass, also known as cochin or Malabar grass is native to India, while West Indian lemongrass is native to southern India and Ceylon. The lemongrasses are cultivated commercially in Guatemala, India, the People's Republic of China, Paraguay, England, Sri Lanka, and other parts of Indochina, Africa, Central America, and South America (11.1-73). The plant grows in dense clumps up to 2 meters in diameter and has leaves up to 1 meter long.

The reported life zone for lemongrass is 18 to 29 degrees centigrade with an annual precipitation of 0.7 to 4.1 meters with a soil pH of 5.0 to 5.8 (East Indian) or 4.3 to 8.4 (West Indian) (14.1-9). The plants need a warm, humid climate in full sun. They grow well in sandy soils with adequate drainage. Since the plants rarely flower or set seed, propagation is by root or plant division. The plants are harvested mechanically or by hand about four times each year with the productive populations lasting between four and eight years (14.1-9). Extensive breeding programs have developed many varieties of lemongrass.

The quality of lemongrass oil is generally determined by the content of citral, the aldehyde responsible for the lemon odor. Some other constituents of the essential oils are -terpineol, myrcene, citronellol, methyl heptenone, dipentene, geraniol, limonene, nerol, and farnesol (14.1-9). West Indian oil differs from East Indian oil in that it is less soluble in 70 percent alcohol and has a slightly lower citral content (14.1-9).

Lemongrass is used in herbal teas and other nonalcoholic beverages in baked goods, and in confections. Oil from lemongrass is widely used as a fragrance in perfumes and cosmetics, such as soaps and creams. Citral, extracted from the oil, is used in flavoring soft drinks in scenting soaps and detergents, as a fragrance in perfumes and cosmetics, and as a mask for disagreeable odors in several industrial products. Citral is also used in the synthesis of ionones used in perfumes and cosmetics (11.1-73, 14.1-9).

As a medicinal plant, lemongrass has been considered a carminative and insect repellent. West Indian lemongrass is reported to have antimicrobial activity (1.8-84, 1.8-130). Oil of West Indian lemongrass acts as a central nervous system depressant (7.6-187). Oil of East Indian lemongrass has antifungal activity (1.8-132). The volatile oils may also have some pesticide and mutagenic activities (11.1-96, 11.1-136).

Cymbopogon nardus is a source of citronella oil. *Cymbopogon martinii* is reportedly toxic to fungi (1.8-53).

Lemongrass is generally recognized as safe for human consumption as a plant extract/essential oil (21 CFR section 182.20 [1982]).

Scientific name: *Cyperus rotundus* L. syn. *C. hexastachyos* Rottb.
Family: Cyperaceae
English Name: Nut Grass
Common Indian Names
Gujarati: Motha
Hindi: Motha, Mutha
Canarese: Koranarigadde, Tungegaddo, Tungehullu
Marathi: Bimbal, Nagarmotha, Motha
Sanskrit: Bhadramusta, Granthi, Kachhda, Mustako, Sugandhi-granthila
Tamil: Korai
Telugu: Tungagaddi

Botanical Description: A perennial, stolaniferous, rhizomatus, halophytic sedge. Rhizome many, slender; Tuber-white, succulent when young, hard and black when mature; stem-leafy at base arising from a tuber. Culm-dark green, glabrous. Leaf dark green above, with reddish brown sheaths, clustered at the base of stem. Inflorescence 3-9 spreading rays bearing tassels of few, large spikelets; spikelet 20-40 flowered, red brown to almost black. Fruit oblong ovate.

Useful Parts: Tubers

Medicinal Uses: According to the Ayurveda, root is pungent, acrid, cooling, astringent, appetizer, stomachic, anthelmintic and useful in treatment of leprosy, thirst, fever, blood diseases, biliousness, dysentery, pruritis, pain, vomiting, epilepsy, opthalmia, erysipelas etc. According to the Unani system of medicine, the root is diuretic, emmenagogue, diaphoretic, anthelmintic, vulnerary and useful for ulcers and sores, fevers, dyspepsia, urinary concretions etc.

Other Uses
Useful in checking soil erosion.
The tuber yields an essential oil (0.5-0.9%), which is used in perfumery and incense.

Cyperus papyrus L.

Cyperaceae
Papyrus

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Very important in ancient Egypt (as early as 2,400 BC), papyrus was used for food, medicine, fiber and shelter. According to Tackholm and Drar (1973), Egyptians have used papyrus additionally for formal bouquets funeral garlands, boats, cordage, fans, sandals, mattings corkage, boxes, and paper. It was one of the most favorite plants of Ancient Egypt. The pith of papyrus was recommended for food, while the starchy rhizomes and lowermost parts of the stem were cut off and consumed raw, boiled or roasted. They were also chewn, sucked, and spit out, much as sugar cane is done today. Papyrus was also a favorite ornament in ancient art and craft. Umbel impressions were often used as handles for mirrors, fans, doors, chairs and various household furniture. Papyrus stems were used for caulking seams in wooden ships. Papyrus mats are used for making fences and huts. For paper, the ancients stripped the fibrous coverings off the stem, and slit the inner pith into waferlike strips. Laid side by side, with others placed crosswise on top, the strips were dampened, pressed, so the glue-like sap cemented them together, and dried into a sheet. (NAS, 1976)

Folk Medicine

Galen, Dioscorides and later Islamic pharmacologists, e.g. Ibn Gulgul and El Ghafiqi, included papyrus among medicinal plants. The pith was recommended for widening and drying of fistula. The main use, anyhow, seems to have been confined to burnt papyrus sheets, the ash of which was reputed to have the action of pulverised charcoal and used for certain eye diseases. Dioscorides (in 78 AD) writes that its ash checks malignant ulcers from spreading in the mouth or elsewhere. Galen (129-200 AD) says that the plant is not used in a raw state but if macerated in vinegar and burnt, the ash heals wounds. Europeans also list this among their folk cancer cures.

Chemistry

Glucose, fructose, unreduced polysaccharides and xylan are (List and Horhammer, 1969-1979). A sample of the stems of papyrus representing the new growth of 1917 was forwarded to the Imperial Institute, London, by the Ministry of Agriculture next year. The Institute reported that the results of the investigation indicated that these stems only furnish a moderate yield of pulp of fair quality which contained a quantity of parenchyma and was rather difficult to bleach. Pulp suitable for brown paper was prepared from the stems by mild treatment, but only cream-colored paper could be produced by treating the stems under more drastic conditions similar to those employed technically for the manufacture of white paper.

Description

Tall, robust, leafless aquatic, up to 4 m high. Culms stout, smooth, trigonous, surrounded at base with coriaceous, large acuminate sheaths. Umbel-rays numerous, filiform, 10-45 cm long, each surrounded at base with a narrow, brown, cylindrical sheath, up to 3 cm long. Secondary umbels 3-5-rayed, supported by narrow, elongated bracts. Spike 1-2 cm long, 6-10 mm broad. Spikelets 6-10 mm long, 1 mm broad, 6-16-flowered.

Germplasm

The plant cultivated in Egypt belongs to the subsp. *antiquorum* (Willd.) Chiov. It differs from the type by its lax, shortly peduncled spikes, also by the connective which is not or hardly exserted above the anther halves (in type producing a point 1-3 times as long as the breadth of the anther). ($2n$ = ca 102)

Distribution

The papyrus reeds form vast stands in swamps, in shallow lakes, and along stream banks throughout Africa. It is considered a weed in the Sudan, Dahomey and Egypt. Uganda has ca 6,500 km^2 of permanent swamp or wetlands, much of it covered in papyrus. Occurs also in Sicily and Palestine. According to Baumann (1960) the plant grows over a wide area bounded roughly by the

38th and 26th parallels on the north and south, and by the 65th and 32nd on the east and west, but is virtually absent in the lower Nile marshes where it flourished in ancient times.

Ecology

Many African swamps known as the Sudd in Central Africa, are dominated by papyrus thickets, which totally block navigation. It is estimated that the Sudd areas of the White Nile, and the "Papyrus Swamps" around Lake Kioga and Victoria are responsible for the loss of 50% of that river's water through evaporation and plant transpiration. Engineers plan to shortcut the Sudd and hence increase Egypt's summer water supply. In Egypt the plant flowers throughout the year, except winter. Papyrus is estimated to range from Subtropical to Tropical Desert to Wet Forest Life Zones, tolerating annual precipitation of 1-42 dm, annual temperatures of 20-30°C, and pH of 6.0-8.5.

Cultivation

Propagation is done in Egypt by rootstock divisions any time in spring and summer. It is recorded, however, to produce fertile seeds under our climatic conditions. In Egypt, it is sufficient to keep seed pots under boxes covered with glass to obtain the required result. Seedlings can be raised from seed. No escape seedlings, however, have been found in Egypt, and it is said that under the most favorable conditions seeds do not germinate without the intervention of man. The rootstock should remain submerged under water, especially during summer, or at least, the soil must be kept sufficiently moist during the growing season to obtain a remunerative crop of fairly thick and long shoots. Plants grown in ordinary field beds are weaker than those grown in deeper channels at the same garden.

Harvesting

No data available.

Yields and Economics

A C4 plant, this species has reported to produce above-ground biomass of 30-50 MT/ha/yr, highest of ten emergent species studied by Kresovich et al. (1981), and higher than the 15-33 MT they report for corn and sweet sorghum. They estimate, in 1979 dollars, the costs of cultivating such emergents as $70-580/ha for planting 138-297 for crop maintenance, 37-199 for harvesting, and 55-234/ha for drying and densification.

Energy

Since early this century, Egypt has devoted great effort to clear the swamp vegetation which could, of course, be converted to an energy resource. Cleared channels are blocked again with the vegetation. Still harvesting papyrus for commercial use is seldom seriously considered, Westlake (1963) reports standing DM biomass as high as 70 MT/ha.

Biotic Factors

No data available.

Cyphomandra betacea (Cav.) Sendt.

syn. *Solanum betaceum* Cav.

Solanaceae

Tamarillo, Tomarillo, Tree tomato, Palo de tomate, Tomate de arbol

NewCROP has Tamarillo - Tree tomato information at:

Tree Tomato—Julia Morton, Fruits of Warm Climates

New Horticultural Crops in New Zealand—Errol W. Hewett

Neglected Crops: 1492 from a Different Perspective—J.E. Hernándo Bermejo and J. León (eds.)

"New" Solanums—Charles Heiser and Gregory Anderson

Magness J.R. et al. 1971. Food and feed crops of the United States.

Outside links:

Tamarillo can be found in Lost Crops of the Incas from National Academy Press

TREE TOMATO "FRUIT FACTS" (Fruit Facts are a series of publications of the California Rare Fruit Growers, Inc. that contain information on individual fruits, including botanical identification, description and culture notes based on California research, and characteristics of cultivars).

Tamarillo info from the Department of Food and Agriculture, California.

Fruit nutritional information from Freida's Inc.

There are about 30 *Cyphomandra* species from the American tropics. Other *Cyphomandra* species sometimes cultivated are:

- *Cyphomandra casana* - Casana
- *C. crassifolia* - Mountain tomato
- *C. fragrans* - Guava tamarillo

Ladyslipper

(1) *Cypripedium pubescens* Willd.; (2) *C. parviflorum* Salisb.

Figure 71.—Common yellow ladyslipper (*Cypripedium pubescens*)

Other common names.—(1) Common yellow ladyslipper, large yellow ladyslipper, yellow ladyslipper, yellow moccasin flower, Venus's-shoe, Venus's-cup, yellow Indian shoe, American valerian, nerveroot, male nervine, yellow Noah's-ark, yellows, monkeyflower, umbil-root, yellow umbil; (2) small yellow ladyslipper.

Habitat and range.—Both of these species frequent bogs and wet places in deep shady woods and thickets. The large yellow ladyslipper may be found from Nova Scotia south to Alabama and west to Nebraska and Missouri. The range for the small yellow ladyslipper extends from Newfoundland south along the mountains to Georgia and west to Missouri, Washington, and British Columbia.

Description.—These plants are readily recognized by the peculiar shape of their flowers. These appear in May and June, are very showy, and have a curiously formed lip which resembles an inflated bag, pale or bright yellow in color, variously striped or blotched with purple. In Cypripedium pubescens this lip is 1 to 2 inches in length, while in C. parviflorum it is smaller and somewhat more prominently striped. Both species grow from 1 to 2 feet in height and have rather large leaves from 2 to 6 inches long and from 1 to 3 inches wide, with numerous parallel veins. The rootstock is horizontal, crooked, and fleshy with numerous fibrous roots. It has a heavy disagreeable odor and a sweetish, bitter, and somewhat pungent taste.

Part used.—The rootstock and roots, collected in autumn.

Dalbergia sissoo Roxb. ex DC.

Fabaceae
Sisu, Sissoo, Indian rosewood

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Timber tree, the young branches and foliage eaten by livestock. After teak, it is the most important cultivated timber tree in India, planted on roadsides, and as a shade tree for tea plantations. Sissoo makes first class cabinetry and furniture. It is used for plywood, agricultural, and musical instruments, skis, carvings, boats, floorings, etc. The leaves are used for fodder. In the U.S. (Arizona, Florida) it is said to be one of the most desirable shade trees for streets and backyards. It is grown in the sewage-irrigated greenbelt arount Khartoum, Sudan.

Folk Medicine

Reported to be stimulant, sissoo is a folk remedy for excoriations, gonorrhea, and skin ailments (Duke and Wain, 1981). Ayurvedics prescribe the leaf juice for eye ailments, considering the wood and bark abortifacient, anthelmintic, antipyretic, apertif, aphrodisiac, expectorant, and refrigerant.

They use the wood and bark for anal disorders, blood diseases, burning sensations, dysentery, dyspepsia, leucoderma, and skin ailments. Yunani use the wood for blood disorders, burning sensations, eye and nose disorders, scabies, scalding urine, stomach problems, and syphilis. The alterative wood is used in India for boils, eruptions, leprosy and nausea (Kirtikar and Basu, 1975).

Chemistry

Per 100 g, the leaves contain on a zero-moisture basis 12.6-24.1 g protein, 2.0-4.9 g fat, 42.1-54.8 g N-free extract, 12.5-26.1 g fiber, 6.6-12.0 g ash, 840-2870 mg Ca, 120-420 mg P. On a dry basis, the silage contain 14.0% CP 3.6% EE, 30.0% CF, and 34.1% NFE. Fresh leaves from Nigeria contained (ZMB) 21.8% CP, 15.6 g CF, 8.7 g ash, 3.6 g EE, 50.3 g NFE, 1,180 mg Ca, and 250 mg P per 100 g (Gohl, 1981). Pods contain 2% tannin.

Description

Tree 15-35 m tall, deciduous, the sometimes >2m, the clearbole up to 12 m, more often with crooked trunk and light crown. Leaves alternate, imparipinnate, the leaflets 3-5, alternate, orbicular, abruptly acuminate, puberulous but glabrescent, 3.5-6.5 cm long, not quite so broad. Flowers sessile, or short-stalked in axillary panicles shorter than the leaves. Sepals 4-5 mm long, pubescent, the lobes short. Petals yellow, 6-8 mm long. Ovary pubescent; ovules 2-4. Pods to 10 cm long, 1.5 cm broad, the stipe longer than the calyx. Seeds 1-4.

Germplasm

Reported from the Hindustani Center of Diversity, sissoo, or cvs thereof, is reported to tolerate disease, drought, frost, insects, porous soils, salt, sand, savanna, sewage, and wind. On clay soils the growth is stunted. ($2n = 20$)

Distribution

Indigenous to India, Nepal, and Pakistan, the tree is now widely planted in the tropics. Said to be escaping from cultivation in tropical Florida. It is grown at Cayey, El Verde, and Guayabol in Puerto Rico.

Ecology

Ranging from sealevel to >1500 m, it can stand temperatures from below freezing to nearly 50°C. Apparently adapted to savanna woodlands where annual rainfall is 7-20 dm with droughts of 3-4 months duration (NAS, 1979). Sometimes gregarious in alluvial forests along the rivers of the subhimalayan tract (C.S.I.R., 1948-1976). Ranging from Subtropical Thorn to Moist through Tropical Dry to Moist Forest Life Zones, sissoo is expected to tolerate annual precipitation of 6 to 40 dm, annual temperature of 21 to 28°C, and pH of 6-8.

Cultivation

Directly sown seed attain 15-25 cm after the first rains, 90-120 cm after the second rains in India. For seedling transplantation, only tender plants with small taproots should be used. Root suckers transplant satisfactorily in dry climates. Planting should be in spring (March in India). Raising of monocultural sissoo is discouraged. Stump planting is widely employed in irrigated plantations in India. Trenches are dug ca 1.5 m apart, earth thrown a little away from the trenches and the berms used for sowing seed or pod segments. Sowing is done on both sides of the trenches, between middle March and middle June, earlier sowing being preferred. Plants are big enough by the beginning of the next season to yield stumps. Plants are pulled out and stems and roots chopped off leaving 3-5 cm of the former and 22-35 m of the latter; ther lateral roots are also removed. Stumps thicker than 2.5 cm and thinner than 2 cm diam. at the collar are rejected. The yield of stumps is 160,000 per ha. For transport over long distances, stumps are made into bundles, wrapped in leaves or grass, sprinkled with water, and carried in gunny bags. Stumps are planted in spring, not earlier than the third week of March, perhaps April. In no case should it be put off to August. Where subsoil water is low or rainfall poor and uncertain, irrigation is essential. Stumps are planted along trenches or on berms of pits and the field is irrigated. Shallow and frequent irrigation or constant flooding is harmful and induces superficial root formation. Depending upon the weather and the condition of plants, 10-15 irrigations are adequate in the first season and 4-6 in the second. Under proper irrigation, sissoo roots tap the subsoil water within 2 years. Irrigation in later years is required only for supplementing subsoil water supplies.

Harvesting

Trees may be grazed or cut as needed. Young trees coppice vigorously and reproduce vigorously from suckers.

Yields and Economics

According to the Wealth of India, irrigated plantations yield fair quantities of timber and high returns of fuel. In irrigated plantations trees may attain a girth of 1.2 m in ca 25 years. A height of 7 m has been reported in 20 months. Based on studies of 40 natural riverine sites, it was concluded that 10 year stands yield about 10 m^3/ha, 20 year ca 100 m^3/ha (5m^3/ha/yr), 30 year old stands ca 210 m^3/ha (7 m^3/ha/yr), 40 year old stands ca 2 80 m^3/ha (7 m^3/ha/yr), 50 year old stands 370 m^3/ha (7.5 m^3/ha/yr), and 60 year old stands 460 m^3/ha (ca 7.5 m^3ha/yr) (C.S.I.R., 1948-1976). Pakistan has more than 100,000 ha of sissoo plantation.

Energy

The calorific value of the sapwood is 4,908 calories or 8,835 Btu, the heartwood 5,191 calories or 9,326 Btu (probably per cu. ft., but not specified in WOI). The wood is an excellent fuel, eminently suitable for making charcoal. Heartwood yields 5.35% of an oil which, on cooling, approaches the texture of vaseline. It is suitable as a lubricant for heavy machinery.

Biotic Factors

Roots are said to be so astringent as not to be eaten by ants or rodents, at least rats. Browne (1968) lists: Fungi. *Auricularia auricula-judae, Colletoglocum sissoo, Diplodia dalbergiae, Fomes durissimus, Fomes robiniae, Fusarium oxysporum, Ganoderma applanatum, Ganoderma lucidum, Hypoxylon hypomiltum, Hypoxylon investiens, Hypoxylon rubiginosum, Irpex flavus, Marasmius equierinis, Maravalia achroa, Meliola bicornis, Mycosphaerella dalbergiae, Nectria haematococca, Phellinus gilvus, Phyllachora dalbergiae, Phyllachora spissa, Phyllactinia guttata, Phyllosticta sissoo, Polysporus anebus, Poria ambigua, Rosellinia aquila, Schizophyllum commune, Thanatephorus cucumeris, Trametes corrugata, Uredo sissoo.* Angiospermae. *Cuscuta reflexa, Dendrophthoe falcata, Loranthus pulverulentus, Tapinanthus dodoneifolius, Tapinanthus* sp., *Tolypanthus involucratus.* Coleoptera. *Adoretus caliginosus, Amblyrrhinus poricollis, Anomala dalbergiae, Apate monachus, Apate terebrans, Apoderus blandus, Apoderus sissu, Aulacophora foveicollis, Batocera rufomaculata, Bruchus pisorum, Dorysthenes hugeli, Gonocephalum depressum, Halyzia sanscrita, Illeis cincta, Mimastra cyanura, Myllocerus blandus, Myllocerus cardoni, Myllocerus discolor, Myllocerus lefroyi, Myllocerus sabulosus, Myllocerus setulifer, Myllocerus transmarinus, Myllocerus undecimpustulatus, Perissus dalbergiae, Platymycterus sjoestedti, Rhinyptia indica, Sinoxylon anale, Tanymecus hispidus.* Hemiptera. *Acaudaleyrodes rachipora, Aleurolobus marlatti, Aonidiella orientalis, Aspidoproctus bifurcatus, Atelocera stictica, Dialeuropora decempuncta, Drosicha dalbergiae, Drosicha mangiferae, Drosicha octocaudata, Drosicha stebbingi, Gargara mixta, Gargara varicolor, Hemaspidoproctus cinerea, Hemiberlesia lataniae, Kerria lacca, Myzus persicae, Nipaecoccus vastator, Oxyrhachis formidabilis, Oxyrhachis mangiferana, Toxoptera aurantii.* Isoptera. *Bifiditermes beesoni*. Lepidoptera. *Anomis sabulifera, Archips micaceanus, Ascotis selenaria, Bucculatrix mendax, Buzura suppressaria, Caloptilia tetratypa, Charaxes fabius, Cladobrostis melitricha, Cusiala raptaria, Cydia jaculatrix, Dasychira dalbergiae, Dasychira mendosa, Dichomeris eridantis, Eresia hylas, Euproctis scintillans, Euproctis sulphurescens, Euproctis virguncula, Hamodes propitia, Heliothis zea, Hypena iconicalis, Hypoglaucitis benenotata, Hyposidra talaca, Leucoptera stenograpta, Pandesma anysa, Philodoria laeta, Plecoptera ferrilineata, Plecoptera reflexa, Sataspes scotti, Thosea cana, Trichoplusia orichalcea*. Orthoptera. *Brachytrupes portentosus, Chrotogonus* spp., *Gymnogryllus erythrocephalus, Gymnogryllus humeralis, Kraussaria angulifera, Schistocerca gregaria*. Mammalia. *Bos taurus, Ovis aries, Presbytis entellus.* Nematoda. *Meloidogyne javanica*. The tree is sometimes killed by mistletoe. Fusarium wilt is often fatal in India, especially in monoculture, or in polyculture with other susceptible species (C.S.I.R., 1948-1976).

Dallisgrass

Gramineae *Paspalum dilatatum* Poir.

Source: Magness et al. 1971

This is a major pasture grass in the Cotton Belt. It was introduced from South America around 1875. It is an upright-growing bunchgrass, which requires moist soil. It is not hardy north of the Cotton Belt. It does not form a dense sod, so is well suited to mixed planting with legumes or other grasses. It is palatable and nutritious. It tolerates fairly close grazing, and should be grazed to prevent accumulation of dead leaves and stems. It is susceptible to ergot fungus which is poisonous to livestock.

Solanaceae

NewCROP has the following information:

Jimson weed —A.F. Seivers, The Herb Hunters Guide

Datura or Dhattura, *Datura stramonium* L.—Pankaj Oudhia

Pongamia pinnata (L.) Pierre

Syn.: *Pongamia glabra* Vent.
Derris indica Bennet
Fabaceae
Pongam, Indian beech

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

The pongam tree is cultivated for two purposes: (1) as an ornamental in gardens and along avenues and roadsides, for its fragrant Wisteria-like flowers, and (2) as a host plant for lac insects. It is appreciated as an ornamental throughout coastal India and all of Polynesia. Well-decomposed flowers are used by gardeners as compost for plants requiring rich nutrients. In the Philippines the bark is used for making strings and ropes. The bark also yields a black gum that is used to treat wounds caused by poisonous fish. In wet areas of the tropics the leaves serve as green manure and as fodder. The black malodorous roots contain a potent fish-stupefying principle. In primitive areas of Malaysia and India root extracts are applied to abscesses; other plant parts, especially crushed seeds and leaves are regarded as having antiseptic properties. The seeds contain pongam oil, a bitter, red brown, thick, non-drying, nonedible oil, 27–36% by weight, which is used for tanning leather, soap, as a liniment to treat scabies, herpes, and rheumatism and as an illuminating oil

(Burkill, 1966). Also used for lubrication and indigenous medicine. Pongam oil showed inhibitory effects on *Bacillus anthracis, Bacillus mycoides, Bacillus pulilus, Escherichia coli, Pseudomonas mangiferae, Salmonella typhi, Sarcina lutea*, *Staphylococcus albus*, *Staphylococcus aureus*, and *Xanthomonas campestris*, but did not inhibit *Shigella* sp. (Chaurasia and Jain, 1978). The oil has a high content of triglycerides, and its disagreeable taste and odor are due to bitter flavonoid constituents, pongamiin and karanjin. The wood is yellowish white, coarse, hard, and beautifully grained, but is not durable. Use of the wood is limited to cabinetmaking, cart wheels, posts, and fuel (Allen and Allen, 1981). Both the oil and residues are toxic. Still the presscake is described as a "useful poultry feed." Seeds are used to poison fish. Still it is recommended as a shade tree for pastures and windbreak for tea. The leaves are said to be a valuable lactagogue fodder, especially in arid regions. It is sometimes intercropped with pasture, the pasture grasses said to grow well in its shade (NAS, 1980a). Dried pongam leaves are used in stored grains to repel insects. Leaves often plowed green manure, thought to reduce nematode infestations. Its into ground as spreading roots make it valuable for checking erosion and stabilizing dunes. Twigs are used as a chewstick for cleaning the teeth. The ash of the wood is used in dyeing.

Folk Medicine

According to Hartwell (1967–1971), the fruits and sprouts are used in folk remedies for abdominal tumors in India, the seeds for keloid tumors in Sri Lanka, and a powder derived from the plant for tumors in Vietnam. In sanskritic India, seeds were used for skin ailments. Today the oil is used as a liniment for rheumatism. Leaves are active against *Micrococcus*; their juice is used for colds, coughs, diarrhea, dyspepsia, flatulence, gonorrhea, and leprosy. Roots are used for cleaning gums, teeth, and ulcers. Bark is used internally for bleeding piles. Juices from the plant, as well as the oil, are antiseptic. It is said to be an excellent remedy for itch, herpes, and pityriasis versicolor. Powdered seeds are valued as a febrifuge, tonic and in bronchitis and whooping cough. Flowers are used for diabetes. Bark has been used for beriberi. Juice of the root is used for cleansing foul ulcers and closing fistulous sores. Young shoots have been recommended for rheumatism. Ayurvedic medicine described the root and bark as alexipharmic, anthelmintic, and useful in abdominal enlargement, ascites, biliousness, diseases of the eye, skin, and vagina, itch, piles, splenomegaly, tumors, ulcers, and wounds; the sprouts, considered alexeteric, anthelmintic, apertif, and stomachic, for inflammation, piles and skin diseases; the leaves, anthelmintic, digestive, and laxative, for inflammations, piles and wounds; the flowers for biliousness and diabetes; the fruit and seed for keratitis, piles, urinary discharges, and diseases of the brain, eye, head, and skin, the oil for biliousness, eye ailments, itch, leucoderma, rheumatism, skin diseases, worms, and wounds. Yunani use the ash to strengthen the teeth, the seed, carminative and depurative, for chest complaints, chronic fevers, earache, hydrocele, and lumbago; the oil, styptic and vermifuge, for fever, hepatalgia, leprosy, lumbago, piles, scabies, and ulcers.

Chemistry

Reported to contain alkaloids demethoxy-kanugin, gamatay, glabrin, glabrosaponin, kaempferol, kanjone, kanugin, karangin, neoglabrin, pinnatin, pongamol, pongapin, quercitin, saponin, β-sitosterol, and tannin. Air-dry kernels have 19.0% moisture, 27.5% fatty oil, 17.4% protein, 6.6% starch, 7.3% crude fiber, and 2.4% ash. Fatty acid composition: palmitic, 3.7–7.9%, stearic 2.4–8.9, arachidic 2.2–4.7, behenic 4.2–5.3, lignoceric 1.1–3.5, oleic, 44.5–71.3, linoleic 10.8–18.3, and eicosenoic 9.5–12.4%. Destructive distillation of the wood yields, on a dry weight basis: charcoal 31.0%, pyroligneous acid 36.69, acid 4.3%, ester 3.4%, acetone 1.9%, methanol 1.1%, tar 9.0%, pitch and losses 4.4%, and gas 0.12 cu m/kg. Manurial values of leaves and twigs are respectively: nitrogen 1.16, 0.71; phosphorus (P_2O_5), 0.14, 0.11; potash (K_2O), 0.49, 0.62; and lime (CaO), 1.54, 1.58%. Such manure reduces the incidence of *Meloidogyne javanica*.

Description

Fast growing, glabrous, deciduous, tree to ca 25 m tall, branchesdrooping; trunk diameter to 60 cm; bark smooth, gray. Leaves imparipinnate, shiny; young leaves pinkish red, mature leaves glossy, deep green; leaflets 5–9, the terminal leaflet larger than the others; stipels none; stipules caducous. Flowers fragrant, white to pinkish, paired along rachis in axillary, pendent, long racemes or panicles; calyx campanulate or cup-shaped, truncate, short-dentate, lowermost lobe sometimes longer; standard suborbicular, broad, usually with 2 inflexed, basal ears, thinly silky-haired outside; wings oblique, long, somewhat adherent to the obtuse keel; keel petals coherent at apex; stamens monadelphous, vexillary stamen free at the base but joined with others into a closed tube; ovary subsessile to short-stalked, pubescent; ovules 2, rarely 3; style filiform, upper half incurved, glabrous; stigma small, terminal. Pod short stalked, oblique-oblong, flat, smooth, thickly leathery to subwoody, indehiscent, 1-seeded; seed thick, reniform (Allen and Allen, 1981).

Germplasm

Reported from the Hindustani Center of Diversity, pongam, or cvs thereof, is reported to tolerate drought, frost, heat, limestone, salinity, sand, and shade. ($2n$ = 22)

Distribution

An Indomalaysian species, a medium-sized subevergreen tree, common on alluvial and coastal situations from India to Fiji, from sealevel to 1200 m. Now found in Australia, Florida, Hawaii, India, Malaysia, Oceania, Philippines, and Seychelles, for example.

Ecology

Probably ranges from Tropical Dry to Moist through Subtropical Dry to Moist Forest Life Zones. Withstanding temperatures slightly below 0°C to 50°C and annual rainfall of 5–25 dm, the tree grows wild on sandy and rocky soils, including oolitic limestone, but will grow in most soil types, even with its roots in salt water.

Cultivation

Seeds, remaining viable for sometime, require no special scarification. Direct sowing is usually successful. Seedlings transplant easily from the nursery after about a year. Root suckers are rather plentiful as well. It is a rapid-growing coppice species that can be cloned.

Harvesting

Pods are collected and shells removed by hand. Grown in 30-year rotations for fuel in West Bengal.

Yields and Economics

Trees of ten reach adult height in 4 or 5 years, bearing at the age of 4–7 years. A single tree is said to yield 9–90 kg seed per tree, indicating a yield potential of 900—9000 kg seed/ha, 25% of which might be rendered as oil (assuming 100 trees/ha). In general, Indian mills extract 24–27.5% oil, village crushers, 18–22% oil.

Energy

Wherever it is grown, the wood (calorific value 4,600 kcal/kg) is burned for cooking fuel (NAS, 1980a). The thick oil from the seeds is used for illumination, as a kerosene substitute, and lubrication. It would seem that with upgraded germplasm one could target for 2 MT oil and 5 MT firewood per hectare per year on a renewable basis. The oil has been tried as fuel in diesel engines, showing a good thermal efficiency (C.S.I.R., 1948–1976).

Biotic Factors

Two rhizobial strains produced nodules on 18 species of 12 different genera in the cowpea miscellany. The strains, culturally and physiologically typical of slow-growing rhizobia, elicited ineffective responses on *Clitoria ternatea* and *Stizolobium utile*. One was ineffective on *Lespedeza stipulacea* and *Samanea saman*. Browne (1968) lists: Viruses. Sandal Spike Virus. Fungi. *Fusicladium pongamiae, Ganoderma lucidum, Phyllachora pongamiae, Ravenelia hobsoni, Ravenelia stictica.* Angiospermae. *Cuscuta reflexa, Loranthus* sp. (?). Wild Yam

Dioscorea villosa L.

Figure 120.—Wild yam (*Dioscorea villosa*)

Synonym.—*Dioscorea paniculata* Michx.

Other common names.—Dioscorea, colicroot, rheumatism root, devil's-bones.

Habitat and range.—Wild yam grows in moist thickets, trailing over adjacent shrubs and bushes, its range extending from Rhode Island to Minnesota and south to Florida and Texas. It is most common in the central and southern portions of the United States.

Description.—The wild yam is a vine growing to a length of 15 feet with a smooth stem and heart-shaped leaves from 2 to 6 inches long and 1 to 4 inches wide, hairy on the under side, borne on long, slender stems. The small, greenish-yellow flowers are produced from June to July, the male flowers being borne in drooping clusters about 3 to 6 inches long and the female flowers in drooping, spikelike heads. The fruit, which is a yellowish-green 3-lobed capsule, ripens in September and remains on the vine for some time during the winter. The rootstock runs horizontally underneath the surface of the ground. It is only about one-fourth to one-half inch in diameter.

Part used.—The rootstock, generally collected in autumn.

Diplotaxis tenuifolia (L.) DC.

Diplotaxis muralis (L.) DC.

Brassicaceae = Cruciferae

Arrugula, Rocket, Roquette, Rucola, Rughetta

Two species along with *Eruca sativa* known under the collective name Arrugula, Rocket, Roquette, Rucoloa, Rughetta.

We have information from several sources:

Arugula: A Promising Specialty Leaf Vegetable—Mario Morales and Jules Janick

---

Outside links:

Rocket: A Mediterranean Crop For The World from the International Plant Genetic Resources Institute

Diplotaxis tenuifolia (L.) DC.: a diploid and perennial species, in the sense that the roots can survive winters and produce new sprouts in the next spring; it flowers from late spring to autumn and its seeds are generally ready for collecting in autumn. It seems to be very well adapted to harsh and poor soils, and often it can compete well with other species in calcareous shallow soils. This species has succulent leaves and is much apprciated in cuisine. In some Italian areas *D. tenuifolia* is also cultivated, but it is mostly collected from the wild and sold in small bunches in local markets.

Diplotaxis muralis (L.) DC.: polyploid and perennial, in the same sense as *D. tenuifolia*. It flowers from summer to autumn and its seeds are ready for sollecting in autumn. It grows in similar habitats as *D. tenuifolia* and is also collected from the wild to be sold in the markets. It seems less adapted to cultivation because of its procumbent growth habit, which is the main character distinguishing it from*D. tenuifolia*.

Tonka bean oil

Leguminosae *Dipteryx odorata* (Aubl.) Willd.

Source: Magness et al. 1971

The oil is obtained from the seed of the above species, a tree native to Central and South America, but now cultivated to some extent in other tropical areas. The fruit is a pod about 2 inches long, containing a single fragrant seed. The seed after curing is used chiefly for scenting tobacco and snuff. The non-drying oil is used in flavoring.

DITTANY OF CRETE

Family: Lamiaceae (Labiatae), *Origanum dictamnus* L.

Source: Simon, J.E., A.F. Chadwick and L.E. Craker. 1984. Herbs: An Indexed Bibliography. 1971-1980. The Scientific Literature on Selected Herbs, and Aromatic and Medicinal Plants of the Temperate Zone. Archon Books, 770 pp., Hamden, CT.

Dittany of Crete, *Origanum dictamnus* L. (formerly *Amaracus dictamnus* Benth. or *Amaracus tomentosus* Moench.), is one of the best-known healing herbs of folklore. Native to the mountains of Crete and also called dittany or dictamnus, this perennial plant can reach a height of 0.3 meters. Procumbent white, woolly stems, usually trailing, develop pink or purplish flowers in the summer. The small gray leaves have a velvety texture.

Of minor importance today, dittany of Crete is primarily used as a potted plant or as an ornamental plant in garden borders. The flowers have been used in herbal teas, but the plant has no culinary value. As a medicinal plant, the herb has been utilized to heal wounds, soothe pain, cure snake bites, and ease childbirth. In addition, it has been used as a renedy against gastric or stomach ailments and rheumatism.

Dictamnus albus L. (*Dictamnus fraxinella* Pers.), known as dittany and fraxinella, is often confused with dittany of Crete. This perennial plant is of the Rutaceae family and reaches a height of approximately one meter. Grown as a garden plant with showy pink, purple or white flowers, its dried leaves can be used in teas. The plant has been used medicinally as a diuretic, emmenagogue, and expectorant. However, the seed pods can cause contact dermatitis. The plant is known as the gas plant because it will often give a burst of flame when a lighted match is held beneath the flower cluster (14.1-3).

Cunila origanoides Britt. is called dittany, Maryland dittany, and stone-mint. This low-growing perennial with a minty flavor is native to the eastern United States. The plant, which has been classified as *Satureja origanoides* L. and *Cunila mariana* L., is primarily used as an ornamental border in gardens, although the leaves may be used in herbal teas.

Dittany of Crete is generally recognized as safe for human consumption as a natural flavoring (21 CFR section 172.510 [1982]).

Dock

Spinach dock, Herb patience

Polygonaceae *Rumex patientia* L.

Source: Magness et al. 1971

Spinach dock is a strong growing perennial, reaching 5 feet when in flower. Rosette leaves are 8 to 12 inches long, tapering at both ends. Stem leaves are rounded at the base. Leaves are used as greens, especially leaves which develop in early spring. Leaf exposure is similar to that of spinach.

Season, seed to harvest: 4 to 5 months. Leaves available in early spring from established roots.

Production in U.S.: No data. Negligible.

Use: Pot herb greens.

Part of plant consumed: Leaves only Last update February 18, 1999 by ch

Dronpushpi or Guma (*Leucas cephalotes*): A Useful Weed

Pankaj Oudhia
Society for Parthenium Management (SOPAM)
28-A, Geeta Nagar, Raipur - 492001 India
pankaj.oudhia@usa.net
www.celestine-india.com/pankajoudhia

Leucas cephalotes (Roxb.) Spreng, Labiatae. is one of the common weeds found in Central and South India. It is upland rainy season weed. In India, it is commonly known as Dronpushpi (Dron = bunds, Pushpi = flowering plant). It is commonly occur in Drona (earthen berm). Other names in different Indian languages include *Barahalkura* (Bengali); *Gubo, Kubi* (Gujrati); *Dhurpisag*, *Guma*, *Gumma*, *Goma* (Hindi); *Devakhumba* (Marathi) and *Peedalumni* (Telugu) (Krishnamurthy, 1993). The genus *Leucas* includes about 100 Asiatic and African species. Common species found in India are *L. aspera* Spreng., *L. linifolia* Spreng, and *L. uritcaefolia* R. Br. (Caius 1986). Although Dronpushpi is a problematic weed for farmers, it is a tasty potherb for many rural people and a valuable medicinal herb for herbalists and is cultivated for herbal drugs in some parts of India. In village markets. Dronpushpi can be seen easily in rainy season. (Oudhi 1999, 2000; Oudhia and Tripath 1998, 1999, 2000; Oudhia et al. 1999). In tribal regions of India, Dronpushpi is a valuable drug for snake bite. a property reported in ancient Indian literatures, and is used both externally and internally. In many parts of India, people plant this weed in front of their homes to repel snakes and other venomous animals. The juice extracted from leaves is used to cure skin problems. In rainy season, many Indian tribal communities take bath with water having Dronpushpi leaf extract. They also wash their cattle and other domestic animals with this water. According to *Ayurveda*, the plant is mild stimulant and diaphoretic and used in fevers and coughs. The flowers mixed in honey is used as domestic remedy for cough and colds (Caius 1986). The seed also yields medicinal oil. Labellenic acid (Octadeca – 5, 6-dienoic acid) has been reported in seed oil. Beta sitosterol have been isolated from the plant of *Leucas cephalotes.* Anti bacterial activity of *Leucas aspera* leaf extract against *Micrococcus pyogenes* and *Escheria coli* have also been reported (Rastogi and Mehrotra 1991). Dronpushpi is valuable homoeopathic drug and as such is used for the treatment of chronic malaria and asthama (Ghosh 1988). In many parts of India particularly in North India.

Leather Woodfern

(1) *Dryopteris marginalis* (L.) A. Gray; (2) *D. filixmas* (L.) Schott.

Synonyms.—(1) *Aspidium marginale* Sw.; (2) *A. filixmas* Sw.

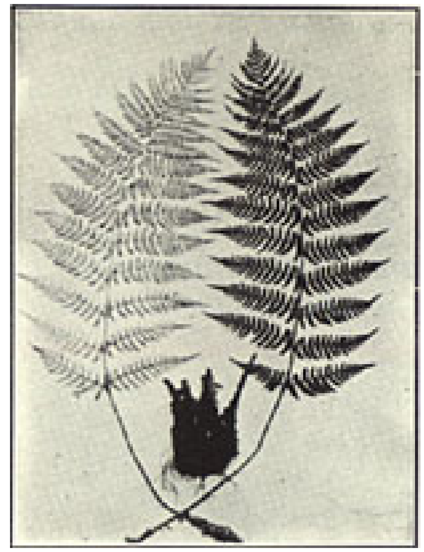

Figure 72.—Leather woodfern (*Dryopteris marginalis*)

Other common names.—(1) Marginal-fruited shield fern, evergreen woodfern; (2) male fern, male shield fern, sweet brake, knotty brake, basket fern, bear's-paw root.

Habitat and range.—These ferns are found in rocky woods, the male shield fern inhabiting the region from Canada westward to the Rocky Mountains and Arizona. The marginal-fruited shield fern, one of our most common ferns, occurs from Canada southward to Alabama and Arkansas.

Description.—Both of these plants are tall handsome ferns. They differ little in their general appearance, although the male shield fern, which grows to a height of about 3 feet, is somewhat larger than the other. The principal difference is in the arrangement of the fruit dots on the backs of the fern leaves. In the male shield fern these are located along the midrib, while in the marginal-fruited shield fern they are placed on the margins of the divisions of the fronds. These ferns have stout, erect rootstocks from 6 to l2 inches in length and 1 to 2 inches thick, covered with brown, closely overlapping leaf bases and soft, brown, chaffy scales. The inside of the rootstock is pale green. It has a disagreeable odor and a bitter-sweet, astringent, nauseous taste.

Part used.—The rootstock, collected from July to September, which should be carefully cleaned, but not washed, dried out of doors in the shade as quickly as possible, and marketed at once. The drug deteriorates rapidly unless carefully preserved,

Bhringraj or Bhengra [*Eclipta alba* (L.) Hassk.]

Contributor: Pankaj Oudhia

Copyright (c) 2002. All Rights Reserved. Quotation from this document should cite and acknowledge the contributor.

Common (Indian) Names:
Hindi: Balari, Bhangra, Bhringraj, Bhengra, Mochkand.
Gujerati: Bhangro, Dadhal, Kalobhangro
Canarase: Ajagara, Garagadasoppu, Kadigga-garaga
Marathi: Bhangra, Maka
Sanskrit: Bhringraj, Markara, Pitripriya, Sunilaka, Keshrangana

Family: Compositae

Habitat/Occurrence: In paddy growing areas of India, it occur as common weed. In many parts of India it is grown commercially as a medicinal crop.

Related Species: Four species have been reported so far in warmer parts of America, Africa, Asia and Australia.

Botany: An annual herb.

Stem: Stems and branches are strigose and hairy.

Leaves: Opposite, sessile, oblong- lanceolate; also strigose and hairy.

Flowers: In heads, involucral bracts, axillary, ray flowers ligulate; disk ones tubular.

Fruit: Achene.

Flowering Time: October to December in Indian conditions.

Useful Parts: Whole plant.

Medicinal Properties and Uses: The herb is an Ayurveda and Yunani medicine. According to Ayurveda philosophy Eclipta is bitter, hot fattening, alterative, anthelminticum, and alexipharmic. It is useful in inflammations, hernia, eye diseases, bronchitis, asthama, leucoderma, anaemia, heart and skin diseases, right blindness, syphilis etc. It is reported as beneficial for complexion, hair, eyes, and teeth.

Popular Ayurvedic Formulations: Bhringraj ghrit, Bhringraj taiil, Bhringrajadi churana etc.

Chemical Constituents: The plant contains the alkaloid ecliptine. Other chemicals identified are

wedelolactone, wedelic acid, apigenin, luteolin, β-amyrin etc.
Cultivation

Season: Kharif (June–July in Indian conditions)

Propagation: Through seeds

Seed Rate: 3 kg/ha

Major Insects & Diseases: No major insect and diseases have been reported in India conditions.

Manures: In India, Bhringraj is grown organically. No chemical inputs are used, only 15–20 tonnes farm yard manure/ha at the time of sowing is applied.

Maturity: 3–3.5 months after sowing.

Yield: Average yield 5 tonnes dry herbage/ha.

Perennial veldtgrass

Gramineae, Poaceae *Ehrharta calycina* J.E. Smith

Source: Magness et al. 1971

This is a cool season bunchgrass native to South Africa and introduced via Australia in 1929. It is a highly palatable, drought resistant grass adapted to light soils. The leafy stems reach to 3 feet in height. It has proved valuable on sandy, coastal soils in California where it is used for range reseeding.

Water chestnut

Jesuit nut, Water caltrops, Ling

Cyperaceae *Eleocharis dulcis* (Burm. f.) Trin. ex Henschel, *Trapa natans* L.

Source: Magness et al. 1971

Two types of aquatic plants are grown under the name water chestnut: One, *E. dulcis*, is a rush-like plant grown extensively in China for its near round turnip-shaped tubers. They are grown in ponds, and the tubers are harvested by scooping them off the bottom with forks. This is the water chestnut or "ling" widely used in Chinese foods. The other plant also called water chestnut, or Jesuit nut, or Water caltrops, is *T. natans*, a water plant with large leaves that float on the water surface. It is grown to some extent in Southern Europe and Asia. The edible part is the nutlike fruit, 1 to 2 inches in diameter, with 4 spined angles, which grows below the leaf blade. It is roasted and eaten like chestnuts. Neither type of water chestnut is produced commercially in the U.S., although there has been some effort with *E. dulcis*.

Season: Perennial plants, with a crop harvested annually.

Production in the U.S.: No data. Negligible.

Use: Cooked, eaten out of hand, or in other foods.

Parts consumed: Tuberous bulbs in *E. dulcis*; nut-like fruits in *T. natans*.

Israelsen, L.D. 1993. Phytomedicines as a new crop opportunity. p. 669-671. In: J. Janick and J.E. Simon (eds.), New crops. Wiley, New York.

Phytomedicines as a New Crop Opportunity

Loren D. Israelsen

Phytomedicines, simply defined, are a special category of plant drugs. They are standardized, which means that certain compounds in the plant material are quantified and elucidated so as to have a replicable final product, batch after batch. One of the criticisms traditionally leveled against natural medicines is the lack of standard levels of biological materials from the natural plants.

In many parts of the world, the United States is considered a third world country when it comes to phytomedicines. Unfortunately, our European colleagues are far ahead of us; they have a multi-billion dollar industry in phytomedicines, whereas ours is only a two hundred million dollar industry. Even so, there are a lot of exciting developments in the United States. Over the last five years, I estimate that the American medicinal herb industry has grown at a rate exceeding 20% per year and this trend continues today.

Phytomedicines represent new crop opportunities for several reasons. First, the companies who use these products are very keen to get high quality, sanitary material. This is becoming quite a serious problem. One example we have seen quite recently relates to problems in Eastern Europe, the source of many of these plants. Would you buy plant material which has been growing next to a steel plant in Eastern Europe? Most people would not. The United States is a good growers market because it has a stable political environment, has many different growing climates and conditions, excellent choice of growers, and the ability to grow according to industrial specifications. The Appalachian region, in particular, is very rich in medicinal flora.

Of growing concern is the extinction of medicinal plant species in this country. Given the growing demand for these botanicals and current problems in over-collecting, it is quite likely that some of the last populations of these plants will be collected over the next five to ten years if we don't begin to cultivate them commercially. Finally, these specialty crops could provide profitable growing opportunities for small farmers. Some of these crops appear to be ideally suited to the small farmer.

IMPORTANT MEDICINAL PLANTS

***Ginkgo biloba*.** The nuts of this tree are quite tasty when properly roasted. An extract (Fünfgeld 1988) derived from the leaf of this tree is the single largest selling drug in Germany and France today (Foster 1991). The extract is used for peripheral circulation and has the unique property of making red blood cells more elastic and selectively dilating capillaries. Consequently, this extract is used in Europe for treating conditions of tinnitus, vertigo, cold hands, cold feet, macular degeneration, and dementia. In order to meet the demand for the leaf, there is a 400 hectare farm in South Carolina which produces over a million kilograms of dried leaves a year. There are other plantations now being developed to meet the international demand for this product.

American ginseng (*Panax quinquifolium*). In Marathon County, Wisconsin, alone, this crop represents a one hundred million dollar a year crop (raw and finished product) which is primarily exported to China where it is widely used and appreciated. Oddly enough, we buy *Panax ginseng* from China because Americans prefer their material and they ours.

Saw palmetto (*Serenoa repens*). The berries of the Saw Palmetto are quite useful for benign prostatic hypertrophy. This is a very big pharmaceutical in Germany and France. There is a well developed industry in Florida which produces berries for export to Europe.

***Goldenseal* (*Hydrastis canadensis*).** This is one of the fastest growing products in the United States in the natural products industry and used to be in the United States Pharmacopoeia until about 40 years ago. It is native to Appalachia and is one of the crops that is most threatened by extirpation because of growing demand. Ginseng growers in Wisconsin have been contacted to see if they could grow Goldenseal. To date, the project is showing signs of success, and it seems likely that a large percentage of this product will come from cultivated plots rather than naturally occurring populations.

Bloodroot (*Sanguanaria canadensis*). This is very popular and is the active ingredient in a toothpaste product called Viadent. It is used to control plaque and gingivitis (Bennet et al. 1990).

Siberian ginseng (*Eleutherococcus senticosus*). This is a very popular and interesting product. It is called an adaptogen. It was developed in Russia by Dr. Breckman. Adaptogens are body regulators which promote proper balance. Many medical doctors question this hypothesis, but there is a significant amount of empirical and clinical data from Russia to support this (Farnsworth et al. 1985).

***Echinacea* (*Echinacea purpurea*).** This is a popular nonspecific immunostimulant in Germany and much of Europe. There are hundreds of hectares of cultivated Echinacea in Europe. There is also a large organic farm, Trout Lake Farm in Washington State, which grows significant amounts of this product. Echinacea is used as a preventative for colds and flues and is quite effective when used in this way. It is one of Europe's most popular natural products.

Milk thistle (*Silybum marianum*). This is used in Europe for liver conditions, treatment of acute mushroom poisoning, and other hepatoxic compounds.

Black cohosh (*Cimicifuga racemosa*). This is an interesting native American plant. It has a rich tradition among Native Americans and by people who live in the Appalachian region. It is used by women for regulation of hormonal cycles (Foster and Duke 1990).

Valerian (*Valeriana officinalus*). This is one of the more popular sleep aids in Europe and has been widely used for hundreds of years. There is no reason why this cannot be grown in the United States.

Feverfew (*Tanacetum parthenium*). Research in England has shown promising results in the treatment of migraine. A small amount of feverfew when taken orally can reduce the frequency and severity of migraine. It has great medical potential and could most definitely be grown in this country (Awang 1989).

St. John's wort (*Hypericum perforatum*). This is a popular European product. It has antiviral properties and also antidepressant properties (Hobbs 1988/1989).

Catnip (*Nepeta cataria*). Not only is it my cat's favorite play thing, but it is also used as a mild sedative (Tyler 1987). This is currently being grown in the United States as a sedative, although not commercially.

Pacific yew (*Taxus brevifolia*). At the moment, this is a most controversial and interesting phytomedicine. The pacific yew tree is the source of taxol which shows great promise for the treatment of ovarian and other cancers. However, there are not enough trees. These trees grow very slowly, and if harvested for taxol, the natural stands of the yew tree would be exhausted. The ability to obtain taxol from ornamental sources of *Taxus* as well as planting nurseries of the western yew for taxol extraction are underway.

Ginger (*Zingiber officinale*). It is not only a well known spice, but it has been proven to be as effective as dramamine in reducing nausea and motion sickness (Holtman et al. 1989). It has also been quite useful for pregnant women who are suffering nausea in early pregnancy and is quite safe (Bone et al. 1990).

CONCLUSIONS

In the United States, the policies of the Food and Drug Administration (FDA), historically, have been unhelpful to natural products. These plant products are polypharmaceutics, meaning they have multiple compounds, and FDA is not presently prepared to review products containing more than one compound. Demanding evidence that each individual component in an extract is safe and effective is a matter of scientific curiosity, but has little to do with the inherent questions of safety and effectiveness of the extract. Unfortunately, FDA still struggles with this concept.

The natural healthcare market is a very fast growing one. It is projected that at current inflation rates for health care, by the year 2030, health care costs could consume 100% of the gross national product. Something must be done. People are turning more and more to prevention and wellness programs, including natural medicines. As this trend develops, phytomedicines could become an important new alternative crop in the United States.

Giant wild-rye

Gramineae *Elymus condensatus* Presl

Source: Magness et al. 1971

This grass, native throughout the western states, is the most robust of the native rye grasses, reaching to 10 feet. It is a perennial bunchgrass, forming large clumps. Leaves are large, up to 2 feet long and 0.75 inch wide. It grows abundantly on wet and saline soils, but also occurs on moderately dry soils. Giant rye is suitable for grazing while succulent. The ripened clumps provide winter sustenance feed for cattle and horses. Propagation is by seed.

Last update February 18, 1999 by ch

Russian wild-rye

Gramineae, Poaceae *Elymus junceus* Fisch.

Source: Magness et al. 1971

This is a cool season bunch grass introduced in 1927 from Russia. It has proved adapted to the Northern Great Plains and Intermountain Regions, where it is used primarily for pasture. Growth starts early in spring. Plants are leafy and nutritious, with dense basal leaves. Seedling vigor is low, but once established, plants are deep rooted, drought resistant and salt tolerant.

Last update July 1, 1996 bha

Wild-rye grasses

Gramineae *Elymus* sp.

Source: Magness et al. 1971

Wild-rye species are well distributed among the native grasses of the Western States. Most species are perennial bunch growers, but some form sods. These grasses are coarse and of low palatability for livestock. Because of their vigor and ease of establishment they form a quick cover and are useful in mixtures with slower growing kinds. Wild-rye grasses are susceptible to ergot fungus, which replaces the seed kernel and is highly toxic to livestock. The most useful wild-rye species are Canada wild-rye, giant wild-rye, blue wild-rye, Russian wild-rye, and basin wild-rye.

Trailing-Arbutus

Epigaea repens L.

Trailing-arbutus

Figure 108.—Trailing-arbutus (*Epigaea repens*)

Other common names.—Gravel plant, Mayflower, shadflower, ground laurel, mountain pink, winter pink.

Habitat and range.—Trailing- arbutus spread out on the ground in sandy soil, being found from Newfoundland to Michigan and Saskatchewan and south to Kentucky and Florida.

Description.—This plant, generally referred to in the drug trade as gravel plant but more popularly known as "trailing-arbutus" spreads on the ground with stem 6 or more in length. It has rust-colored, hairy twigs bearing leathery, evergreen leaves from 1 to 3 inches long and about half as wide. The flower clusters, which appear from March to May, consist of fragrant, delicate, shell pink, waxy blossoms.

Part used.—The leaves, gathered at flowering time.

Lehmann lovegrass

Gramineae *Eragrostis lehmanniana* Nees

Source: Magness et al. 1971

This is a warm season, slightly spreading grass introduced from South Africa in 1932. It is used for range reseeding in the warm semidesert areas of Southwestern United States. It forms prostrate stems which root at the nodes and is readily established by seeding. The plants are smaller and less cold-tolerant than Boer or Weeping lovegrasses.

Last update September 22, 1997

Sand lovegrass

Gramineae, Poaceae *Eragrostis trichodes* (Nutt.) Wood

Source: Magness et al. 1971

This is a vigorous, long-lived, native bunchgrass occurring on sandy soils of the Central and Southern Great Plains. it is drought resistant, with a deep root system. Stems may reach to 6 feet. Leaves are abundant, slightly hairy, 12 inches long and 0.25 inch wide. Plants start growth early in spring and continue through the summer. This grass is highly palatable and nutritious, and often is overgrazed. It is easily established from seed.

Horseweed

Erigeron canadensis L.

Horseweed

Figure 68.—Horseweed (*Erigeron canadensis*)

Synonym.—*Leptilon canadense* (L.) Britton.

Other common names.—Erigeron, mare's-tail, Canada erigeron, butterweed, bitterweed, cow's-tail, colt's-tail, fireweed, bloodstanch, hogweed, prideweed, scabious.

Habitat and range.—Horseweed is common in fields and waste places and along roadsides throughout almost all of North America.

Description.—This weed varies greatly in height according to the soil it grows in. The erect stem, sometimes smooth, but usually bristly hairy, is generally branched near the top. The leaves are usually somewhat hairy, the lower ones 1 to 4 inches long and toothed, those scattered along the stem are rather narrow and smooth. From June to November the plant produces numerous heads of small, inconspicuous white flowers, followed by an abundance of seed.

Part used.—The entire herb, collected during the flowering period. Oil of erigeron, obtained from the plant by distillation, is produced commercially in Michigan and Indiana.

Information on the extraction of volatile oils from plants is contained in the following publication: Sievers, A.F. Methods of extracting volatile oils from plant material and the production of such oils in the United States. U.S. Dept. Agr. Tech. Bul. 16, 36 p. illus. 1928

Yerba Santa

Eriodictyon californicum (Hook. and Arn.) Greene.

Figure 128.—Yerba santa (*Eriodictyon californicum*)

Synonym.—*Eriodictyon glutinosum* Benth.

Other common names.—Mountain balm, consumptive's weed,* bear's-weed, gum plant, tarweed.

Habitat and range.—Yerba santa is common on the Pacific coast along the coastal ranges from central California north to Oregon.

Description.—This evergreen shrub, which reaches a height of from 3 to 4 feet, has a smooth stem which exudes a gummy substance. The narrow, dark-green, leathery leaves are from 3 to 4 inches in length and are covered with a resinous substance which makes them appear as if varnished. The rather showy, whitish, or pale-blue flowers are borne in clusters at the top of the plant.

Part used.—The leaves.

*This is a popular but misleading name.

Eruca sativa Miller

Brassicaceae = Cruciferae

Rocket, Roquette, Arrugula

We have information from several sources:

Arugula: A Promising Specialty Leaf Vegetable—Mario Morales and Jules Janick

Neglected Crops: 1492 from a Different Perspective—J.E. Hernándo Bermejo and J. León (eds.)

Evaluation of Tropical Leaf Vegetables in the Virgin Islands—Manuel C. Palada and Stafford M.A. Crossman

Food and feed crops of the United States—Magness, J.R., G.M. Markle, C.C. Compton. 1971.

Outside links:

Rocket: A Mediterranean Crop For The World from the International Plant Genetic Resources Institute

Eruca sativa Miller: a diploid, annual, species which flowers in spring and whose seeds are ready for collecting in late spring. It seems to prefer rather rich soils even through it can be found mixed with ruderal flora in very marginal areas. It is frequently cultivated, although demestication cannot be considered complete. A wild type, known as subspecies *vesicaria* (L.) Cav., is also rather well represented in the Mediterranean flora.

Erythrina poeppigiana (Walp.) O.F. Cook

Fabaceae
Poro

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Allen and Allen (1981) describe the tree as invaluable shade for coffee and cocoa. Since they are readily propagated from cuttings, they are also used for living fence posts. Both the shade trees and fence posts can be lopped as green manure, a system in use in Costa Rica and perhaps elsewhere. With its handsome orange-red f lowers, it is sometimes planted as an ornamental. Unpruned trees grew too large for coffee shade trees in Puerto Rico, according to Little and Wadsworth (1964), so its recommendation for coffee shade has been discontinued in Puerto Rico. It is still a popular coffee shade tree in the Andes. Flowers are said to be eaten in salads and soups (Little and Wadsworth, 1964).

Folk Medicine

According to Little and Wadsworth (1964), the bark, twigs, and seeds of various *Erythrina* species, more or less toxic, have provided local drugs and medicines. I have no specific data on this species.

Chemistry

Per 100 g, the seed is reported to contain 36.8 g protein, 12.4 g fat, and 5.5 g ash. The seeds, possibly poisonous, proved negative for starch test, alkaloid test, and tannin test (Earle and Jones, 1962). Willaman and Schubert (1961) report the alkaloids erysodine, erysopine, erysothiovine, erysovine, and hypaphorine from the seeds.

Description

Deciduous tree to as much as 25 m tall, 1 m DBH, the crown spreading. Bark is greenish brown to gray brown, smooth or slightly furrowed, warty, or spiny. Leaves trifoliate, 20–30 cm long including the pubescent petioles, the leaflets with paired cupular glands near the bases of the lateral leaflets. Racemes 10–20 cm long, the flowers caducous, orange red; petals 5; stamens 10, the anthers brown. Pods 12–25 cm long, several seeded, falcate, slightly depressed between the seeds, long-stalked, pointed at both ends. Seeds 1–2 cm long, weighing ca .183 g each.

Germplasm

Reported from the South American Center of Diversity, poro, or cvs thereof, is reported to tolerate acid soils as well as moist limestone soils. ($2n = 42$)

Distribution

Probably native from Venezuela to Panama, south to Bolivia, Brazil, Ecuador, and Peru. Cultivated in Florida, Guatemala to Costa Rica, the West Indies, and the Old World Tropics.

Ecology

I estimate that the species ranges from Tropical Moist to Tropical Wet through Subtropical Dry to Subtropical Rain Forest Life Zones, where annual precipitation is 15 to 40 dm, annual temperature is 20 to 28°C, and pH is 4.0 to7.5. Studied at Turrialba, mean annual temperature 22.3°C, the annual precipitation 2639 mm with only one month with less than 100 mm. The relative humidity is 87.6%, the mean monthly evaporation 92.3 mm, and the mean daily radiation 432 cal/m^2/day. Soils were alluvial with moderate to deficient drainage, the pH 4.6, organic matter 6.7–7.2%, nitrogen 0.25–0.43% exchangeable potassium 0.45.

Cultivation

In Costa Rica, the trees are spaced roughly at 6 x 6 m, with > density of ca 280 trees/ha, interspersed with ca 4300 coffee plants/ha (Russo, 1982).

Harvesting

The trunks, some nearly 30 cm in diameter, are lopped ca head height or higher twice a year. The prunings are added to the soils as green manure (Russo, 1982).

Yields and Economics

The addition of organic matter due to the biennial loppings can run to 10 MT/yr, improving, if anything, the yield of the coffee intercrop (Russo, 1982).

Energy

Although not producing very good fuel, the biomass production could probably approximate or surpass 25 MT/ha/yr in monoculture, fixing N all the while.

Biotic Factors

The following diseases are reported from species of *Erythrina: Cercospora erythrinae* (on leaves), *Cercospora erythrinicola*, *Clitocybe tabescens* (root rot), *Colletotrichum erythrinae* (on leaves), *Dicheirinia binata* (rust), *Meliola bicornis*, *Meliola crenatissima*, *Meliola erythrinae* (black mildew), *Meloidogyne* sp. (root knot nematodes), *Mycosphaerella erythrinae* (on leaves), *Nectria cinnabarina* (on stems), *Pellicularia kolerogna* (thread blight), *Phoma erythrinicola* (on stems), *Phyllosticta erythrinicola* (leaf spot), *Phymatotrichum omnivorum* (root rot), *Rhizoctonia ramicola* (thread blight), and *Verticillium* sp. (probably *albo-atrum*) (wilt) (Agriculture Handbook 165).

Myrtaceae
Redgum eucalyptus

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Important timber, firewood, shelter belt, and honey tree. In the Sudan, it is planted to protect crops from blowing sands. The wood, durable, easy to saw, yet resistant to termites, is widely used in Australia for strong durable construction, interior finish, flooring, cabinetry, furniture, fenceposts, cross-ties, sometimes pulpwood. Australian aborigines made canoes from the bark. Survivalists in Australia and elsewhere might learn how the aborigines obtained water from the superficial roots, usually those ca 3 cm in diameter. The roots were excavated or lifted to the soil surface. Then the root was cut into segments ca 45 cm long, debarked, held vertically, and blown into, the water then draining into the receptacle provided.

Folk Medicine

Reported to be anesthetic, antiseptic, astringent, the redgum eucalyptus is a folk remedy for colds, colic, coughs, diarrhea, dysentery, hemorrhage, laryngalgia, laryngitis, pharyngitis, sore throat, spasm, trachalgia, and wounds (Duke and Wain, 1981).

Chemistry

Leaves contain 0.1–0.4% essential oil, 77% of which is cineol There is some cuminal, phellandrene, aromadendren (or aromadendral), and some valerylaldehyde, geraniol, cymene, and phellandral (C.S.I.R., 1948–1976). Leaves contain 5–11% tannin. The kino contains 45% kinotannic acid as well as kino red, a glucoside, catechol, and pyrocatechol. Leaves and fruits test positive for flavonoids and sterols. The bark contains 2.5–16% tannin, the wood 2–14%, and the kino 46.2–76.7% (Watt and Breyer-Brandwijk, 1962).

Description

Large evergreen tree 24–40(-50) m high with stout trunk often short and crooked, to 2 m in diameter; crown open, widely spreading, irregular. Bark smoothish, white, gray, or buff. Twigs reddish, long, slender, angled, drooping. Trunk can form air roots. Root system deep and spreading. Leaves alternate, drooping, narrowly lanceolate, 8–22 cm long, 1–2 cm wide, often curved or sickle-shaped, tapering to long point, short-pointed at base, entire glabrous, dull pale green on both surfaces or occasionally grayish. Umbels single at leaf base, ca 2.5 cm long on slender stalk 6–19 mm long. Flowers 5–10, each on slender stalk 5–12 mm long from ovoid buds 6–10 mm long, 4–5 mm wide. Stamens many, threadlike, white, 5–6 mm long; anthers with small round gland. Pistil with inferior, long-pointed, 3–4-celled ovary and long, stout style. Capsules several, clustered, hemiglobose or ovoid, 7–8 mm long, 5–6 mm wide, light brown, with wide raised disk and 3–4 prominent triangular teeth almost 2 mm long. Seeds many, tiny, 1.5 mm long, light brown (Little, 1983).

Germplasm

Reported from the Australian Center of Diversity, redgum eucalyptus, or cvs thereof, is reported to tolerate alkali, drought, fire, light frost, heat, high pH, poor soil, salt, savanna, and waterlogging. It is rather intolerant of weeds. The NAS catalogs four outstanding provenances, 'Katherine' and 'Petford' for tropical climates, 'Lake Albacutya' for Mediterranean climates, and 'Broken Hill' for arid climates. Some Provenances can tolerate -5°C and up to 20 frosts per year. ($2n = 22$)

Distribution

This is said to be the most widely distributed eucalypt, ranging over 23° lat. in most of arid and semiarid Australia but not the humid eastern and southwestern coasts. It is regarded as one of the most widely planted eucalypts in the world (ca 500,000 ha planted) (NAS, 1980a). Plantations occur in Argentina, Arizona, California, Egypt, Kenya, Morocco, Nigeria, Pakistan, Senegal, Sierra Leone, Spain, Sri Lanka, Sudan, Tanzania, Upper Volta, Uruguay, and Zimbabwe.

Ecology

Ranges from tropical through subtropical and warm temperate, and from arid to semiarid. Tolerates temperatures from 3° to 5°C in winter with 0–50 frosts according to locality. Annual rainfall from minimum of about 250–625 mm to as high as 1000–1250 mm (Little, 1983). In Duke's ecogeographic data base, redgum eucalyptus is estimated to range from Tropical Thorn Forest to Dry through Warm Temperate Desert to Dry Forest Life Zones, and is reported to tolerate annual precipitation of 10.3 to 20.6 dm (mean of 9 cases = 15.9) and annual temperature of 18.0 to 26.6°C (mean of 9 cases = 24.7). It is reported in areas with only 2 dm rainfall, but the lower limit for commercial plantations is 4 dm. Some provenances tolerate many different soil conditions, high calcium, high salt, periodic waterlogging. Occasionally pure stands may develop naturally along flood plains and stream banks. The mean maximum temperature of the warmest month where it grows well is ca 29°C. The dry season lasts 4–8 mos or more and may be severe. Frosts are rare (5–20 days/yr) (Mariani et al., 1981).

Cultivation

Seeds, long lived when sealed in dry cold storage, are usually started in nursery containers, then transplanted to the field (as close as 2 x 2 m for firewood). Extensive weeding may be mandatory. During the seedling stage, this species develops gall-like structures, at least in the Philippines, which offer resistance to drought and fire (Agpaoa, 1980).

Harvesting

Some provenances coppice well for six or more rotations, on good sites, plantations are managed on coppice rotations of 7–10 years.

Yields and Economics

According to NAS (1980a), annual wood yields or 20–25 m^3/ha in Argentina, 30 m^3 from Israel, 17–20 from Turkey in the first rotation, and 25–30 in subsequent coppice rotations. On poor arid sites, yields are only 2–11 m^3 (ca 1–5 cords) on 14 or 15 year rotations. Litterfall ran about 3.6–5.8 MT/ha/yr in an Australian redgum swamp (Briggs and Maher, 1983).

Energy

According to the phytomass files (Duke, 1981b), standing biomass in an Israeli plantation is ca 110 MT/ha. At Calistoga, California, this was calculated to yield 4.3 m^3/ha/yr or 2 cords and total energy yields of 15,000,000 kcal/ha/yr (Standiford and Donaldson, 1982). "As firewood, the timber from *Eucalyptus camaldulensis* has few equals. It is also a good charcoal wood, and the steel industry in Argentina, for example, relies on its charcoal for steel-making. The fuel value of the wood (sp. grav. 0.6) is 4,800 kcal/kg. In World War II, Australians used the charcoal for their producer gas plants." (C.S.I.R., 1948–1976).

Biotic Factors

According to Browne (1968), the following affect *Eucalyptus camaldulensis:* (Bacteria) *Agrobacterium tumefaciens*. (Fungi) *Cercospora eucalypti, Corticium salmonicolor, Fomes setulosus, Gymnopilus junonius, Hypholoma fasiculare, Inonotus chondromyelus, Polyporus portentosus, Sclerotinia fuckeliana*. (Angio-spermae) *Tapinanthus* sp. (Coleoptera) *Alcidodes biangulatus, A. haemopterus, Anaemerus tomentosus, Apate monachus, Chrysolagria neavei, Dicasticus affinis, Gonipterus scutellatus, Opseotrophus sufflatus, Phoracantha recurve, P. semipunctata, Siderodactylus sagittarius, Sinoxylon transvaalense, Systates pollinosus, Xyleborus truncatus.* (Hemiptera) *Agonoscelis pubescens, Atelocera stictica.* (Hymenoptera) *Perga affinis, Phylacteophaga eucalypti.* (Isoptera) *Ancistrotermes amphidon, Odontotermes feae.* (Lepidoptera) *Archips occidentalis, Cleora dargei, Desmeocraera cyprianrii, Eumeta cervina, Kotochalia junodi, Nadasia amblycalymma, Nola lugens, ophiusa tirhaca, Orgyia basalis, Parasa ananii, Strepsicrates rhothia.* (Orthoptera) *Staurocleis magnifica.* (Mammalia) *Lepus whytei.* Young and/or drought-weakened shrubs can be badly infested by the eucalyptus snout beetle, eucalypt borer, moth larvae, and termites. Even the young trees are not favored by livestock and wildlife. The tree is said to kill other tree species (NAS, 1980a). This is one of the few species whose leaves are eaten by sheep (Watt and Breyer-Brandwijk, 1962). The litter may provide an important food source for detritivorous invertebrates and hence for waterfowl in redgum swamps (Briggs and Maher, 1983).

Chemical Analysis of Biomass Fuels

Analysing 62 kinds of biomass for heating value, Jenkins and Ebeling (1985) reported a spread of 19.42 to 18.23 MJ/kg, compared to 13.76 for weathered rice straw to 23.28 MJ/kg for prune pits. On a % DM basis, the wh.plant contained 81.42% volatiles, 0.76% ash, 17.82% fixed carbon, 49.00% C, 5.87% H, 43.97% O, 0.30% N, 0.01% S, 0.13% Cl, and undetermined residue.

Eucalyptus citriodora Hook.

Myrtaceae
Lemon-scented gum

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Leaves yield a lemon-scented oil rich in citronellal, and favored in perfumery. The wood is good for saw-timber, used for general construction, poles, railroad ties, and tool handles. Bark may contain up to 12% tannin. Kenyans favor the honey produced by this species.

Folk Medicine

Reported to be antiseptic and fumigant. Cubans place the leaves under the sheets of fever patients, and inhale the steam from boiled leaves for cold and various pulmonary problems. Cubans also poultice the leaves onto ulcers, wounds, and other skin ailments. Guatemalans decoct the leafy shoots for coughs (Morton, 1981). Orally administered leaf extracts in rabbits artifically diabetic, produced temporary hypoglycemia and reduced the blood sugar levels (Watt and

Breyer-Brandwijk, 1962). Myrtillin, in the leaf extract, is said to induce a temporary hypoglycemia (Atal and Kapur, 1981).

Chemistry

Dayal reported betulinic and ursolic acids, eucalyptin and β-sitosterol in the leaves. Glabrous leaves may contain oil with 65.5% citronellal, 12.2% citronellol, and 3.6% isopulegol; hairy leaves contain more oil with 86.6–90.1% citronellal, 4.6–6.0% citronellol, and 0.7–0.8% isopulegol, 1-pinene, β-pinene, and isovaleric aldehyde are also recovered (Morton, 1981). Bark contains ca 9% tannin (Watt and Breyer-Brandwijk, 1962). The young leaf is reported to contain citric-, glutaric-, malic-, quinic-, shikimic- (carcinogenic), and succinic-acids (Watt and Breyer Brandwijk, 1962). Leaves and fruits test positive for flavonoids and sterols.

Toxicity

Citronellal found in Eucalyptus and Melissa is reported to be mutagenic (Lewis and Elvin-Lewis, 1977).

Description

Evergreen tree 24–40 m high with tall straight trunk 0.6–1.3 m in diameter, and thin, graceful crown of drooping foliage. Bark smooth, gray, peeling off in thin irregular scales or patches and becoming mottled, exposing whitish or faintly bluish inner layer with powdery surfaces appearing dimpled. Twigs slender, slightly flattened, light green, tinged with brown. Leaves alternate, narrowly lance-shaped, 10–20 cm long, 1–2.5 cm wide, apically acuminate, basally acute, entire, glabrous, thin, light green on both surfaces, with many fine parallel straight veins and with vein inside edge. Corymbs terminal and at leaf ba"s, to 6 cm long, branched. Flowers many, 3–5 on equal short stalks (umbels) from ovoid buds 8–12 mm long, 5–8 mm wide. Stamens many, threadlikes, white, 6 mm long, spreading ca 12 mm across, anthers with long gland. Pistil inferior 3-celled ovary and long, stout style. Capsules few, urn-shaped or ovoid, narrowed into short neck, 10–12 mm long, 8–10 mm wide, brown with scattered raised dots. Seeds few, irregularly ellipsoid, 4–5 mm long, shiny black (Little, 1983).

Germplasm

Reported from the Australian Center of Diversity, lemon-scented gum, or cvs thereof, is reported to tolerate clay, drought, gravel, laterites, light frosts, podzols, poor soil, and slopes, but is not very tolerant of waterlogging. The hybrid with *E. torelliana* is showing promise in Nigeria (NAS, 1980a). Gupta et al. (1981) obtained multiple shoots from 20-year old terminal bulbs in culture. Shoots were also obtained from seedling explants. They estimate they can produce 100,000 plants from one mature tree bud in one year.($2n$ = 20, 22, 28)

Distribution

Said to occur naturally only on the central and northern coasts of Queensland, Australia, but to fare well in much of Africa, Brazil, California, Hawaii, India, even Portugal.

Ecology

Said to grow where the rainfall, mostly summer, is 6 to 13 dm, with 5–7 month dry season, withstanding high temperatures (29–35°C mean monthly maximum) and light frosts. In tropical and subtropical arid to semiarid zones, in infertile clays, laterites, poor and gravelly soils and podzols, preferrably well drained.

Cultivation

In Zimbabwe, seeds are broadcast successfully on the ashes of recently burned tracts. More usually seedlings are transplanted from the nursery. Seed require no special treatment.. Though needing protection from frost and weeds when young, older saplings show more tolerance to both. According to Irvine (1961), seedlings transplant badly.

Harvesting

For oil extraction, trees are not allowed to mature to the timber stage. Instead, they are lopped for the foliage; sucker shoots produce copious foliage.

Yields and Economics

Tanzania plantations, harvested on an 8-year coppice, produced an annual 15 m^3/ha. Back in 1925, the essential oil from this species commanded twice the price of that of *E. globulus* (MacMillan, 1946).

Energy

Firewood yields run 10–21 m^3/ha/yr (Fenton et al., 1977). The hard heavy wood (sp. grav. 0.75–1.1) burns steadily and makes a good charcoal with an ash content of 1–2%. This is the chief charcoal species of the Brazililan steel industry.

Biotic Factors

Browne (1968) lists the following as affecting this species: (Bacteria) *Agrobacterium tumefaciens.* (Fungi) *Armillaria mellea*, *Fusarium* spp., *Ganoderma colossum, G. lucidum, Phytophthora parasitica, Polyporus rubidus, Puccinia psidii, Sclerotinia fuckeliana*, *Trametes cubensis,* *Verticillium albo-atrum.* (Coleoptera) *Anomala cupripes, Dicasticus affinis, Elytrurus griseus, Entypotrachelus meyeri, Systates surdus, Xyleborus truncatus.* (Hemiptera) *Atelocera stictica, Eucalyptolyma maideni.* (Isoptera) *Ancistrotermes amphidon, Coptotermes truncatus, Microtermes* spp., *Pseudacanthotermes militaris.* (Lepidoptera) *Carea angulata, Colocleora divisaria, Neocleora nigrisparsalis, Nudaurelia krucki, Strepsicrates holotephras, Sylepta balteata, Thalassodes sp., Uzucha borealis.* (Orthoptera) *Schistocerca gregaria*.

---

Last update Tuesday, January 6, 1998 by aw

Eucalyptus globulus Labill.

Myrtaceae
Eucalypt, Tasmanian bluegum

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

A handsome ornamental shade, most widely planted of the subtropical/eucalypts. Grown for firewood in India (C.S.I.R., 1948 1976). This is one of the best eucalypts for pulp production. The timber is used for carpentry, construction, fences, piles, platforms, plywood, poles, sheds, and stations, tool handles, veneer, etc. Essential oil, widely used in cough drops, is antiseptic, rubefacient, and stimulant (Morton, 1981). A type of kino extracted from the tree in Argentina. Eucalyptus hybrid 'Mysore' is a promising source of pinenes, which are used in synthetic camphor, pine oil, terpineol, and in dry cleaning fluids, solvents, and cheap deodorants (Verma et al., 1978). The leaves have proven antibiotic acitivty. Their decoction is used for repelling insects and vermin (Morton, 1981). Africans use finely powdered bark as an insect dust. Mexicans chew the leaves to strengthen the gums. Said to be a good honey plant, Portuguese bee farmers like to raise their bees near this eucalyptus.

Folk Medicine

Reported to be anodyne, antiperiodic, antiphlogistic, antiseptic, astringent, deodorant, diaphoretic, expectorant, febrifuge, hemostat, inhalant, insect repellant, rubefacient, sedative yet stimulant, suppurative, and vermifuge, the bluegum eucalyptus is a folk remedy for abscess, arthritis, asthma, boils, bronchitis, burns, cancer, catarrh, cold, cough, croup, cystitia, diabetes, diptheria, dysentery, dyspepsia, fever, flu, grippe, inflammation, laryngitis, leprosy, malaria, miasma, phthisis, rhinitis, sores, sorethroat, spasms, tuberculosis, tumors, vaginitis, wounds, and worms (Watt and Breyer-Brandwijk, 1962; Duke and Wain, 1981; List and Horhammer, 1969–1979; Morton, 1981). Venezuelans take leaf decoction for cheat airments or colds, inhaling the vapors or drinking the decoction. Guatemalans use the leafy shoots for coughs and grippe, Jamaicans put the leaves in the bed, the bath, or the teapot for colds and fever. Cubans use the essential oil for bronchitis, bladder and liver infections, lung ailments, malaria, and stomach trouble. Mexicans chew the fresh leaves to strengthen the gums. Mexicans also use the leaf decoction as a vaginal douche. They argue that daily drinking of the leaf infusion can reverse diabetes in 8 days. Leaves are placed in the bath for rheumatism (Morton, 1981). Homeopaths use the plant for bronchitis, colds, flu, laryngitis, and rheumatism. In Asia, the leaf oil, clearly poisonous in large quantities, is regarded as anesthetic, antibiotic, antiperiodic, expectorant, febrifuge, and vermifuge, and it is used for asthma, bronchitis, influenza, and tuberculosis (Perry, 1980). In Australila, the leaves of the bluegum are still widely used as a household remedy in the treatment of many diseases and minor complaints. In Britain and Europe the essential oil, which is powerfully antiseptic, was given for fevers and febrile conditions, for pulmonary tuberculosis, and was applied or inhaled for relieving asthma, bronchitis, sorethroat, croup, whooping-cough, scarlet fever, and even diptheria and typhoid. The dried leaves were also smoked like cigarettes for asthma while the oil in the form of an aperitif was taken as a digestive (Brooker et al., 1981). Europeans in Africa and Africans themselves may wear the leaf in the hat or place it around the residence as a flu preventative. It is also regarded as a malaria preventitive. African herbalists believe the root is purgative.

Chemistry

Leaves contain 70–80% eucalyptol (cineol). Also includes terpineol, sesquiterpene alcohols, aliphatic aldehydes, isoamyl alcohol, ethanol, and terpenes (Morton, 1981). Tannin is not so copious in the leaves as of many other *Eucalyptus* species. The kino, containing 28.7% kino-tannin and 47.9% catechin contains the very antibiotic citriodorol (Watt and Bryer-Brandwijk, 1962). Verma et al. (1978) found 20.2% α-pinene, 25.2% β-pinene, and only 16.8% cineole in the cv 'Mysore'. Fresh leaves contain caffeic and gallic acids, dry leaves, ferulic and gentisic (Boukef et al., 1976), and quercetol, quercitrine, rutin, and a mixture of quercetol hyperoside and glaucoside. N-titriacontan-16, 18-dione was identified as the compound responsible for antioxidant activity in the leaf wax (Osawa and Namik, 1981).

Toxicity

In large doses, oil of eucalyptus, like so many essential oils has caused fatalities from intestinal irritation (Morton,1981). Death is reported from ingestion of 4–24 ml of essential oils, but recoveries are also reported for the same amount. Symptoms include gastroenteric burning and irritation, nausea, vomiting, diarrhea, oxygen deficiency, ,weakness, dizziness, stupor, difficult respiration, delirium, paralysis, convulsions, and death, usually due to respiratory failure (Duke, 1984b). Reported to cause contact dermatitis (Brooker et al, 1981). Sensitive persons may develop urticaria from handling the foliage and other parts of the plant (Watt and Bryer- Brandwijk, 1962).

Description

Evergreen tree 40–70 m tall with straight massive trunk 0.6–2 m in diameter with narrow, irregular crown of large branches and drooping aromatic, camphoraceous foliage. Root system deep and spreading. Bark smoothish, mottled gray, brown, and greenish or bluish, peeling in long strips, at base becoming gray, rough and shaggy, thick, and finely furrowed; inner bark light yellow within thin green layer. Leaves alternate, drooping on flattened yellowish petioles 1.5–4 cm long, narrowly lanceolate, 10–30 cm long, 2.5–5 cm wide, mostly curved, acuminate at tip, acute at base, entire, glabrous, thick, leathery, with fine straight veins and vein inside marlin, shiny dark green on both surfaces. Flowers 1 (rarely 2–3), at leaf base, more than 5 cm across, the very numerous, white stamens ca 12 mm long. Buds top-shaped, 12–15 mm long, 12–25 mm wide. Stamens many, threadlike, white, anthers oblong opening in broad slits with round gland. Pistil with inferior 3–5-celled ovary and long stout style. Capsules single at leaf base, broadly top-shaped or rounded, 1–1.5 cm long, 2–2.5 cm wide, 4-angled, warty. Seeds many, irregularly elliptical, 2–3 mm long, dull black (Little, 1983).

Germplasm

Reported from the Australian Center of Diversity, bluegum, or cvs thereof is reported to tolerate narrower extremes of temperature and soil than many of the more tropical species. ($2n$ = 20, 22, 28)

Distribution

The most extensively planted eucalypt species in the world...a total of 800,000 ha in dozens of countries...About half the world's plantation area is in Portugal and Spain (Little, 1983). Also cultivated in California, Arizona, and Hawaii.

Ecology

Ranging from Cool Temperate Moist to Wet through Subtropical Dry to Moist Forest Life Zones, bluegum eucalyptus is reported to tolerate annual precipitation of 8 to 16 dm and annual temperature of ca 16 to 20°C. Major successes have been in mild temperate climates and in cool highlands. Elsewhere it fails (NAS, 1980a).

Cultivation

Propagated by seed and basket transplants ca 6 mos old. No seed treatment is required. Fresh seeds germinate well but deteriorate rapidly. The tree is readily established, easily reproducing from self-sown seed. In California, seed collections from a single tree exhibit wide variation (2–80%) in germinative capacity after a 30-day germination period (Ag. Handbook 450). Seedlings like the adults are susceptible to drought, fire, and frost. Grasses need to be weeded, as the tree does not compete well with grasses (NAS, 1980a). Tree grows rapidly and coppices readily (reaching a meter or more in a few months).

Harvesting

Usually grown on rotations of 5–15 years. In India's Nilgiris, bluegum plantations are worked for fuel purposes on a 15-year coppice (C.S.I.R., 1948–1976).

Yields and Economics

Annual wood production of 10–30 m^3 has been reported from sites in Italy, Peru, Portugal, and Spain (NAS, 1980a). Verma et al (1978) estimated essential oil yields between ca 40 and 45 kg/ha from 6–8 MT green leaves. Completely dry leaves contain 1.27% oil in the cv 'Mysore'. The Wealth of India suggests 30 MT biomass/ha/yr in the Nilgiris (C.S.I.R., 1948–1976).

Energy

About 30 MT/ha biomass are reported. Verma et al. (1978) calculated little more than 7 MT leaves per hectare, green, or 6–8 MT for the cv 'Mysore', 3–4 MT dry leaves. In his compilation, Cannell (1982) cites data on trees 9.5 years old, spaced at 2,196 trees/ha. The stem wood on a DM basis weighed 19–58 MT/ha, the stem bark 5–11, the branches 2.6–5.5, the foliage 4.0–6.7, for a total standing aerial biomass of 35–110 MT/ha. The CAI (current annual increment) of stem wood was 2.9–7.7 m^3/ha/yr, stem bark 0.7–1.5, branches 0.5–0.7, foliage 2.6–ca 6 for a total aerial CAI of 6.7–15.6 MT/ha/yr, the low figures representing unfertilized trees, the high reflecting ca 200 kg/ha N and 90 kg/ha P. These data were taken at Victoria, Australia (38°20'S, 146°20'E, elev. 150 m). The wood burns freely, leaving little ash, and carbonizes easily, making good charcoal. With calorific value of 4,800 kcal/kg, the heavy wood (sp. grav. 0.8–1.0) is widely used for fuelwood and charcoal (NAS, 1980). Even the dead leaves and fallen bark are highly flammable. The charcoal is used for producer gas plants (C.S.I.R., 1948–1976). Cromer and Williams (Austr. J. Bot. 30:265. 1982) report that it took 9.5 years to accumulate 30 MT/ha biomass unfertilized, but only 4 years in heavily fertilized plots.

Biotic Factors

Listed as affecting *Eucalyptus globulus* are the following: *Actinopelte dryina, Armillaria mellea, Cercospora epicoccoides, C. eucalypti, Corticium salmonicolor, Cryptosporium eucalypti, Cytospora australiae, C. eucalyptina, Diaporthe medusaea, Didymosphaeria circinnans, Diplodia australiae, Fomes applanatus, F. scruposus, Fusarium oxysporum* var. *aurantiacum, Ganoderma lucidum, Harknessia uromycoides, Hendersonia eucalypticola, Laetiporus sulphureus, Macrophoma molleriana, Macrophomina phaseoli, Monochaetia desmazierii, Mycosphaerella molleriana, Pestalotia truncata, Pestalotiopsis funerea, Pezizella carneo-rosea, Pezizella oenotherae, Phellinus gilvus, Phyllostica extensa, Physalospora latitans, P. rhodina, P. suberumpens, Polyporus gilvus, P. hirsutus, P. schweinitzii, P. sulphureus, P. versicolor, Poria cocos, P. versipora, Sclerotinia fuckeliana, Septonema multiplex, Septosporium scyphophorum, Stereum hirsutum,* and *Valsa eucalypti* (Ag. Handbook 165; Browne, 1968). Also listed in Browne (1968) are the following: Angiospermae: *Dendrophthoe, neelgherensis,* and *Viscum album.* Coleoptera: *Gonipterus scutellatus, Paropsis obsoleta, Phoracantha semipunctata,* and *Triphocaris mastersi.* Hemiptera: *Ctenarytaina eucalypti* and *Eriococcus coriaceus.* Hymenoptera: *Rhinopeltella eucalypti.* Lepidoptera: *Metanastria hyrtaca, Mnesampela privata,* and *Spilonota macropetana.* Foliage unpalatable to livestock. The oil rich wood is resistant to termites (NAS, 1980a).

Eucalyptus gomphocephala A. DC.

Myrtaceae
Tuart

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Widely planted as a windbreak and sandstabilizer, as well as an avenue and shade tree. Seasoning well, the wood works nicely and is good for boxcars, construction, fenceposts, stakes, trucks, and wagons (NAS, 1980a; Little, 1983). Bees working the flowers produce a choice light creamy honey.

Folk Medicine

No data available.

Chemistry

The leaf is reported to contain only 0.03% essential oil, rich in α-phellandrene and α-pinene (C.S.I.R., 1948–1976); the bark and kino contain tannin (Watt and Breyer-Brandwijk, 1962).

Description

Evergreen tree 12–42 m high. Trunk short, 1–2.3 m in diameter; crown dense, broad, with large spreading to nearly upright branches. Bark light ashy-gray, fibrous, finely fissured, not shedding. Leaves alternate, narrowly lanceolate, 12–17 cm long, 1.5–2.5 cm wide, slightly curved, acuminate, acute at base, entire, glabrous, thick, both surfaces shiny gray-green with faint regular veins. Umbels single at leaf base, with broad flat stalk 2.5–3.5 cm long and 1–1.5 cm wide. Flowers 3–7, stalkless from buds 20–25 mm long. Stamens many, long, threadlike, white, with oblong anthers and oblong gland. Pistil with inferior 4-celled ovary and short style. Capsules 13–20 mm long, 11–15 mm in diameter. Seeds many, tiny, 2–3 mm long, light brown (Little, 1983).

Germplasm

Reported from the Australian Center of Diversity, tuart, or cvs thereof, is reported to tolerate calcareous soil, limestone, salt, sand, and wind (NAS, 1980a). While tolerating slightly saline soils, it will not tolerate water-logging. This species is one of the best for winter rainfall areas.

Distribution

Grows naturally in pure or almost pure stands, less commonly in mixed forests with other eucalypts, restricted to a narrow sandy coastal plain behind the coastal dunes near Perth, from sea level to 30 m. Cultivated and/or promising in Cyprus, Ethiopia, Greece, Israel, Italy, Libya, Morocco (66,000 ha), Tunisia, Turkey, and Uruguay (NAS, 1980a).

Ecology

Tuart is reported to tolerate annual precipitation of 3 to 10 dm and annual temperature of ca 16 to 18°C, with 6 dry summer months. It grows naturally on neutral yellow or brown sand over limestone. Growing well on coarse, well-drained sands, it will tolerate 25% active Ca. Still it is said to be unsuitable for high lime soils and for frosty areas. It tolerates lower fertility than *E. camaldulensis*.

Cultivation

Easily propagated from seed and coppice (Little, 1983). Cultivation by dry farming techniques is best in the first year or two to suppress weed growth.

Harvesting

Rotations of 7–10 years are used. Trees regenerate readily from coppice.

Yields and Economics

Irrigated fertile Moroccan soils have yielded annually 21–44 m^3/ha, but yields of 6–7 are more usual on difficult sites.

Energy

One of the densest woods known (sp. grav. 1.17), tuart burns well and makes good firewood.

Biotic Factors

The eucalypt borer (*Phoracantha semipunctata*) may be a pest, especially in drier sites. In addition, Browne (1968) lists the following as affecting this species: (Fungi) *Armillaria mellea*, *Fusarium oxysporum*. (Coleoptera) *Systates surdus*, *Triphocarisa acanthocera*. (Hemiptera) *Apiomorpha egeria*.

Chemical Analysis of Biomass Fuels

Analysing 62 kinds of biomass for heating value, Jenkins and Ebeling (1985) reported a spread of 19.23 to 18.03 MJ/kg, compared to 13.76 for weathered rice straw to 23.28 MJ/kg for prune pits. On a % DM basis, the wh. plant contained 81.60% volatiles, 1.10% ash, 17.30% fixed carbon, 48.18%C, 5.92%H, 44.18% O, 0.39% N, 0.01% S, 0.20% Cl, and undetermined residue.

Eucalyptus grandis Hill ex Maiden

Myrtaceae
Flooded gum

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

This is a rather widely planted ornamental shade tree, also useful as a honey plant. The pale red timber is softer and lighter than that of many eucalypts. Easily worked, the wood is extensively used for medium-quality joinery in offices and hotels. They are good for crafts, and older trees, for telephone poles. It is occasionally used for veneer.

Folk Medicine

No data available.

Chemistry

The bark and kino contain tannins (Watt and Breyer-Brandwijk, 1962).

Description

Evergreen tree 40–60 m high with a tall straight trunk and 1–2 m in diameter. Crown spreading and thin in open; small and compressed in dense plantations. Bark white, gray or green, smooth, shedding in long narrow strips. Leaves alternate, lanceolate, 10–20 cm long, 2–4 cm wide, acuminate, inaequilateral, wavy, glabrous. Umbels single at leaf base, 2.5–3 cm long with flattened stalk of 12 mm. Flowers 5–12, short-stalked or stalkless. Buds pyriform, 10 mm long, 5 mm wide. Stamens many, threadlike, white, anthers oblong with large round gland. Pistil with inferior 4–6-celled ovary. Capsules several, short-stalked, pyriform or conical, 8 mm long, 6 mm wide (Little, 1983).

Germplasm

Reported from the Australian Center of Diversity, flooded gum, or cvs thereof, is reported to tolerate frost, heat, and poor soil. Adapted to a rather wide range of soil types, the species is relatively free of disease but somewhat frost tender. The tree grown in Africa and Brazil, possibly a hybrid with *E. saligna*, is superior to wild types in yield and bole straightness (NAS, 1980a).

Distribution

Ranging spottily from 17°S to 30°S in Australia, the plant is widely planted. It is so important in Brazil that it is said to be planted at the rate of 100,000 ha/yr. Mariani et al. (1981) mention its cultivation in Angola, Argentina, Australia, Brazil, Cuba, Ghana, Indonesia, Papua, Peru, Sri Lanka, and Zimbabwe.

Ecology

Seedlings of *E. grandis* are more resistant to waterlogging than those of *E. robusta*, which are more resistant than those of *E. saligna.* Estimated to range from Tropical Thorn to Moist through Warm Temperate Thorn to Moist Forest Life Zones, flooded gum is reported to tolerate annual precipitation of (6.0-)7.0 to 17.3(-25) dm (mean of 3 cases = 11.8), annual temperature of 18.8 to 27.5°C (mean of 3 cases = 23.2), and pH of 5.0 to 7.5 (mean of 2 cases = 6.2). Grows where summer temperatures reach 40°C, winter minima -1 to -3°C. While tolerating gradual temperature falls to frost, sudden freezing is very damaging. Does best where the rain is mostly in summer/fall with a spring dry period. Does well in moist, well-drained soils from shales, slates, sandstones, even granites and basalts. Seems to tolerate poor soils with low P content.

Cultivation

Since weeds severely limit growth, mechanical or chemical site preparation is essential if rapid rates of growth are to be achieved and maintained." (NAS, 1980a). The plant is sensitive to boron deficiency. Fertilizer applied at the time of planting can have a spectacular effect. Seedlings 2–5 months old are outplanted, best at the beginning of the wet season, spaced at 2 x 2 m to 5 x 5 m (NAS, 1980a).

Harvesting

Usual rotations in Kenya are 6 years for domestic fuelwood, 10–12 years for industrial fuelwood, 7–8 years for telephone poles. Forests are commonly regenerated by coppice from stumps, sprouting within 3 months, then thinned to 2–3 shoots per stump.

Yields and Economics

In Kenya, the initial crop averages ca 30 m^3/ha/yr over the first 6 years, the coppice crop closer to 46 m^3/ha/yr over the same period. Irrigated stands in Zimbabwe yield; 40 m^3, good stands in Uganda 17–45, and up to 35 m^3/ha in S. Africa. At Dehra Dun the MAI was 22 m^3/ha (Fenton et al., 1977). Webb et al. (1980) report yields of 24–70 m^3/ha/yr.

Energy

According to the phytomass files (Duke, 1981b), annual productivity ranges to 22 MT/ha in California. Introduced into E. Africa as railroad fuel early this century, flooded gum provides a lightweight (sp. grav. 0.40–0.55) fuelwood. In New South Wales, total biomass increases with age to 394 MT at 27 yrs. old, with foliage biomass increasing gradually to 6.2 MT. Though variable, understory biomass increased through recruitment to 42 MT at 27–yrs-old, the stick and bark component having reached a steady state 7 MT at age 15, the leaf component rather steady around 2, the humus content stabilizing at 17–18 (Bradstock, 1981). The Sri Lanka apellation turpentine-gas certainly suggests energy implications. Although this species produces more wood than *Acacia mearnsii*, it is inferior to that species for fuel and charcoal (Duke, 1981a). Eucalyptus scored lower than Melaleuca on yield (ca 6 MT/ha/yr cf 28 MT/ha/yr) and nothing had as high a heating value as the bark of Melaleuca (>25,000 kj/kg). The bark of *Eucalyptus grandis* has a relatively low heat value (14,683 kj/kg), perhaps due to a plethora of inorganic noncombustibles in the bark. The average ash content is 10.1%. The stem wood had a heat value of 19,213 kj/kg.

Biotic Factors

In Brazil, the fungus *Diaportha cubensis* attacks the flooded gum. Termites may be a problem in savanna plantations. Root rot is a serious problem (Fungi) in Zambia. Browne (1968) lists the following as affecting this species: *Cylindrocladium scoparium, Daldinia concentrica.* (Coleoptera) *Anomala cupripes, Automolus depressus, Phoracantha recurva, P. semipunctata, Triphocaris acanthocera, T. mastersi.* (Hemiptera) *Cardiaspina fiscella, C. maniformis.* (Isoptera) *Macrotermes natalensis.* (Lepidoptera) *Neocleora herbuloti, Nola lugens, Xyleutes boisduvali.* (Mammalia) *Trichosurus vulpecula.*

Chemical Analysis of Biomass Fuels

Analysing 62 kinds of biomass for heating value, Jenkins and Ebeling (1985) reported a spread of 19.35 to 18.15 MJ/kg, compared to 13.76 for weathered rice straw to 23.28 MJ/kg for prune pits. On a % DM basis, the wh. plant contained 82.55% volatiles, 0.52% ash, 16.93% fixed carbon, 48.33% C, 5.89% H, 45.13% O, 0,15% N, 0.01% S, 0.08% Cl, and undetermined residue.

Complete list of references for Duke, Handbook of Energy Crops

---

Last update Tuesday, January 6, 1998 by aw

Eucalyptus occidentalis Endl.

Myrtaceae
Swamp yate

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Reported as one of the hardest and straightest timbers of the world, with a tensile strength only slightly below that of wrought iron. The wood is used for wheelwright work (frames, vehicles, wheel parts) and construction. In Western Australia, the tree is recommended as a shade tree, suitable for parks because its light shade doesn't prevent grass. The bark was once used as a source of tannin.

Folk Medicine

No data available.

Chemistry

The leaf is reported to contain 0.95% oil with aromadendren (or aromadendrol), pinene, cineol, and sesquiterpenes. The bark is reported to contain 35–52% tannin (Watt and Breyer Brandwijk, 1962).

Description

Evergreen tree 15–28 m high, with stout erect trunk to 80 cm diameter; flat-topped or umbrellalike crown. Bark dark gray or almost black, thick, rough, fissured, fibrous, not shedding. Leaves alternate, narrowly to broadly lanceolate, 10–14 cm long, 2–3 cm wide, acute at both ends, sides nearly equal, entire, glabrous, thick, shiny dark green on both surfaces, petiole to 2 cm long. Umbels single at leaf base, the stalk 15–25 mm long. Flowers 3–7, short-stalked, the bud to 20 mm long. Stamens many, long, 8–20 mm long, yellowish-white, thread-like, with tiny gland-dots, oblong anthers with oblong gland. Pistil with inferior conical 4-celled ovary and long slender style. Capsules short-stalked, bell-shaped, 10–18 mm long, 8–12 mm wide. Seeds few, tiny, 2 mm long, brown (Little, 1983).

Germplasm

Reported from the Australian Center of Diversity, swamp yate, or cvs thereof, is reported to tolerate alkalinity, drought, heavy soils, salinity, sand, and brief waterlogging (NAS, 1980a; Little, 1983). It is reported to fare well on soils with 8% chlorides. ($2n = 22$)

Distribution

Native to the southwestern part of Western Australia (elev 50–300 m), the species has been introduced to northern Africa and southwestern Asia. Successful plantations are reported from Algeria, California, Hawaii, Iran, Israel, Morocco, and Sri Lanka (NAS, 1980a).

Ecology

Estimated to range from Subtropical Thorn to Dry through Warm Temperate Thorn to Dry Forest Life Zones, swamp yate is estimated or reported to tolerate annual precipitation of 3 to 10 dm, annual temperature of 16 to 23°C, and pH of 6.0 to 8.2. Summers where the species naturally grows may attain 38°C, with a dry season up to 7 months; the winters may dip down to 2°C, with up to 20 frosts. Trees often occur in seasonally flooded alluvial flats and adjacent to salt lakes, on clays.

Cultivation

No data available.

Harvesting

No data available.

Yields and Economics

Compared to other species of eucalypt, this is a slow grower. Webb et al. (1980) reported wood yields of 3–8 m^3/ha/yr.

Energy

The wood burns steadily with a hot fire.

Biotic Factors

NAS (1980a) reports no pests or diseases.

Last update Tuesday, January 6, 1998 by aw

Eucalyptus robusta Sm.

Myrtaceae
Swamp mahogany, Iron bark

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

One of the most widely planted eucalypts, this has moderately hard and heavy wood (sp. grav. 0.51) which is strong but brittle and stiff, elastic, coarse-textured, and fairly straight-grained but with some interlocking. Difficult to season and split, it works well and takes a good polish, and is durable in contact with the ground. The wood is employed in general construction, for underground piling, utility poles, fenceposts, and firewood. An attractive ornamental honey-producing tree, it is also planted as a windbreak. The plant is used as an insecticide in China (Perry, 1980).

Folk Medicine

Reported to be preventitive, swamp mahogany is a folk remedy for abscesses, boils, cellulitis, colds, dysentery, encephalitis, enteritis, erysipelas, flu, gangrene, mastitis, and sores (Duke and Wain, 1981).

Chemistry

The kino contains the antibiotic citriodorol. Leaves and fruits were positive for flavonoids, sterols, and tannins. The bark contains only 1.4% tannin, while the leaves may contain 12% (Watt and Breyer-Brandwijk, 1962). Leaves contain 0.16% essential oil, with aromadendren (or aromadendral) and pinene.

Description

Evergreen tree 24–40 m with relatively large, short, straight, trunk 1–1.2 m in diam. ca half the height of the tree. Trunk may have air roots. Bark gray or brown, reddish brown beneath surface, very thick, rough, deeply furrowed, fibrous. Leaves alternate, blades broadly lanceolate, 10–18 cm long, 3–6 cm wide, acuminate, acute at base and often with curved, unequal sides, glabrous, thick, leathery, stiff, shiny or dull dark green upper surface, dull light green beneath. Petiole to 25 mm, umbels single at leaf base, to 6 cm long, peduncle 2–3 cm. Flowers 5–10, equally short-stalked, large, 3 cm across. Buds pyriform, 12–20 mm long, 7–10 mm wide. Stamens many, threadlike, spreading, white or cream-colored, ca 12 mm long, anthers oblong with large oblong gland. Pistil with inferior 3–4-celled ovary and straight, stout style. Capsules several in rounded cluster, stalked, 12–15 mm long, 10–12 mm wide. Seeds tiny, dull light brown, 1–2 mm long (Little, 1983).

Germplasm

The hybrid with *E. grandis* is regarded as having better firewood potential.

Distribution

Native to southeastern Australia on a very narrow coastal strip (0–100 m elev.), but now widely introduced in tropical and subtropical areas. According to Little (1983), it is the best adapted species to Puerto Rico. Cultivated, for example, in Angola, Argentina, Arizona, Brazil, California, Cameroon, China, Congo, Costa Rica, Florida, Ghana, India, Indonesia, Israel, Ivory Coast, Malagasy, Malaysia, Mauritus, New Hebrides, Nigeria, Peru, Philippines, Puerto Rico, Sri Lanka, Tanzania, and Vietnam.

Ecology

Estimated to range from Tropical Dry to Moist through Frostfree Subtropical Very Dry to Moist Forest Life Zones, swamp mahogany is estimated to tolerate annual precipitation of 8 to 15 dm, annual temperature of 18 to 25°C, and pH of 5 to 7.5. Where native, this species is found mainly in swamps and at the edge of brackish estuaries. It grows better on slopes, but doesn't compete as well as the mixed forest species (Little, 1983).

Cultivation

Out of a gram of seed, about 100 germinate. Seed is usually sown, immediately after collecting and sundrying.

Harvesting

In Malaysia, it starts fruiting as early as year 4. Fruits take two years to ripen in China. Fruits are collected when the capsules start to turn black.

Yields and Economics

In Argentina, 5 year old stands 9 m tall (1,583 trees/ha) had a basal area of 10 m^2 and a volume of 89 m^3 for an average of 18 m^3/ha/yr. Webb et al. (1980) report wood yields of 14–28 m^3/ha/yr. In Malaysia, the MAI was 4 cm planted under shade, 6 planted in slash/burn situation, and 11 planted in an abandoned vegetable garden (Fenton et al., 1977).

Energy

Little (1983) mentions the use of the species for fuel, but it was not recommended by NAS (1980a). Planted for fuel reserves at 1,000–2,000 m elevation in Sri Lanka (MacMillan, 1925). Comparing potential energy trees for Panama, Curtis and Duke (1982) cite Puerto Rico studies showing green weight of 14,556 kg/ha for *Eucalyptus robusta*, 8,922 for *Albizia procera*, 6,932 for *Casuarina equisetifolia*, 4,360 for *Leucaena* (K-8), 599 kg only for native *Leucaena*, and only 402 for *Cassia siamea*. The data from Puerto Rico were provided by a team promoting energy grasses as energy sources. They concluded that energy grasses will produce 6–7.5 times more green biomass. They cited 53 MT for sordan, 82 for napier grass, and 84 MT/ha DM for sugarcane (in 12 months). Perhaps the data of Smith and Dowd, in Florida, are equally reliable. They projected only ca 6 MT/ha for Eucalyptus (perhaps *E. grandis*, *robusta*, or *viminalis*) with ca 60 for napier grass, 32–54 for sugarcane, and 16–37 for sorghum, only 22 for sordan. Both the Puerto Rican and Florida tabulations suggest that the energy grasses may be 10 times as productive of DM as Eucalyptus. Eucalyptus scored lower than Melaleuca on yield (ca 6 MT/ha/yr) and nothing has as high a heating value as the bark of Melaleuca (>25,000 kj/kg). The stemwood (density 0.53 g/cm^3) ofi *E. robusta* had a heat value of 19,628 kj/kg, the stembark (0.22 g/cm^3), 18,074 (Wang et al., 1982).

Eucalyptus saligna Sm.

Myrtaceae
Saligna eucalypt

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Often confused with *E. grandis*, a bottomland species, this slope species is an important general purpose hardwood and construction timber in Australia. Also used for cabinetry, crossties, furniture, shipbuilding, turnery, veneers. Since it is not a "greasy" wood, the Australians favor it for floorings and steps. A good honey plant, is often grown as an ornamental and/or shade tree (Little, 1983). Much used in South Africa for paper pulp and artificial silk (Watt and Breyer-Brandwijk, 1962). The oil has insecticidal properties against bedbugs, black beetles, flies, lice, and mosquitoes (Kambu et al., 1982).

Folk Medicine

No data available.

Chemistry

Leaves contain 0.12% essential oil, largely composed of α-pinene and p-cymene. Kambu et al. (1982) add 1,8-cineole, borneol, α-terpineol, and linalol. The bark contains 5.9-8.4% tannin.

Description

Evergreen tree 40–70 m high with open, spreading, irregular crown. Trunk 1.2–1.8 m in diameter, straight. Bark dull, bluish or greenish-gray, smooth, peeling off slightly and exposing yellow layer. Roots may have lignotubers near the surface. Leaves alternate, lanceolate, 10–20 cm long, 1.5–3 cm wide, often curved, acuminate, acute at base, glabrous, dull green or dark green above, dull light green below. Petiole 12–25 mm long. Umbels single at leaf bases and along twigs, 2–2.5 cm long. Flowers 3–9, usually 7, equally short-stalked or nearly stalkless, 12–19 mm across. Buds 8–9 mm long, 4–5 mm wide. Stamens many, threadlike, white, anthers oblong with large round gland. Pistil with inferior 3–5-celled ovary and short style, Capsules on short stalk or subsessile, campanulate or conical, 5–6 mm long and wide, dark brown. Seeds many, tiny, 1–2 mm long, dull light brown (Little, 1983).

Germplasm

Reported from the Australian Center of Diversity and is reported to tolerate slopes. ($2n = 22$)

Distribution

Native to southeastern Australia, from sea level to 1,000 m. Introduced in Argentina, Brazil, California, Guyana, Hawaii, India, Indonesia, New Zealand, South Africa, and Sri Lanka.

Ecology

Estimated to range from Subtropical Dry to Moist through Warm Temperate Dry to Moist Forest Life Zones, saligna eucalypt is reported or estimated to tolerate annual precipitation of 8 to 15 dm, annual temperature of 16 to 22°C, and pH of 6.0 to 8.0. Inhabits soils derived from shales and deep well drained clays in valleys.

Cultivation

No data available.

Harvesting

No data available.

Yields and Economics

This is the fastest growing eucalypt in Hawaii where one 71 m specimen represents the tallest hardwood species in the US.

Energy

A 4-year old stand in Brazil had standing biomass of 56 MT/ha (38 aboveground, 8 litter, and 10 belowground). But annual biomass productivity was estimated at 15–17 MT/ha (Andrae and Krapfenbauer, 1979). Fenton et al. (1977) report wood yields of 19 m^3/ha/yr; Webb et al. (1980), 20–38.

Biotic Factors

Browne (1968) lists the following as affecting this species: (Fungi) *Fomes robustus, Sclerotinia fuckeliana, Thanataphorous cucumeris.* (Coleoptera) *Chaetastus tuberculatus, Doliopygus kenyaensis, Entypotrachelus meyeri, Nematocerus lindblomi, Phoracantha semipunctata, Triphocaris acanthocera, T. solida, Xyleborus truncatus.* (Hemiptera) *Cardiaspina pinnaeformis, Glycaspis baileyi.* (Hymenoptera) *Phylacteophaga eucalypti.* (Isoptera) *Macrotermes natalensis, Pseudacanthotermes militarism* (Lepidoptera) *Acrocercops laciniella, Agrapha limbirena, Axiologa pura, Cleora dargei, Eumeta junodi, Nola lugens, Nudaurelia gueinzii, Oenetus virescens, Pachypasa subfascia, Spilonota macropetana, Spodoptera littoralis, Strepsicrates rhothia, Zelotypia staccyi.* (Orthoptera) *Brachytrupes membranaccus.* (Mammalia) *Lepus whytei, Tragelaphus scriptus.*

Eucalyptus tereticornis Sm.

Myrtaceae
Forest redgum

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Recommended as a fuelwood species for arid and semiarid tropical regions, this shade and shelterbelt species has heavy wood (sp. grav. 0.75–1.05), is hard, durable, and strong but difficult to work. It is used for fuel, pulp, pilings, fiberboard, and construction; also for crossties and fenceposts.

Folk Medicine

No data available.

Chemistry

Leaves contain 0.48–0.66% essential oil, 0–10.4% of which is cineol. The bark and kino contain tannin.

Description

Evergreen tree 18–46 m high with straight stout trunk 1–1.8 m in diameter, large and open or fairly dense crown. Bark smooth, whitish, peeling in irregular thin sheets or large flakes, becoming mottled with white, gray, or blueish patches. Leaves alternate, lanceolate, 10–21 cm long, 12–25 mm wide, often curved, acuminate, acute at base, slightly thickened, shiny green on both surfaces, glabrous. Umbels single at leaf base, 2.5–3 cm long including the rounded stalk of 1 cm. Flowers 5–12, spreading on equal stalks on 5–7 mm. Buds 12–16 mm long, 5 mm wide. Stamens many, threadlike, white, 10–12 mm long, anthers small and elliptical, with small round gland. Pistil with inferior 4–5-celled ovary and long stout style. Capsules several, hemiglobose or turbinate, 6–9 mm long, 8–10 mm in diameter. Seeds many, tiny, 1 mm long and broad, shiny dark brown to black (Little, 1983).

Germplasm

Reported from the Australian Center of Diversity, forest redgum, or cvs thereof, is reported to tolerate drought and light frosts. It does not tolerate acidic soils or waterlogging. ($2n = 22$)

Distribution

With a wide latitudinal range (6–38°S) of ca 3,000 km from sea level to 1,800 m, the forest redgum is native from eastern Australia into New Guinea and Papua, the species is widely introduced, faring notably in South Africa for example. Reported in Argentina, Botswana, Brazil (national average yield 18 m^3/ha/yr), Congo, Cuba, Fiji, Ghana, Guyana, India, Indonesia, Pakistan, Papua, Paraguay, Peru, Sudan, Uruguay, and Zimbabwe (Mariani et al., 1981; Fenton et al., 1977).

Ecology

Estimated to range from Tropical Very Dry to Moist through Warm Temperate Dry to Moist Forest Life Zones, forest redgum is reported to tolerate annual precipitation of 5 to 20 dm, annual temperature of 16 to 25°C, and pH of 6.5 to 7.5. Where it grows naturally, it may tolerate 0–15 frosts a year. The dry season may extend for 7 months. The mean maximum temperature of the warmest month is ca 27°C, while the mean minimum of the coolest month is 7°C. Soils, usually not acidic, are rather rich, moist, alluvial, sandy loams and gravels, not usually waterlogged (Mariani et al., 1981).

Cultivation

No data available.

Harvesting

In Argentina it is harvested on 7–8-year rotations for charcoal, 9–12-year cycles for construction timber (Mariani et al., 1981).

Yields and Economics

On good sites in Argentina, an MAI of 18–30 m^3/ha/yr is obtainable, but in poor sites in India, the MAI may be closer to 3. At Dehra Dun, the 'Mysore' hybrid yielded only 3 m^3/ha/yr compared to 22 for *E. grandis* (Fenton et al., 1977).

Energy

In his compilation, Cannell (1982) cites data showing that trees 5 years old, spaced at 1,670 trees/ha, averaged a basal area of 18 m^2/ha. The stemwood and bark on a DM basis weighed 53.7 MT/ha, the branches 10.1, the foliage 6.7, and the roots were estimated at 10.6 MT/ha for a total standing biomass of 81.1 MT/ha. Nine-year olds spaced at 840 trees/ha averaged basal area of 42 m^2/ha. The stemwood and bark weighed 139.2 MT/ha, the branches 30.9, the foliage 8.0, and the roots were estimated at 18.6 for a total standing biomass of 196.7; suggesting an annual increment exceeding 20 MT/ha. The wood is used for firewood and charcoal. In Argentina, it is grown for the charcoal iron industry on a 7–8-year rotation. Calorific values were measured of different parts of 5–9-year old trees and their litter. Values for living material ranged from 3.2 to 5.7 kcal/g, similar to published values for forest communities. Energy content, annual production, retention and release through litter fall are tabulated for each stand age. Net annual production (in kcal/ha x 108) increased from 0.93 (of which 0.83 is retained in the tree and 0.10 released as litter) at 5 yr old to 1.56 (1.32 retained and 0.24 released) at 9 yr old. Energy fixation by *E. tereticornis* appears more efficient than in some other tree species reported in the literature (Singh, 1980).

Biotic Factors

Fenton et al. (1977) mention *Alternaria tenuissima, Corticium salmonicolor, Cylindrocladium scoparium, Ganoderma lucidum*, and *Sclerotinia fuckeliana* among diseases. Scarab beetles may defoliate this and other species. The coreid, *Amblypelta cocophaga,* has been associated with trees suffering dieback.

Eucalyptus viminalis Labill.

Myrtaceae
Manna eucalyptus

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

The wood (51 lb/cu ft) is used for building, construction, joinery, and vehicles. It is considered suitable for paper pulp (C.S.I.R., 1948–1976). The red gum or manna exuding from cracks in the bark is eaten eagerly by South African boys and has been used for making adhesives and birdlime (Watt and Breyer-Brandwijk, 1962). Eucalyptus manna, which exudes from punctures in summer months, is sometimes consumed. The essential oil shows the same antiviral (influenza) effect as that of *E. dalrympleana* (Vichkanova et al, 1973). Leaves inhibit *Staphylococcus aureus*.

Folk Medicine

The leafy twig decoction was used to bathe rheumatic limbs in South Africa.

Chemistry

Leaves contain 0.35–0.75% essential oil, of which 50–65% is cineol, 5% is pinene, and 10% is eudesmol. The "manna" contains arabinose, raffinose, dextrose, and sucrose. The bark contains 4.8–8% tannin, the kino 92.7% (Watt and Breyer-Brandwijk, 1962). The kino contains 7.1% moisture, 0.25% ash, and 92.7% catechin + tannin (C.S.I.R., 1948–1976).

Toxicity

The species is suspected to cause poisoning in koala bears, perhaps due to HCN (0.09% HCN has been reported) (Watt and Breyer-Brandwijk, 1962).

Description

Seedling phanerocotylar, the cotyledons reniform.

Germplasm

Reported from the Australian Center of Diversity, manna eucalyptus, or cvs thereof, is reported to tolerate more frost than most species of eucalypt. ($2n$ = 22)

Distribution

Native to Southeastern Australia, but cultivated in Argentina, California, Hawaii, India, Peru, et al.

Ecology

No data available.

Harvesting

No data available.

Yields and Economics

At Calistoga, California, Standiford and Donaldson (1982) calculated 7.8 m^3/ha/yr, equivalent to 3.2 cords or 20 million kcals/ha/yr.

Energy

NAS (1980a) suggested this as a promising firewood species. Webb et al. (1980) report wood yields of 10–30 m^3/ha/yr.

Biotic Factors

Browne (1968) reports the following as affecting this species: (Fungi) *Fomes robustus, F. setulosus, Inonotus chondromyelus, Phytophthora parasitica, Polyporus portentosus, P. zonatus.* (Coleoptera) *Entypotrachelus meyeri, Gonipterus scutellatus, Paropsis obsoleta, Phoracantha semipunctata, P. tricuspis.* (Hemiptera) *Eriococcus coriaceus.* (Lepidoptera) *Spilonota macropetana.*

Wahoo

Euonymus atropurpureus Jacq.

Other common names.—Burningbush, spindle tree, Indian arrowwood, bursting-heart, strawberry-tree, strawberry bush, American spindle tree, bitter ash, pegwood.

Figure 113.—Wahoo (*Euonymus atropurpureus*)

Habitat and range.—Wahoo is found in woods and thickets from Ontario and the eastern United States to Montana.

Description.—This shrub or small tree, which is from 6 to 26 feet in height, more often reaching only 10 feet, has an ashy gray bark and rather thin, pointed leaves from 1 1/2 to 5 inches in length and about half as wide. The purple flowers are produced in June in loose, slender-stemmed clusters of from 6 to 15 flowers each. The pale-purple fruit consists of four deeply cleft, flattened lobes. In autumn the capsules open and disclose the seed surrounded by a red, false seed coat, giving the bush a bright and showy appearance

The name wahoo is applied indiscriminately to *Euonymus atropurpureus* and *E. americanus* L., the latter a low and trailing bush having roughened, crimson capsules, to which the name burningbush more properly belongs.

Part used.—The bark of the root and the stem.

American False-Hellebore

Veratrum viride Ait.

Figure 5.—American false-hellebore (*Veratrum viride*)

Other common names.—True veratrum, green veratrum American veratrum green hellebore, swamp hellebore, big hellebore, false hellebore, bear corn, bugbane, bugwort, devil's-bite, earth gall, Indian poke, itchweed, tickleweed, duck-retter.

Habitat and range.—American false-hellebore is native in rich wet woods, swamps and wet meadows, its range extending from Canada, Alaska, and Minnesota south to Georgia and Tennessee.

Description.—The large bright-green leaves of this plant make their way through the ground early in spring, followed later in the season by a stout, erect leafy stem, sometimes growing as tall as 6 feet. It is round and solid, pale green, closely surrounded by the sheathing bases of the leaves and unbranched except in the flowering head. The large leaves, the lower ones of which are from 6 to 12 inches in length and 3 to 6 inches in width, are hairy and pleated like a fan. The numerous greenish-yellow flowers are produced from May to July in rather open clusters. The plant is very poisonous.

Part used.—The rootstock, dug in autumn when the leaves have died down.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Small, E. 1999. New crops for Canadian agriculture. p. 15–52. In: J. Janick (ed.), Perspectives on new crops and new uses. ASHS Press, Alexandria, VA.

New Crops for Canadian Agriculture

Ernest Small

The designation "new crop" may be applied to virtually any useful plant that in some respect is new. The following categories of newness (which are not all mutually exclusive) are economically important in discussing new crops: (1) gathering new wild crops from nature; (2) cultivating an undomesticated plant not previously grown; (3) domesticating (changing genetically) an undomesticated plant; (4) breeding improved cultivars of domesticated plants; (5) growing crops in new areas; (6) growing crops for new uses; (7) growing crops with new management techniques; (8) selling crops in new markets.

Category 2 and (especially) category 3 represent "new crops" in the narrow sense perhaps most widely understood. Although all domesticated crops originally came from the wild, in recent times the domestication of wild plants relatively infrequently produces crops of notable economic significance. Based on 160 crops grown and/or imported in the US that had a value of at least $1 million, Prescott–Allen and Prescott–Allen (1986) found that only six crops with this value were domesticated since 1900, a rate of success of less than 7 per century. Almost all potentially important new crops for a political or agronomic region are cultivated elsewhere, and indeed the leading domesticated crops of Canada all originated in foreign lands. Crop diversification, especially involving new crops, is considered to be a fundamental area deserving support in Canada (Small, in 1999; note Fig. 1).

The following reviews what is significantly new (for any of the eight kinds of newness pointed out above) with respect to the major classes of crops in Canada, such as cereals, oilseeds, forages, vegetables, and fruits. These crop classes represent arenas of competition, and new crops generally can only compete within one of these arenas. As will be noted, some of these arenas thrive on the introduction of new entities, while others are like clubs that are very hostile to the entry of new members. Given the breadth of the topic, only a limited amount of detail and selected examples will be presented for the crop categories, and minor crops that either have had very limited success in Canada or show little potential will not be discussed or will be given only incidental mention. For those seeking additional information on new crop development in Canada, it should be noted that the following present a wealth of information on the World Wide Web: (1) the federal department of agriculture, i.e. Agriculture and Agri-Food Canada (AAFC), Canada's primary plant breeding institution, which has research stations in all provinces; (2) the provincial agriculture or resource departments; and (3) a wide variety of farm-oriented organizations.

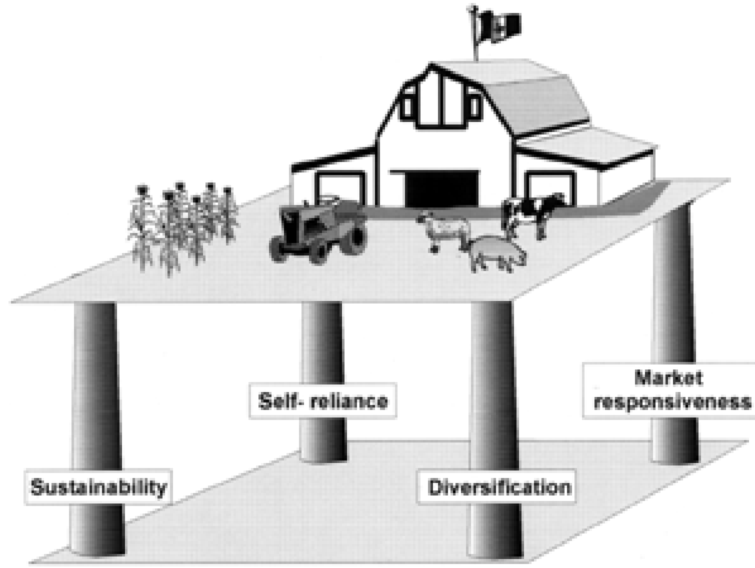

Fig. 1. A vision of agriculture in Canada, conceptualizing crop diversification as one of four essential supporting pillars (Agriculture Canada 1989).

CANADIAN AGRICULTURE

Agriculture is the most important of the industries dealing with the biological resources of Canada, exceeding the value of forestry, fishing, and trapping. Agriculture and the allied agri-food industry are respectively responsible for about 2 and 6% of the Gross National Product (GDP), and about 14% of Canada's employment. In 1996 (the year of the last comprehensive census) the agri-food industry of Canada was worth over $70 billion* (about 8.8% of Canada's GDP), of which 24% represented on-farm production, the remainder accounted for by allied food industries, commercial sales, and the food service industry. The equivalent of 70% of Canada's agricultural production, with a value of about $20 billion, was exported in 1996, while the value of imported agricultural and food products was about two-thirds of this. This overall trade surplus shows that Canadian agriculture is dependent on world markets, and suggests that new crops represent an important measure to address market fluctuations and declines. The most important commodities exported by Canada are grains and grain products (35% of total agri-food exports), red meat and live animals (20%), and oilseeds and oilseed products (13%). The US is Canada's most important trading partner, taking about half of Canada's agri-food exports. In return, about 60% of Canada's agri-food imports are from the US. Imports include fruits and nuts (19% of total agri-food imports), vegetables (10%), and red meats (8%). The relatively short growing season of Canada necessitates a wide variety of agricultural imports, most notably hot-region plantation crops such as coffee, tea and spices (10% of all imports).

Fig. 2 shows the distribution of farmland in Canada. More than 40% of Canada is forested; about half of this area is capable of producing timber, and about a quarter is currently managed for timber production. Adverse climate, soil, and other circumstances prevent profitable agriculture in most of the country. Although Canada has close to 10 million square kilometers, making it the world's second largest country, only 67.7 million ha (0.677 million square kilometers) are arable (Canadian Federation of Agriculture 1995; Reid 1995). By comparison, total land in farms in the US in 1997 was 392 million ha, about six times the area used for farming in Canada. (The value of US crops in this year was about 109 billion dollars, about 10 times the value of Canadian production.) The arable area of Canada, about 7% of the country, is equal to about three times the land area of Great Britain. However, it has been estimated that less than 5% of Canada's land is actually capable of producing crops, and most of this is already in production (Environment Bureau 1997a). Moreover, only half of this land capable of producing crops is prime agricultural land, and much of this has succumbed to urban development (Science Council 1991). Canada may already be approaching its upper limit of farmland development (Acton 1995). An additional 6% of Canada's land can be used for grazing (Environment Bureau 1997a).

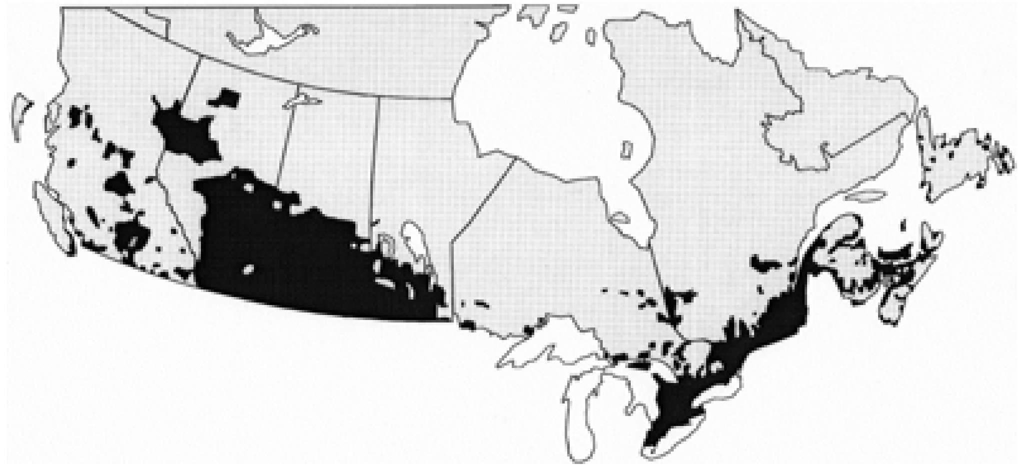

Fig. 2. Distribution of cropland in Canada (blackened area).

Limiting Factors for Agriculture in Canada

All crops grown in Canada (with the exception of greenhouse and cultured mushroom crops) and all potentially new crops are strongly constrained by climate and soil factors (Fig. 3). Of course, length of season, distribution of temperature and precipitation, soil fertility, and physical aspects of land are universal determinants of what crops can be grown. Land use inventories that assess the suitability of land for agriculture, forestry, recreation, and wildlife have been in use for several decades (Statistics Canada 1986). For example, the soil regions of Western Canada differ in the capacity to grow crops. The brown soil in the semi-arid region of the Prairies varies considerably from year to year in crop yield depending on degree of drought, while dark brown soil is not as vulnerable to drought. The black soil retains moisture better than the brown soil, is rarely subject to drought, and produces higher yields. The gray soil zone has higher moisture levels, cooler temperatures, and a shorter growing season. Management practices in the different zones are necessary, since climatic conditions influence the susceptibility of crops to disease and pest infestation.

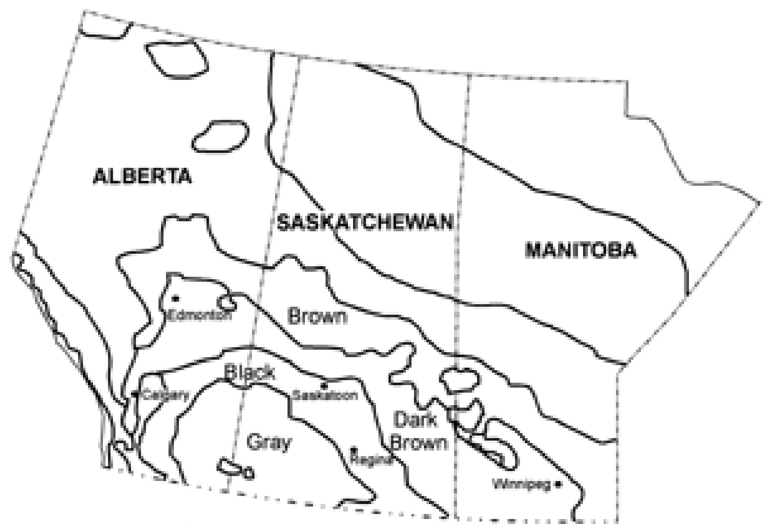

Fig. 3. Principal soil zones of the Western Canadian prairies, Canada's most important agricultural region. These zones heavily influence which crops are advisedly cultivated.

Ideally, knowledge of three factors can be used to produce an excellent identification of what crop should be grown where and when. First, an agricultural knowledge of the growth requirements of crops is necessary. Second, measures of the comparative extent to which local soil, climate, and pests and diseases match the needs of the crops. And third, predictions of markets for the crops, both domestic and foreign. In fact, such detailed budgets are issued by Canada's federal and provincial agriculture departments for various regions (Spak 1998b), and are helpful in making decisions as to what major crops should be planted, especially in the prairie regions described above, for which there are only a few major crops and detailed information is available. In theory, such elegant prediction could be done for every possible crop, so that everyone, everywhere would know exactly what crop to grow. Of course, this is a Utopian scenario, since such detailed knowledge is not available and is only acquired after fairly expensive studies. Nevertheless, it is well to keep in mind that knowledge of both old and new crops is a key to resolving the universal question of farmers, "What should I plant this year?" and indeed the NewCROP website (www.hort.purdue.edu/newcrop) of which this article is a contribution is perhaps the premier source of needed information.

History of Dominant Crops in Canada

Because cereals and oilseeds dominate Canadian agriculture, it is instructive to examine the historical importance of these during this century in Canada. As can be seen from Fig. 4, wheat, oats, barley, maize and flax have been major crops in Canada for at least the last 75 years, and while their relative importance has varied, all have

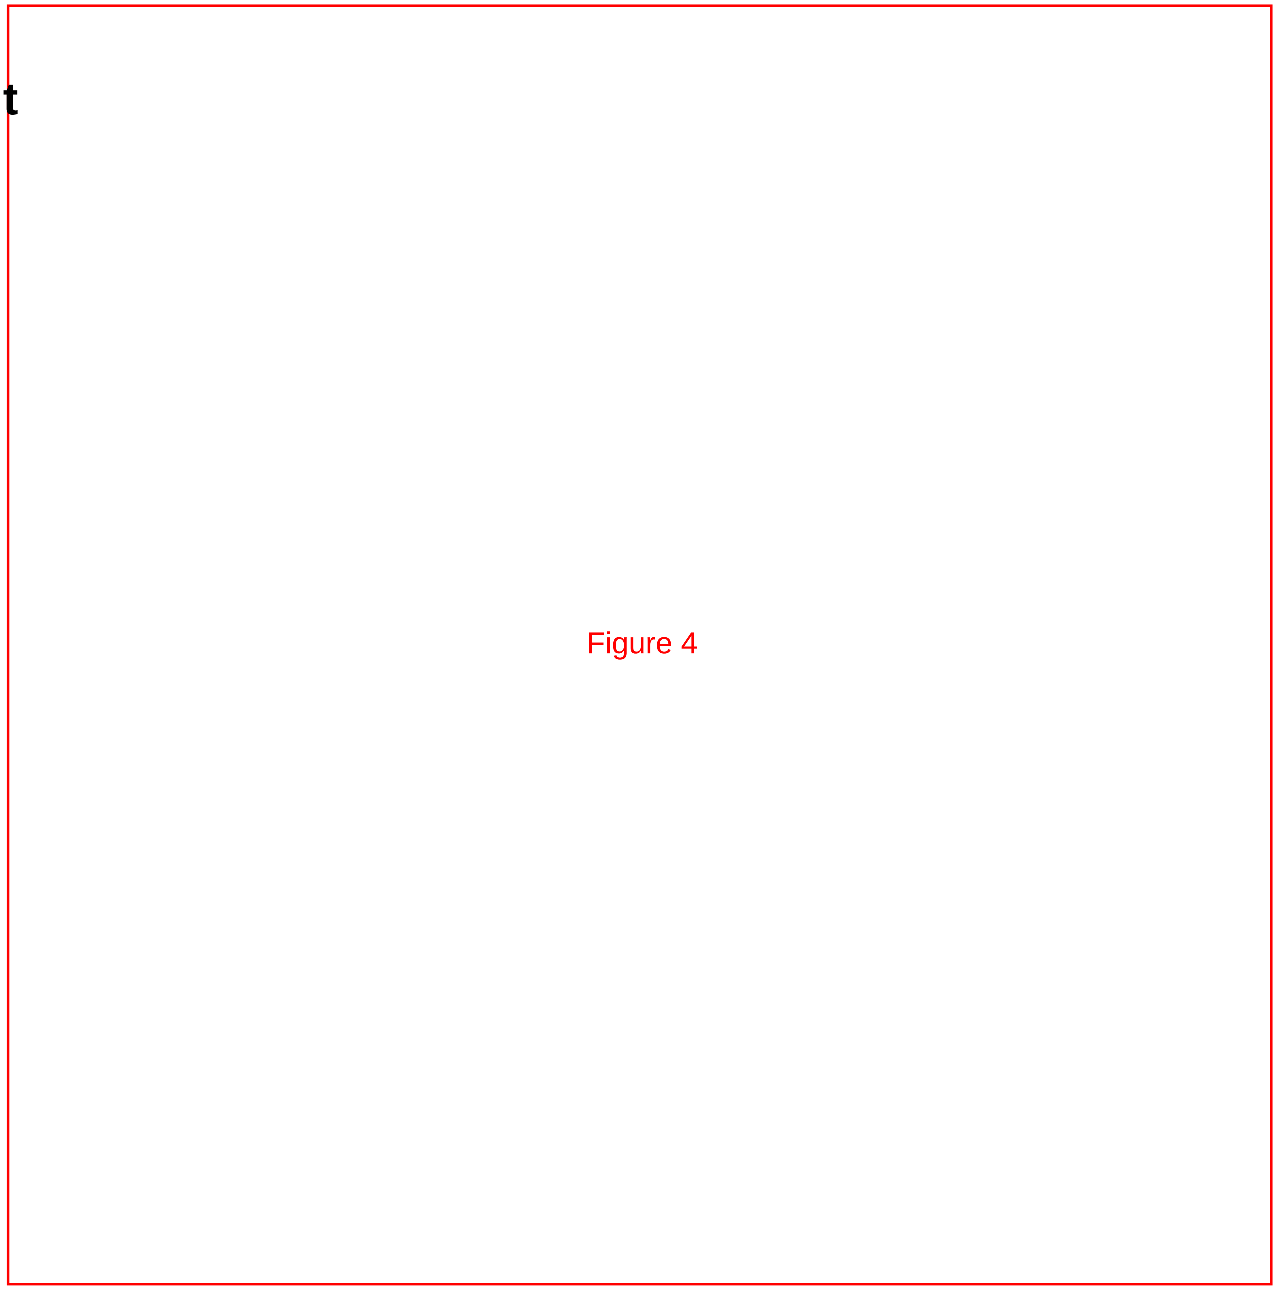

Fig. 4. Areas of the principal cereals and oilseeds grown in Canada for which records are available for all of the comprehensive 10-yearly (1921–1951) and 5-yearly (1951–present) agricultural censuses (data from Statistics Canada 1997a).

remained prominent for many years. No other cereal has become important in Canada, but canola (rapeseed) and soybeans, discussed below, have been the leading Canadian oilseeds for just the last several decades.

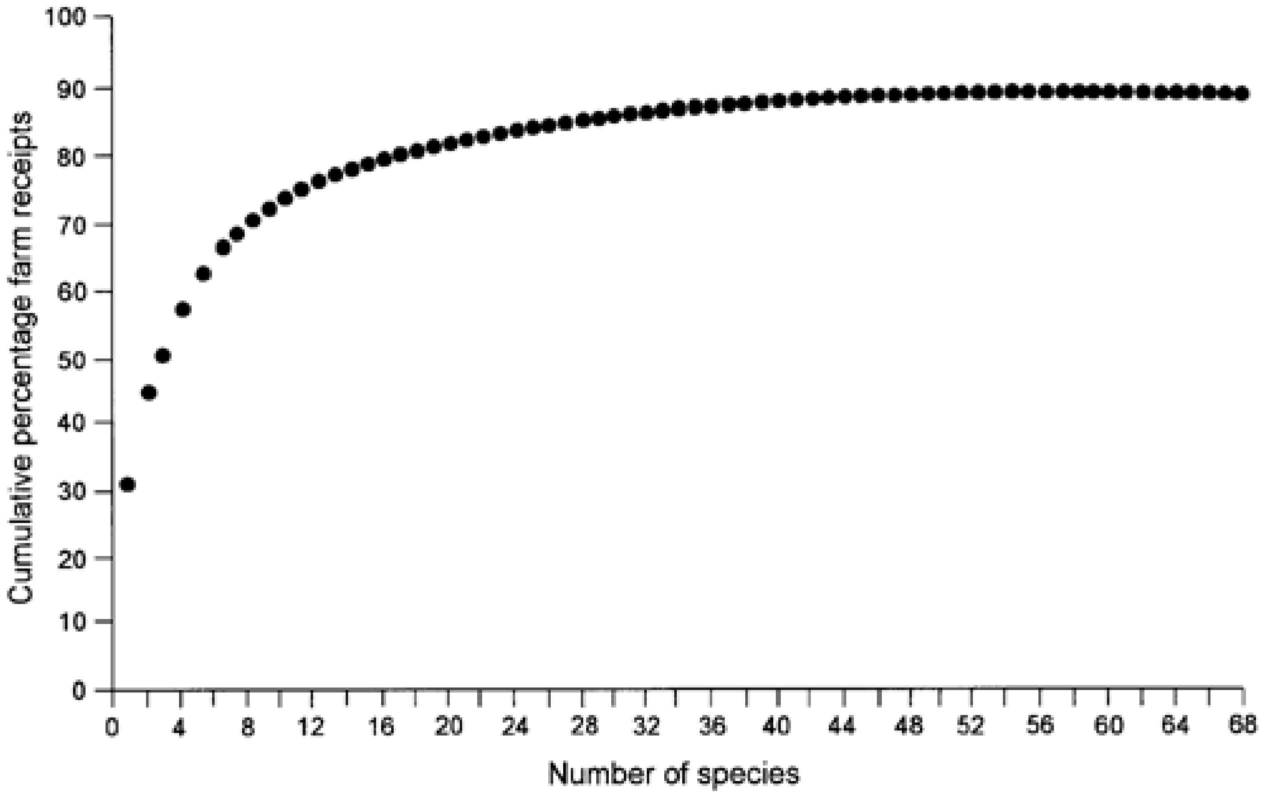

Fig. 5. Progressive cumulative values of the 68 Canadian crops for which national farm gate value or farm receipt statistics are available (compiled from Statistics Canada 1996, 1998a,b).

Fig. 5 illustrates the progressive cumulative value of the 68 Canadian crops for which national statistics are compiled (these range from over 4 billion dollars for wheat to less than 2 million dollars for apricots). This shows that the increased value becomes progressively less as one adds crops to the economy, and superficially it suggests that new crops are not needed. This is an incorrect conclusion for the following reasons: (1) one cannot predict the future value of new crops, which are needed for many reasons; (2) the crops with the highest national incomes are not necessarily profitable; (3) some of the most important crops are not suitable for some regions; (4) farm gate values do not measure the very high value of on-farm use of many crops; (5) farm gate values do not measure the very high value-added aspect of many crops.

Crop Specialization by Region

For simplicity, five regions are discussed, as follows (west to east): British Columbia specializes on fruits (particularly apples) and vegetables, and also has strong livestock and dairy production. The prairie provinces are specialized in grain and oilseeed farms, particularly wheat, oats, barley, canola, rye, and flax. Most of Canada's grazing lands occur in the prairies, and there is a very large red meat industry, with Alberta alone producing half of Canada's beef. Ontario and Quebec are the best areas for maize, and there are strong livestock, dairy, and horticultural sectors. Ontario is the center of soybean cultivation, and there is substantial greenhouse and fruit cultivation. The Maritime (Atlantic) area is particularly suitable for forage crops and an associated livestock industry, as well as potato and fruits such as blueberry. Tables 1 and 2 and Fig. 6 provide summary data for Canada's most important crops, for the five regions, based on crop area and farm receipts.

Table 1. Area of crops grown in Canada in 1996 (based on comprehensive 5-yearly census; excludes Territories; data from Statistics Canada 1997b; in some cases sums for Canada are not additive because of method of data collection).

Crop	Area (ha)					
	British Columbia	Prairie provinces	Ontario	Quebec	Maritime provinces	Canada
Grains						
Wheat	40,146	12,013,427	315,231	34,661	15,801	12,419,264

Relative Importance of Types of Crops

The relative percentage crop area categorized by type of crop (based on Table 1) is shown in Fig. 7. Grains occupy over 60% of Canada's farmland. The oilseeds have about 15% of Canada's farmland, but are a higher-value crop. Forages and fodders occupy about 18% and, along with the coarse grains (barley, oats, maize) and presscake from the oilseeds, contribute to the feeding of the very large livestock population. Vegetables and dry legumes (peas and beans) have only about 3% of the land, but represent very high value crops. In the following discussion of what is new in the crop groups, the length of the treatment is approximately proportional to the importance of the groups in Canada.

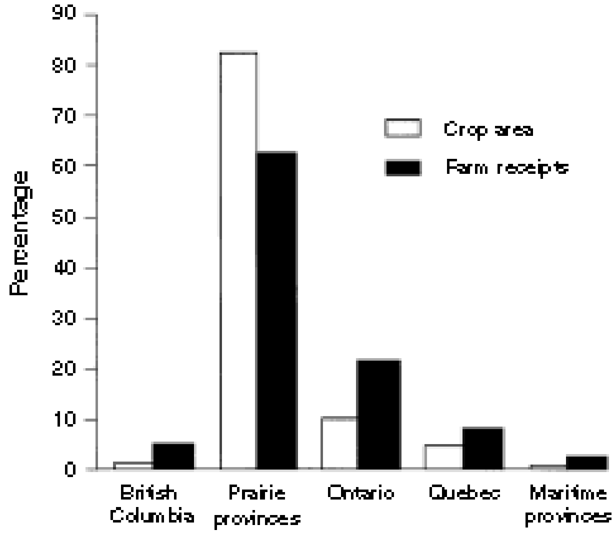

Fig. 6. Relative percentage for crop area and farm receipts for the five regions of Canada discussed in text.

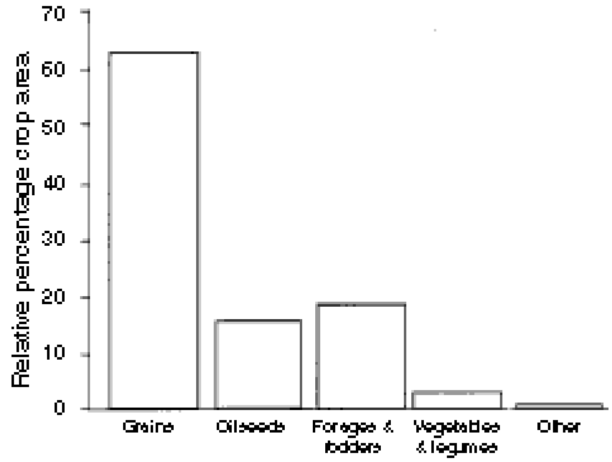

Fig. 7. Relative percentage crop area occupied by the major types of crop in Canada.

GRAINS

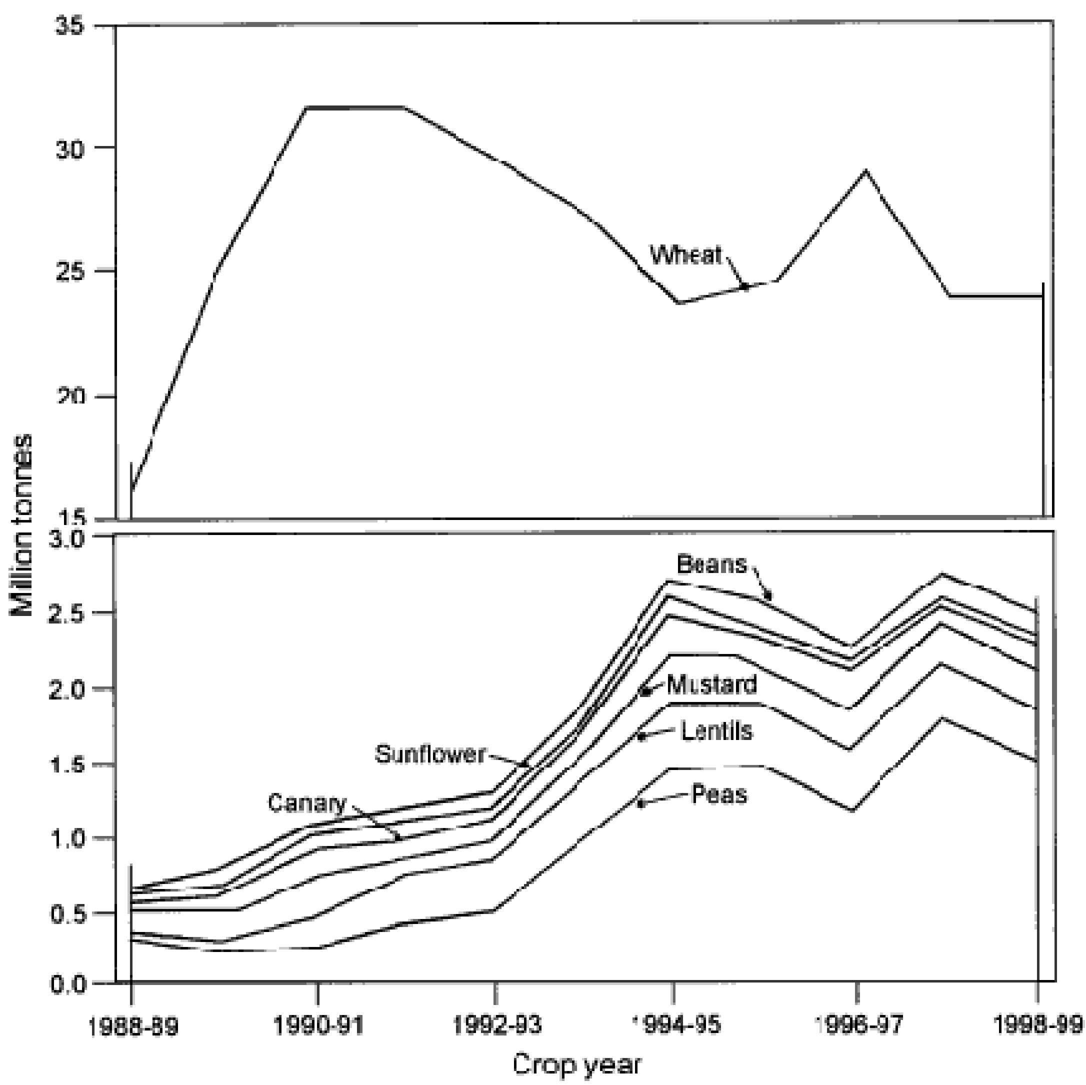
Canada produces about 5% of the world's wheat, 9.9% of the world's barley, 14% of the world's oats, and 1.4% of the world's maize. Canadian grains are used for domestic food consumption, animal feeds and industrial uses, with about half of cereal production exported. The dominance of Canadian crops by the major cereals has been overwhelming throughout this century. As shown in Fig. 4, the total area seeded to wheat increased from 8.2 million ha to 30.7 million ha between 1921 and 1996. Of the 276,548 farms surveyed in the 1996 census, 94,000 (29.4%) grew wheat. The total area of barley increased almost six times to 5.2 million ha between 1921 and 1996; the total area of maize for grain increased more than 12 times to 1.1 million ha. By contrast, the area occupied by oats decreased by over 70% to 2.0 million ha (with an associated drop in the number of horses and ponies from 3.5 million to 444,000). These four cereals represent over 60% of the area currently devoted to crops in Canada, and over 44% of current total crop farm receipts. Most of Canada's maize is grown in Ontario and Quebec, while most wheat, barley and oats are grown in theprairie provinces (Tables 1, 2). Wheat, barley, and oats account for 65.5% of the crop area and 61% of the farm receipts of the prairie region, and canola accounts for another 12.2% of the crop area and 22.7% of the farm receipts. Such dependence on only four crops in the prairies is of particular concern, and not surprisingly it is this important region, which accounts for 62.6% of crop farm receipts of Canada, that one finds the greatest support in Canada for crop diversification. Indeed, in the last decade there has been a concerted effort among grain producers to diversify production to overcome market fluctuations, drought, early frost, and trade wars.

Wheat (*Triticum aestivum* L.)

Wheat and rye are the only grains with the potential to make raised (leavened) breads because their gluten content gives strength and elasticity to bread dough; wheat by far is the most important crop for this purpose. Canada is the world's largest exporter of hard red spring wheat, well known for its excellent milling and baking qualities and for its suitability in blending with lower protein wheats. The typical

Western Canadian growing season of short cool nights and long, sunny dry days is ideal for the production of consistent, high-protein wheat, and normally this type of wheat is priced at a premium to softer and lower-protein wheats. In 1903, William Saunders developed the 'Marquis' cultivar, which set a standard not surpassed until the 1980s by 'Neepawa' of 1987–88. Canadian breeding of superior hard red spring wheat has since been constant. 'AC Barrie', a new, hard red spring wheat was recently released and has proven to be very popular. The three Canadian prairie provinces are the chief wheat-producing provinces of Canada. Canada produces about 5% of the world's wheat, but because of its relatively small population, exports over 75% of its annual production, and accounts for about 20% of the world's wheat exports.

Although hard red spring wheat dominates Western Canada, there have been concerted attempts to breed other types of wheat cultivars, to meet the changing needs of world markets (Dietz et al. 1998). Only a small amount of the class known as "Western Canadian Soft White Spring" wheat is produced in Canada, in part because it requires irrigation in Western Canada. However, there is a very good market for soft wheats, which go into cookies, cakes, crackers, specialty breads, and noodles. The cultivar 'AC Reed' was released from AAFC at Lethbridge in 1994 in an attempt to expand into the soft spring wheat market. AAFC at Swift Current, Saskatchewan, is responsible for the breeding of several recent wheat cultivars of the "Canadian Prairie Spring class:" 'AC Crystal', a high-yielding semi-dwarf red wheat with intermediate protein, and stronger gluten than its predecessors, improving its milling qualities for bread-making (due for release in 1999); and 'AC Karma' and 'AC Vista', white wheats for the oriental-noodle market.



For 1998–99, Canadian non-durum wheat area, mostly spring wheat, declined to 7.7 million ha, the smallest area since 1972 (Fig. 8). In response to wheat surpluses and associated trade problems, many western Canadian farmers have turned to alternative crops (popularly called "specialty crops"). Indeed, this has been the single most important stimulus to crop diversification in Canada, next to the trend of tobacco replacement (Loughton et al. 1991). Figure 8 shows that while wheat area was decreasing, strong compensating increases occurred in the cultivation of the chief specialty crops of the prairie provinces (common bean, sunflower, canary seed, mustard, lentil, and pea).

Fig. 8. Recent increasing cultivation of "specialty crops" (common bean, sunflower, canary seed, mustard, lentil, and pea) in response to decreasing wheat cultivation (above) in Canada.

Durum Wheat (*Triticum turgidum* L. = *T. durum*)

Most types of common wheat can be used to produce bread and Asian-style noodles. For example, bread is produced in most countries from a blend of hard and soft wheats, and where high-protein hard wheat is unavailable, wheat gluten can be added. Durum wheat has an amber yellow endosperm (from which semolina is produced), unlike the white endosperm of common wheat, so that pasta from durum semolina is amber colored. The flavor and cooking qualities of durum pasta are superior, and durum wheat is preferred for the production of pasta products, such as spaghetti and macaroni, and for couscous, the staple food in North Africa. Durum is suited to a dry climate, with hot days and cool nights, and does well under dry conditions. About 8% of the world's wheat production is durum wheat. The leading producers of durum wheat are the European Union, Canada, and the US. Canada is the leading exporter (Lennox 1998). For 1998–99, Canadian durum wheat area rose to a record high 2.9 million ha. In North America, Western North Dakota and southern Saskatchewan are particularly suited to durum wheat, and it is also grown under irrigation in Arizona and the California deserts. Durum wheat, as a crop, compares to common wheat much as alternative and new crops do. It is a relatively high-value commodity with a more stable future in Canada than common wheat. Recently, new technology and consumer taste changes have altered the pasta market toward a stronger, less elastic gluten, particularly in Italy, the main manufacturer of pasta-making equipment, and the country with the most prodigious appetite for pasta. To meet this altered market, new Canadian durum cultivars with stronger gluten content are in the process of being registered for market testing (Anon. 1998b).

Winter Wheat

Winter wheat is the fourth largest crop in Ontario (behind soybean, maize, and tobacco). Ontario is the main producer of winter wheat in Canada, producing about 1 million tonnes annually, using cultivars (e.g. 'Augusta', 'Harus') that can survive the relatively mild winters. Soft white winter wheat is most commonly grown, and this is used for producing soft gluten flour for confectionery products such as cakes, cookies, breakfast cereals, and crackers. Ontario red spring wheat is used primarily for domestic feed, and to a lesser extent for domestic human consumption. Spring wheat is grown somewhat in eastern Ontario, using Western Canadian cultivars, but the quality has often been below the standards demanded by North American millers. In recent years, Ontario wheat growers have been shifting away from traditional soft white winter wheat into both soft red winter and hard red winter wheat cultivars. The shift into hard red wheat is due to the recent availability of new cultivars able to achieve the high protein levels required by the North American milling industry. Improved soft red winter wheat cultivars have also become recently available, and although soft white winter wheat is preferred for the production of breakfast cereals, cakes, and pastry flour, the soft white winter wheat that has traditionally been grown in Ontario suffered a severe fusarium outbreak in 1996, decreasing its popularity. For a review of the changing wheat situation in Ontario, see Lennox (1996) and McKinnon (1997a).

Spelt Wheat (*Triticum spelta* L.)

Spelt is an ancient wheat that has been a staple grain in Ethiopia for centuries. It has become a top-selling organic and health food, grown as a specialist crop, often for people with allergies, and for pasta. Although minor, spelt is increasingly cultivated in Canada, with 825 ha reported in the 1996 Census of Agriculture, mostly in Ontario. Several thousand ha are cultivated in the US.

Triticale (×*Triticosecale* Widdmark)

Triticale is the stabilized hybrid of wheat (*Triticum*) and rye (*Secale*). Poland, Germany, China, and France account for nearly 90% of world triticale production. Globally, triticale is used primarily for livestock feed. In Mexico, which grows the crop, triticale is used mostly for whole-grain tricale breads and tortillas. In the US, triticale is harvested mostly for forage, but there is a small market for pancake mixes and crackers due to a savory, nutty flavor. Ethanol plants will pay a premium for triticale over barley since it has more starch and no hull, making alcohol production more efficient. Although wheat-rye hybrids date back to 1875, it was only in 1953 that the first North American triticale breeding program was initiated, at the University of Manitoba. Although improved cultivars have been bred, triticale has remained unimportant in Canada. However, triticale does well in regions where wheat performs poorly, notably on cold and infertile soils, extremely sandy soils, soils with high levels of boron, salty soils, acidic soils, manganese-deficient soils, and dry soils. Canada does not have large area of such soil types, but there are about 2 million ha of marginal, light mineral, low productivity land in Western Canada where triticale has the potential to displace or supplement traditional feed grain production. Winter triticale is a higher-yielding, earlier-maturing alternative to spring triticale for short season areas of the prairies. 'Pika' and 'Wintri' are the only cultivars found to be suitable for use in Western Canada. Canadian triticale is mostly used for feed and forage. Triticale production in Eastern Canada is growing, with most production in Saskatchewan, followed by Alberta and Manitoba. Forage triticale equals or outperforms barley, oats, rye, and mixed grain in areas of Western Canada, so that there is a reasonable probability that it will become more important. For a review of the triticale situation in Canada, see McKinnon (1996).

Barley (*Hordeum vulgare* L.)

Barley is basically a livestock feed, and is the major feed grain in Canada. Barley is well suited to the Canadian prairies, where most of this crop is grown, while other feed grains such as maize and sorghum are not. Barley is also a good rotation crop with wheat, tends to be higher yielding, matures earlier, and is more resistant to drought and salinity problems. It is also used in brewing beer (see below). Hulless barleys have hulls that are easily removed by threshing, as with wheat. Some hulless cultivars are produced in Canada (such as the two-rowed 'Condor', 'Phoenix', and 'CDC Dawn', and the six-rowed 'Tupper', 'Buck', and 'Falcon'), resulting in more digestible, higher-protein feed, especially for swine and poultry feeding. Pigs and chickens are monogastric (non-ruminant) animals, which are unable to digest the fibrous hull. Barley is useful for most classes of livestock, although poultry lack the enzyme to digest beta-glucans, a water-soluble fiber (this viscous polysaccharide is denatured by adding the enzyme beta-glucanase to the rations; beta-glucans from barley have been shown to reduce cholesterol in people). Although not as palatable as other cereals, some barley is consumed by humans. Barley kernels are polished to remove the inedible part of the grain. "Pearled" barley is highly polished barley; by contrast, "pot barley" is less polished, hence slightly larger than pearled barley. Pearled barley is used in breakfast cereals and infant foods. Hulless barley grains of course already lack much of the inedible portion. Various health advantages have been claimed for human consumption of barley, including benefits for regulating blood sugar levels in diabetics, and for lowering cholesterol and heart disease. A market is emerging for the fractionated components of barley kernels as pharmaceuticals (see Nutraceuticals). Because it is such a major Canadian crop (third-ranking in terms of farm receipts), breeding of Canadian cultivars is given high priority, and new cultivars are constantly emerging. For example, in Eastern Canada where there are frequent strong wind and rain storms and barley often lodges, recent cultivars (the six-rowed 'AC Alma' and the two-rowed 'AB162-9') have strong stems to keep the plants upright.

Malting Barley

About 10% of world barley production is malted, and the other 90% used as animal feed. Malting barley is simply high-quality barley with appropriate characteristics to produce good malt for making beer. Most barley cultivars can be used to make barley malt, but some are specifically bred for the purpose. Two-row malting barley represents the international industry standard outside North America and also in some South American markets. However, six-row barleys are also used. Most malting cultivars are in fact used for feed. About half of Canadian malting barley is two-row. In Canada, three-quarters of the area seeded to barley consists of malting cultivars, the other quarter being feed cultivars, which tend to have higher yields. Growing conditions in western Canada are usually cooler and drier than the US for producing superior six-row malting barley, and so the US has been Canada's major export market for this type of malting barley in recent years. The variable climate on the Prairies sometimes results in only a proportion of the malting barley crop meeting specific malting barley requirements, but as most of the crop is fed to livestock this generally does not compromise the supply for export. China is an increasing importer of Canadian 2-rowed malting barley. The creation of new two-row barley cultivars with improved malting and agronomic performance desired by the export market has been an important development in Canada in the last two decades. Hulless barley cultivars with higher energy content, discussed above, are not suitable for the malting barley process, so that hulled cultivars continue to be grown in Canada. A recent review of the malting barley situation in Canada is McKinnon (1997b).

Oats (*Avena sativa* L.)

Before 1910, the area seeded to oats often exceeded the area for wheat in Canada, in order to feed horses. Up until 1920, the area for oats was similar to wheat area in Canada, but from the early 1920s to the late 1970s, with the introduction of tractors and the replacement of horse power by machine power, the area seeded to oats decreased steadily until the 1970s. Since the 1980s, Canada has consistently captured a significant share of the world export market. Oats are still used primarily as animal feed, but human consumption is increasing, especially in North America, where oats are considered healthy, especially oat bran (see Nutraceuticals). In the US (and to a lesser extent in Canada), oats is used somewhat for pasture, silage, and haylage, and especially as a cover crop to protect soil, notably on marginal land subject to erosion, and as a nurse crop to protect newly planted forages. The world's leading oat producers are Russia, the European Union, Canada, the US, and Australia. Canada is a leading exporter, in 1997–98 accounting for almost half of all world oat exports, excluding products, 95% of this to the US. In 1997–98, about 1.9 million ha were seed to oats, an area exceeded only by wheat, barley, and canola. Over 90% of production is in Western Canada, and this represents a shift from Eastern Canada where oat cultivation has become less economical as a feedstuff. A further shift has been from the Western to the Eastern Prairies, closer to the major oat market in Minneapolis. The cool growing season on the northern Prairies where oat production is concentrated is a problem, being addressed by continuing plant breeding. Alberta is Canada's major oat producing province, and most of the crop is grown in the north in the grey woodland soil, which is quite acidic, freeing up aluminum, which reduces yield by up to 40%. There is currently research (at AAFC at Lacombe) to breed aluminum-tolerant oats to meet this problem. Oat breeding in Eastern Canada, incorporating new molecular techniques, is a specialty of AAFC at Ottawa. Oats are less likely to be traded than other grains because their bulky nature increases transport costs. Oats are about 25% hull, and offer less energy than barley and maize, limiting their use primarily to starting feedlot rations and for feeding horses. Hulless or naked oats, which lose their hull during harvest, have promise as a feed ingredient. 'AC Lotta', 'AC Percy', and very recently 'Cavena' from AAFC at Ottawa are Canadian cultivars. Hulless oats have higher protein and fat than conventional oats, as much energy as maize, and a better balance of amino acids, and have good prospects as a new Canadian crop. Another new trend is the industrial use of oats in Canada, with the establishment of a processing plant in Saskatoon that refines oat extracts used in products such as animal coat washes and diabetes screening tests. In the past 15 years, oat products have increased from virtually nothing to an estimated 200,000 tonnes for 1997–98. A recent review of trends in the Canadian oat crop is McKinnon (1998).

Maize (*Zea mays* L.)

Maize has a very long history of cultivation in Central Canada, dating back over a thousand years. With the introduction of US higher-yielding maize hybrids in the mid 1950s, commercial production expanded in the southernmost regions of Ontario. New cultivars of maize have been instrumental in Canada in lowering susceptibility to early frosts and avoiding harvest problems. With the continual development of Canadian hybrids for cooler and shorter growing seasons, commercial maize production spread beyond southern Ontario, and today maize is widely cultivated in Ontario and Quebec, with limited production in Nova Scotia, Manitoba, and Alberta. About three-quarters of Canada's maize is produced in Ontario and Quebec. Maize is primarily a feed ingredient in Canada, with Central Canada accounting for the bulk of consumption (barley is the major feed grain in Western Canada). Fodder maize, used mainly for silage, requires less heat units and has a wider growing range than grain maize. Fodder maize is generally grown for on-farm use. There is a trend for increasing food and industrial use of maize in Canada (see discussion of ethanol production, below). Canada is normally a net importer of maize, with western Canada acquiring it from the US. For a review of the maize industry in Canada, see Kurbis (1996b).

Canary Seed (*Phalaris canariensis* L.)

Canada is the world leader in the production and export of canary seed from annual canary grass, used in caged and wild bird food mixtures. Commercial production of canary seed started in the US after World War II, concentrated in Minnesota and North Dakota, and production moved to Manitoba and Saskatchewan to become commercially viable in the early 1980s. In 1996, Canada produced 90% of the world supply of canary seed, about 90% in Saskatchewan, the remainder in Manitoba and Alberta. Canary grass is extremely well adapted to the hard red spring wheat of the Prairies, although more sensitive to heat and drought. Ten to 30% of production is used domestically, the remainder, about 125,000 tonnes, is annually exported, largely to Europe, South America, and the US. Canary seed is suited to and mainly produced in the brown soil zone of Western Canada. Substitute bird seeds with the quality of canary seed are generally unavailable (there is occasional substitution with proso millet from the northern US) and, with increasing interest in birds as pets, long term growth of the industry seems assured. A new cultivar known as 'CDC Maria' was recently developed by the University of Saskatchewan's Crop Development Centre. This is expected to revolutionize the industry, eliminating problems such as itchiness and dust associated with the hairy seed coat of older cultivars. 'CDC Maria' and other "hairless" cultivars are expected to replace the traditional canary seed cultivars, which can not be used by humans for food because of the hairs. Dehulled canary seed can be processed into flour and bran, and in addition to this food potential for humans there is some potential for cosmetic purposes. A recent review of the canary seed situation in Canada is Gray (1997b).

Rye (*Secale cereale* L.)

Rye is a relatively minor cereal in Canada, which is perhaps surprising since it has the ability to withstand unfavorable growing conditions and often thrives where other cereals fail. Although rye can have a higher feed value than barley, the high soluble fiber content (pentosans) reduce feed value for poultry and swine. Although Canada is one of the world's major rye exporters and produces high-quality rye, the world market is small, and Europe grows the crop well, mostly for making bread. In Canada, rye is grown mainly for grain, but also for pasture and hay. Fall rye also provides soil cover from fall through spring. There is limited domestic use of rye in Canada for distilling and for food use, compared to the other cereals discussed above. Several new breeding lines of winter rye were recently bred at AAFC at Lethbridge.

Proso millet (*Panicum miliaceum* L.)

Proso millet has long been a staple grain in Africa, and has been grown as a forage crop. This sorghum relative is used mostly in the pet food and birdseed industries in North America, but may have some potential as a Canadian grain for human consumption. 'AC Prairie Gold', a millet line adapted to prairie growing conditions, was recently released by AAFC at Morden. While only 1000–2000 ha are currently grown in western Canada, the potential for proso millet has been estimated to be 10,000–15,0000 ha or more (Kiehn and Reimer 1992).

False Melic Grass [*Schizachne purpurascens* (Torr.) Swallen]

This widespread native grass of Canada produces large grains. It has been suggested that it could be developed into a special cereal like wild rice (Dore and McNeill 1980), although this would require considerable development.

Wild Rice (*Zizania palustris* L.)

Wild rice (not to be confused with wild forms of *Oryza sativa* L.), Canada's only native cereal, is collected from natural or planted stands, particularly by indigenous people (Aiken et al. 1988; Crop Development Centre 1991). It requires considerable development, but is well suited to Canada. Wild rice is an economically attractive crop in that the supply is limited while market demand is increasing, a premium price can be obtained, and the climate and natural aquatic habitats of portions of Canada provide competitive advantages. Semi-domesticated paddy wild rice is in commercial production in California and Minnesota, and provides competition for Canadian producers. However, a natural advantage for Canada is the availability of extensive shallow lake and river systems, which usually do not require much if any drainage control. For wild rice to expand as a crop in Canada, development of non-shattering, disease-resistant cultivars is needed. Fast-maturing strains would be an added advantage for northern regions so that seeds would mature before frost.

Buckwheat (*Fagopyrum esculentum* Moench)

Common buckwheat is grown in many major grain producing countries, especially Russia and China. Major exporters are China, Brazil, France, the US, and Canada. Japan accounts for almost all of the world's buckwheat imports. Buckwheat has been grown in Canada for many years as a special crop, and is an important cash crop in Manitoba, but production is currently low. However, this crop presents opportunities for diversification and value-added activities because the Japanese market is growing. In Japan, buckwheat flour is employed in combination with wheat flour to prepare buckwheat noodles (*soba*), a traditional dish. In some cases, Japanese noodle manufacturers add ground leaves to the buckwheat flour, producing a green noodle. Only about 10% of Canada's buckwheat production is used domestically for human consumption, but this could increase if processors develop new buckwheat products such as snack foods and flour for cr•pes. Buckwheat can be grown as a green manure crop, companion crop, cover crop, and as a source of dark buckwheat honey. The grain and straw can be used for livestock feed, but the nutritive value is lower than that of cereals. The protein in buckwheat flour is of exceptional quality, containing a high amount of lysine, which is deficient in cereals. Foods are prepared from the groats (dehulled seed) or from the flour. The low gluten content of the flour makes it ideal for crêpes, and in mixtures with wheat flour for bread, pancakes, noodles, and breakfast cereals. Groats and grits (groat granules) can be used for porridge and other breakfast cereals. Dehulled groats can be baked or steamed and eaten as a vegetable like rice, or used in appetizers, soups, salads, breads, and desserts. Development of new Canadian cultivars is occurring to counter climatic disadvantages associated with buckwheat production in Canada. The main buckwheat cultivars grown in Canada are 'Mancan' and 'Manor', developed by AAFC at Morden. 'Mancan' is employed as a quality standard by Japanese millers because of its soft white starch. 'Manisoba' is a new, higher-yielding cultivar with a larger seed that is easier to dehull, leaving behind high whole groat content. 'Manisoba' also facilitates popping the seed, like popcorn, to prepare some specialty products. Western Canadian cultivars are not well adapted to eastern Canada, and a high portion of growers in Ontario and Quebec cultivate buckwheat simply as a green manure crop or a cover crop to crowd out weeds. Research is underway to improve buckwheat cultivars in Quebec and Ontario, where lodging is a frequent problem due to excess moisture. Unlike most cereal crops, buckwheat cannot recover from lodging. There has been considerable recent governmental and grower association encouragement to increase production and marketing of buckwheat in Canada. New proposed value-added activities include dehulling, flour-making, noodle making, and roasting for snacks. Buckwheat produces rutin, which increases the elasticity of arteries and prevents their hardening, and is in demand by the pharmaceutical industry. Scientific research on buckwheat is centered at AAFC Morden. Recent achievements include the development of a self pollinating buckwheat with extremely low seed abortion and better frost tolerance. This is expected to result in a new cultivar in the next several years. A high-yielding self-pollinating experimental strain was recently bred in Manitoba (Henckes and Dietz 1997). A good review of buckwheat in Canada is Vincent and Longmuir (1996).

Quinoa (*Chenopodium quinoa* Willd.)

Quinoa originated in the highlands of Peru and Bolivia, where it became a staple crop of the Inca empire. By comparison with most cereals it is rather primitive, requiring dehulling to remove bitter seed coat saponins. Considerable quinoa is sold in Canada as a gourmet item in health food stores, in the form of whole grain, pasta, or flour. Quinoa is considered to have some promise for Canada, and there is a Canadian Quinoa Association (Anon. 1992). Currently available forms are late-maturing, therefore vulnerable to frost, and are also susceptible to insect damage. Quinoa would appear to have some possibility for development through germplasm selection in Canada, but is likely to find a more receptive area of cultivation in other countries. In the US, quinoa seems to represent one of the relatively few apparently successful introductions of a new food plant (Johnson 1990).

Amaranth (*Amaranthus hypochondriacus* L. = *A. leucocarpus* S. Watson)

Grain amaranth, a pseudo-cereal, is another ancient grain used similarly to quinoa. This dietary staple of Aztec and Mayan civilization is still grown in South and Central America, where it originated, and is used as a vegetable in India and China. The seed can be popped like popcorn and flaked like oatmeal, and is notably high in protein. Amaranth is enjoying a renaissance in popularity in North America. It is sold in health food stores, particularly when organically grown, but has achieved little market status. Amaranth has been experimentally cultivated as an annual grain at AAFC at Morden, and has been thought to have fair long-term potential in the southern Canadian prairies (Kiehn and Reimer 1992). Its future in the US has been considered debatable by some (Lehmann 1991), promising by others (see articles in previous proceedings, particularly *Advances in New Crops*, 1990).

OILSEEDS

Oilseeds tend to be higher-value crops than cereals, and are useful as alternatives in crop production and market diversification. Canola, flaxseed, and sunflower seed are particularly considered to be major cash crops for Western Canadian producers, especially when grain markets are poor. In 1996 the farm value of oilseed production in Canada was estimated at $2.883 billion. In addition, oilseed processing contributed $0.5 billion in direct value-added and over $1 billion in spinoff benefits to the Canadian economy. The meal left after oil extraction is also of considerable importance as livestock feed and, as noted below, the grain itself may be a useful animal or human food. In 1997, total vegetable oil production in Canada reached a record level of 1.6 million tonnes, with canola oil accounting for 77%, soybean oil for 17%, linseed oil for 3%, and sunflower oil for 1%. Several of the world's major edible oils, including palm oil, cottonseed oil, peanut oil, coconut oil, olive oil, and palm kernel oil, simply cannot be produced in the climate of Canada, which imports these commodities. Nevertheless, Canada has been a net exporter of vegetable oil since 1992, but this is mostly due to canola exports, especially to the US. In 1997, Canada was responsible for 43% of total world rapeseed/canola oil exports, 10% of linseed oil exports, and less than 1% of soybean and sunflower oil exports. Generally, there is strong regionalization of cultivation of Canada's oilseed species, as noted below. Attempts are underway in Canada to breed new oilseeds (most notably edible oil mustard and edible oil flax, as discussed below). There is also considerable research in Canada to develop new and improved cultivars, which may result in the major oilseeds being cultivated in regions where they are now absent or little grown.

Most of the world protein meal supply is derived from oilseed production. Oilseeds tend to produce meal that differ in their ability to meet the nutritional requirements of the different livestock categories. For example, non-ruminant livestock such as hogs and poultry need high protein feed without the high fiber content suitable for ruminant animals. Small but growing markets for protein meal include the fish feed market (aquaculture) and direct human consumption. Good dietary practice for livestock involves a complementary balance of the base grains of feed rations (such as wheat, barley, and maize), the various high-protein meal supplements, and grass and legume forage/silage crops. Canola meal, Canada's major meal, can be used up to maximum levels in feed rations of 20% for poultry, 15% for grower and finisher hogs, and 25% for dairy cattle.

Canola (*Brassica napus* L., *B. rapa* L.)

Oilseeds in Canada are currently dominated by canola (rapeseed), a high value crop cultivated by some 80,000 farms, that has become Canada's second most important crop after wheat. Canola (a trade-marked name) is primarily used in salad and cooking oils, margarine and shortening, and the mealy residue after the oil is extracted is used in livestock feeds. The 1996 census data show that canola accounts for 75% of all vegetable oils produced in Canada, 87% of salad oils, 49% of margarine oils, and 64% of shortening. The development of the canola industry is the premier example of a successful new crop for Canada. The breeding of new edible oil cultivars occurred as a focussed investment strategy that involved over 200 scientist years, costing $40,000,000, spread over 30 years (Jolliff and Snapp 1988). Canola is a relatively new Canadian crop, having begun with rapeseed cultivation in 1942 in Western Canada as a source of lubricants for the allied war effort. Today, a small area of high erucic acid rapeseed in still produced in Canada to satisfy the industrial market. Limitations of nutritional composition of available wartime cultivars restrained human consumption in Western countries. In the mid-1970s, AAFC and the University of Manitoba produced new cultivars, now known as canola, with less than 2% erucic acid and less than 30 micromoles/g of aliphatic glucosinolates in the meal (current levels have been further reduced, respectively to less than 1% and less than 20 micromoles/g). From 1976 to 1996, the total area of canola increased over five times to 3.5 million ha, representing 10% of Canada's total land in crops. In 1985, The US Food and Drug Administration granted canola GRAS (Generally Recognized as Safe) status, and in the light of its superior nutritional characteristics, canola oil sales to the US increased from virtually nil to over 400,000 tonnes annually. About two-thirds of Canada's exports of canola are to the US. Canola seed and meal sales to the US also increased along with canola oil sales. Canola oil's nutritional properties are responsible for its domination of the salad oil market: of the commercially available edible oils, canola contains the lowest levels of saturated fats (6%), the second highest level of monounsaturated fats (58%), and the highest level of the essential fatty acid, linoleic acid (10%). Globally, Canada produces about 17% of the world's rapeseed.

Given the controversy over the public acceptance of genetically-engineered foods, it is perhaps surprising to learn that close to 50% of the cultivated canola area in Canada consists of transgenic cultivars carrying selective resistance to specific herbicides. There are several new types of canola that are currently being bred and may well have a place in Canadian agriculture. "Super-high erucic acid rapeseed" is a type of genetically modified oilseed. A derivative of erucic acid, eruacmide, is used as a slip agent and plasticizer in the manufacture of plastic films. Other types of products that may be produced include cosmetics, lubricants, pharmaceuticals, plasticizers, and surfactants. "Odyssey 500" high stability oil is another product that may become useful. This is over 20 times more stable than conventional vegetable oils. It remains liquid at lower temperatures than other highly stable oils, and has no flavor or color. It may be useful as a moisture barrier, viscosity modifier, gloss enhancer, anti-duster, and band releaser. Still another new type of canola oil that offers stability, long shelf life, and fresh flavor is a high oleic oil, "Clear Valley 75." This has been praised for its desirable combination of taste and nutrition. It has the lowest level of saturated fats, no trans fatty acids from hydrogenation, and bland neutral taste that makes it ideal for cereals, popcorn, dried fruit, and crackers (Beckman 1998).

The most exciting new prospect in Canada for canola is the breeding of mustard (*Brassica juncea* Coss.) into a new canola species. To date, canola has been represented by the two *Brassica* species *B. napus* (Swede rape) and *B. rapa* (*B. campestris* L., turnip rape). For the past decade, research has been in progress in Canada toward the breeding of a drought-resistant canola-grade mustard. Canola cultivars presently available are not well suited for many of the relatively dry regions of Western Canada. By contrast, mustard cultivars have several advantages: higher-yielding in all but the short season regions of Western Canada, early maturing, more resistant to late spring frosts, more heat and drought tolerant, more resistant to seed shattering, and more resistant to blackleg disease. *Brassica juncea* is in fact used as an edible oil crop in China, India, Russia, and Eastern Europe, where an oil with higher levels of erucic acid is permitted, but this is not accepted in most Western countries. Moreover, the high glucosinolate meal has limited use for animal feed. Researchers at AAFC, Saskatoon have developed a mustard plant whose seeds contain meal and oil indistinguishable from canola (Anon. 1998a). A new cultivar may be available by 1999. Given the spectacular success of canola, this could represent an important new crop that would extend the region of the Prairies where canola-class plants can be grown. For marketing purposes, this new crop could be represented as canola, since the products are about identical. A hurdle that remains is the obtainment from the US of a GRAS designation, a necessity to remove trade restrictions. The fortunes of canola rose dramatically after it obtained GRAS status in 1985.

Soybean [*Glycine max* (L.) Merr.]

Soybean was first cultivated in Canada in 1893, but not in significant amounts until the late 1920s. Most soybeans are currently grown in Ontario (90%) and Quebec (9%). In the mid-1970s, it was almost impossible to find soybean growing in Eastern Ontario because of the inhospitable climate. 'Maple Arrow', a cultivar bred at AAFC Ottawa, provided the key adaptation for soybean to be transformed into the biggest cash crop in Ontario, where it is known as the "miracle crop." Most soybeans are used domestically in Canada, and the increase in the domestic supply has meant that imports from the US are usually equaled by exports. Soybean oil is used in a huge number of products, for example in the manufacture of edible oils, and in industrial products such as paint, varnish, resins, and plastics. Soybean meal is an important livestock feed, although half of Canada's supply is imported (unlike canola which is crushed mainly for its oil, soybeans are processed primarily for the meal). Most of Canada's soybean feed goes to the hog and chicken industries. Due to the presence of enzymes, soybeans must be roasted before being fed to livestock. Canadian research is attempting to eliminate the need for roasting, and has resulted in a reduction in the levels of the deleterious enzymes so that whole unroasted soybeans have become a significant constituent of livestock rations in Eastern Canada. Canadian cultivars have been bred with qualities required by specific soyfood markets of the Asia Pacific region. The large-seeded, white, high-protein types are prized by southeast Asian markets. Cultivars such as 'Special Quality White Hilum Beans' are exported for processing into tofu, natto, misto, and tempe in Asian markets. 'AC Onrei' is a very large-seeded high-protein cultivar suitable for top-quality nigari tofu. 'OX756' is another line produced by AAFC at Harrow designed to expand exports into the premium Asian soy food market. This is low in enzymes that cause a grassy-beany flavor that some consumers dislike. Genetically modified soybean cultivars are prevalent in the US, and are likely also to be established in Canada. As with other genetically modified crops, there is some public resistance to acceptance of human foods produced from transformed plants, especially in Europe, and this may affect the future development of export markets.

Flaxseed (*Linum usitatissimum* L.)

Flaxseed is generally known as linseed outside of North America, where the name flax refers to the fiber form of the crop used for the linen textile industry. Flaxseed was the first oilseed widely grown in Western Canada, and today the fiber form is cultivated only in very small amounts. Canada is the world's largest producer and exporter of flaxseed. Only a small proportion of Canadian flaxseed is crushed domestically. Canadian flaxseed is produced entirely in Western Canada, mostly in Saskatchewan. Flaxseed represents only 1% of the world supply of oilseeds, but as noted in the following is considered to have high potential for increased industrial use, as well as for human food and feed markets. Flaxseed (linseed) oil is a non-edible drying oil used in manufacturing paints, varnishes, linoleum, printing ink, oilcloth, putty, and plastics. The introduction of petroleum-based floor coverings and latex-based paints resulted in a worldwide decrease of the industrial use of linseed oil for paint and floor covering over the last several decades. Nevertheless, industrial use is expected to increase because of the development of new products. The biodegradability and non-allergenic characteristics of linoleum, coupled with quality improvements, have resulted in a resurgence of demand for linoleum in some parts of Europe. There has also been interest in using a linseed oil based concrete sealant. More significantly, there has been recent research into the development of edible oil-type flaxseed or "Linola" as a vegetable oil, and this market is likely to increase in Canada. Linola lines lack the high amounts of omega-3 fatty acids of conventional flaxseed lines, which makes them less nutritional, but they are more stable at high temperatures and less likely to go rancid, and so more competitive in the vegetable oil market. There has been much interest in Canada in the pharmaceutical value of edible linseed. It is well known that hardening of the arteries, heart disease, and strokes have been dietarily linked to overconsumption of saturated fats. It is much less well known that an unbalanced ratio of polyunsaturated fats has the same effects. The ratio of two polyunsaturated fats is considered particularly important—omega-6 and omega-3, recommended in an intake ratio of 3:1. Average dietary ratios in North America range between 12:1 and 20:1. Flaxseed is generally high in alpha linolenic acid, an omega-3 fatty acid, and has an omega-6/omega-3 ratio of 0.3/1, and so is extremely helpful in balancing the ratio to a healthy level. Omega-3 fatty acids lower levels of triglycerides in the blood, thereby reducing heart disease, and also show promise in the battle against inflammatory diseases such as rheumatoid arthritis. Poultry eating feed rations enriched with flaxseed produce eggs that are notably lower in saturated fat in the yolk. Full-fat (whole) flaxseed is in demand by the laying hen market. About 5% of Canadian laying hens are in fact consuming 10–20% flax in their rations, and so producing eggs that are relatively desirable in their balance of polyunsaturated fatty acids. About a dozen Canadian companies are now selling omega-3 eggs, and several US companies are following suit (Henckes 1998a). Dairy cows fed with flaxseed can produce omega-3 enriched milk and butter, and beef and chicken can be similarly enriched, although how practical this is remains to be determined. Crushing flaxseed for linseed oil produces meal/cake that serves as protein supplements in livestock rations, mainly in Western Europe. Flaxseed has been used extensively in baking in Germany and other central European countries, and there is a growing and highly profitable niche for flaxseed bakery products in North America, especially for specialty breads. Since the early 1990s, there has been some cultivation of 'Solin', a light-colored low-linolenic acid type of flaxseed that has a fatty acid profile similar to sunflower oil. New uses for flaxseed fiber are currently being developed. About $20 million of flaxseed fiber and tow were exported from western Canada to the US in 1995, but only 15–20% of available Canadian flaxseed straw is so used because of high transportation costs in moving the flaxseed straw to the processing plant, and the majority of straw is usually burned on the field. There is increasing interest in Canada in using high-quality fiber for fiberboard and similar application (see discussion below), so that a larger market for flax fiber may develop. For a review of flaxseed in Canada, see Beckman (1997).

Mustard [*Brassica juncea* (L.) Czern. & Coss., *Sinapis alba* L.]

Mustard is both a condiment and an oilseed crop, and has been grown in Canada since 1936. There are two species grown, *Brassica juncea* (brown and oriental mustard), and *Sinapis alba* (yellow or white mustard). Mustard has been an exceptional success in Canada, with an average of about 200,000 ha producing an average of 250,000 tonnes of seeds, most of which is exported. How much growth there remains for this crop remains to be seen. A small percentage of Canadian mustard is crushed locally, and some is ground to produce mustard flour, mostly for export. Canada is the world's largest supplier of mustard seed, exporting the seed to Japan, the US, Europe, and Bangladesh for use as a condiment. Nearly 40% of Canada's exports of mustard seed goes to the US, but America is increasing its seeded area. Bangladesh, Canada's second-ranking export destination, crushes mustard seed to produce a hot edible oil that is popular in the Indian sub-continent. A small shift from yellow mustards to brown and oriental mustards has been predicted in Canada (Gray 1998).

Sunflower (*Helianthus annuus* L.)

The first official government breeding program of sunflower in Canada was initiated in 1930. However, as for rapeseed, commercial cultivation began during World War II as a response to the vegetable oil shortage. Sunflower is grown in relatively small amounts, mainly in southern Manitoba and southeastern Saskatchewan, and it has become a minor "specialty" crop in the cereal areas, serving as an excellent rotation crop for wheat that reduces diseases of the latter. About half of current sunflower production is destined for the confectionery market, 40% is crushed for oil, and 10% is used for bird feed. The residual oil-cake or high-protein meal produced after oil extraction is used for animal feed. About 30% of Canadian production is exported, the US accounting for about 70% of exports, the remainder largely to Germany, Belgium, the Netherlands, and Turkey. Confectionery type seeds have striped hulls, and the largest forms are used for human food. Sunflower seeds can be roasted and salted or baked into bread products for human consumption. Oil-type Canadian sunflower seed cultivars (which can also be used for birdseed) are characterized by black hulls. In the early 1990s, sunola, a short-stemmed drought-resistant type of oilseed sunflower that can be grown as a field rather than a row crop, was introduced into the Canadian prairies, and production of this has since been expanding (Anon. 1994). However, the area of sunflower seed cultivation has been fluctuating, generally declining in Canada for the last decade. Minnesota, North Dakota, South Dakota, and Texas are presently superior sites for growing sunflower. Sunflower has not become a major source of vegetable oil in Canada because it is susceptible to diseases, has a longer growing period than desirable (120–130 days), needs specialized equipment, and is relatively expensive to produce. The latter two problems are due to the need to row crop sunflower, because of its tall height, and this requires specialized seeding and harvesting equipment, which represents additional capital costs to the producer. New types of sunflower are needed to overcome these problems. To some extent recent sunflower hybrids with earlier maturity, increased yields, and shorter stalks have generated some expansion, but Canadian production remains limited due to the high heat and moisture requirements of the plant. The sunflower situation in Canada is reviewed by Christie (1995a).

Safflower (*Carthamus tinctorius* L.)

Safflower is a crop that is deserving of attention because of its versatility. It can be grown for edible oil, meal, or whole seed for dairy cattle, birdseed, and oil for industrial uses. Safflower oil is a wholesome oil, high in polyunsaturated fatty acids, that because of its high linoleic acid content commands a premium price among edible oils, and is competitive from a health viewpoint with canola and olive oil. The cool climate of the Canadian Prairies tends to increase the level of oleic acid (e.g. to over 80%, compared to about 73% in California). Industrial uses are limited, but the drying oil produced by safflower, which is intermediate between soybean and linseed oils, can be used in non-yellowing drying paints, alkyd resins in enamels, and caulks and putties. Because it is a long season crop, safflower extracts water from the soil for a longer period than cereal crops, and the long taproot can draw moisture from deep in the subsoil. These properties can help prevent the spread of dryland salinity, using up surplus water from recharge areas that otherwise would contribute to the development or expansion of saline seeps.

Commercial cultivation of safflower began in Alberta in 1943 when wartime new crop adaptation research was in progress, and currently is concentrated in Alberta and southern Saskatchewan.

Production on the Prairies was sporadic from the 1950s through to the 1970s, but in the early 1980s contracts were obtained in southern Manitoba and southern Saskatchewan to produce safflower for processing facilities in Culbertson, Montana. The US cultivars used up to that point were too late in maturing and had severe disease susceptibility, and these problems led to a drastic reduction in cultivation in Manitoba. Most current Canadian cultivars are low in oleic acid and high in linoleic acid, and therefore more appropriate for the birdseed market, and in fact the Canadian safflower crop is currently used as birdfeed, mostly in the US. Oilseed safflower expansion depends on the development of adapted, high-oleic cultivars with high content of oil, improved seedling establishment, and active export efforts and/or a local oil processor becoming established. 'Saffire', the first Canadian safflower cultivar, is a good birdseed cultivar released in 1985, that has a total oil content of only 32%, generally too low for the oilseeed market. A more recent (1991) cultivar, 'AC Stirling', is a dual-purpose birdseed/oilseed cultivar averaging 35% oil, and is considered to have the capability of expanding the oilseed market.

Other Oilseeds

Crambe (*Crambe abyssinica* Hochst. ex R.E. Fries = *C. hispanica* L.), a cool-season annual originating from Ethiopia, has been raised in large areas in North Dakota. Meadowfoam (*Limnanthes alba* Hartw.), a winter annual, originates from and is adapted to the Pacific Northwest of the US, where it has been grown. It has also been grown on Vancouver Island. Both crops seem suitable for Canada. It is too early to judge the potential of these experimental oilseed crops, although the relatively large investments in relation to limited commercial success to date in the US and other countries are discouraging.

PULSE CROPS: DRY BEANS AND PEAS

Pulses grown in Canada as dry beans include common bean, lentil, field pea, chickpea, and faba bean. Pulses are low in fat, rich in fiber and complex carbohydrates, and good sources of vitamins, and consumption of these healthy foods has been increasing. Additionally, these legumes fix nitrogen, reducing the amount of nitrogen fertilizer required, and generally improving the yield of crops that follow in a rotation. Some pulses, most notably peas, have become an important livestock feed. Pulses have been the chief new successful crops that have served to diversify Western Canadian agriculture since the 1980s.

Common Bean (*Phaseolus vulgaris* L.)

Dry edible beans have been a commercial crop in Canada since the mid-19th century, and while not particularly new, recent bean cultivars have allowed the area seeded to expand somewhat from traditional growing areas. Demand for dry common bean has been increasing with world population. In Canada, beans are grown mostly in Ontario (which accounts for about 70%), Alberta, Manitoba, and to a lesser extent in Saskatchewan and Quebec, all areas which provide the necessary warm growing season. White and colored beans are produced in about equal amounts, but this represents a noticeable switch from white to colored bean production, primarily due to increased demand for colored cultivars for export. Indeed, colored bean production continues to increase in Canada, because of the creation of new disease-resistant cultivars, strong promotion and market development, and increasing processing capacity in Western Canada. Ontario produces most of Canada's white beans (also known as white pea beans, navy beans, and alubia chicas). Colored beans are grown mostly in Quebec, Ontario, Manitoba, and Saskatchewan, and in Alberta under irrigation. Most (75–85%) of Canada's beans are exported, about half to Europe, and about 40% to the US. Bean yields are quite variable because of the requirement for warmth and sensitivity to adverse weather, so that new cultivars better adapted to Canadian conditions are desirable. For a more detailed analysis of the bean crop in Canada, see Vincent (1995) and Gray (1997a).

Adzuki Bean [*Vigna angularis* (Willd.) Ohwi & Ohashi]

A new adzuki (azuki) bean cultivar, 'AC Gemco', was recently produced by AAFC at Harrow (Ontario), and has genetic consistency that growers have sought, as well as large seed size and high yields. This annual pulse is a major crop in Asia (second only to soybean in Japan), and a limited crop has been produced to date in North America.

Mung Bean [*Vigna radiata* (L.) R. Wilczek]

Another area of growth for beans is the sprout market, especially mung bean. Canada currently imports almost 2 million kg annually of mung beans for sprouting. The cultivar 'AC Harrowsprout' was recently produced by AAFC at Harrow to meet the demand for a domestic supply of mung beans.

Pea (*Pisum sativum* L.)

In 1997–98, Canada produced about 14% of the world's dry peas (about 13 million tonnes), and most of this was exported to Europe. Saskatchewan, Alberta, and Manitoba respectively account fr about 70, 20, and 10% of the dry pea seeded area. Field pea has become Caada's sixth most important crop. The area cultivated has been rising for the past 20 years, especially recently, due to an expanding export market, particularly in the European Economic Union, where peas are a traditional feed ingredient for hogs. In eastern Canada, where only 1,000 ha were seeded o peas in 196, the crop is used mainly for on-farm livestock feed, and the prospects for peas as a new crop in areas other than the prairies seem limited. A detailed analysis of the pea crop in Canada is Skrypetz (199).

Lentil (*Lens culinaris* Medic.)

Canada produces about 13% of the world's lentils (about 2.9 million tonnes for 199–98),and is the third largest producing country after India and Turkey. About 85% are grown in Saskatchewan, the remainder in Manitoba and Alberta. Lentil is a relatively new crop for Canada, produced on the prairies in significant quantities only since the late 1960s. Canadian cultivars ('Laird', 'Eston', 'Richlea', and others) are all green with yellow cotyledons, unlike the red-cotyledon lentils that comprise the bulk of the world's lentil production. 'CDC Redwing', a new red cultivar, is considered promising in part because of its disease resistance. Lentils have some prospect for being used as livestock feed, like peas. For additional information on the lentil crop in Canada, see Gray (1998).

Chickpea (*Cicer arietinum* L.)

Chickpeas (garbanzo beans) have a wide variety of food uses, and the lower grades can be used as livestock feed. In 1997–98 Canada produced 14,500 tonnes on 10,500 ha. This crop requires a fairly long growing season and prefers dry conditions because of susceptibility to ascochyta blight (caused by *Ascochyta rabiei*, a devastating seed-borne fungal disease) and a need for heat to set seed. Chickpea is well adapted to the brown soils of Western Canada, and its deep, extensive root system provides good drought tolerance. The Crop Development Centre of the University of Saskatchewan has been concerned with breeding shorter season and ascochyta-resistant cultivars suited to the southern Prairies. Although there is appreciable international competition, there does seem to be a good prospect that chickpea could become a more significant crop in Canada.

Faba Bean (*Vicia faba* L.)

The faba bean is a small-seeded form of broadbean, an ancient vegetable bean of Europe. A smaller-seeded type of broadbean (known as "la gourgane") is grown in commercial amounts in the St. Jean region of Quebec, mainly for soup (Munro and Small 1997). Faba bean cultivation started in western Canada in 1972, and the area under production has fluctuated widely since then. Protein content of 24–30% makes faba bean an attractive on-farm protein supplement for livestock feeding, and there is also good potential for use as silage. While faba bean is a very minor crop in Canada, it could well become more important.

Fescue grasses

Gramineae *Festuca* sp.

Source: Magness et al. 1971

Some 100 species of *Festuca* are known, generally found in temperate or cool climates. They vary widely in texture and growth habit. Some are annuals, others perennial. Annual kinds may be troublesome weeds, while perennial kinds are excellent for forage, pasturage and turf. The most valuable are tall fescue, meadow fescue, Idaho fescue, sheep fescue, red fescue, and Chewing's fescue

Last update February 18, 1999 by ch

Idaho fescue

Gramineae *Festuca idahoensis* Elmer

Source: Magness et al. 1971

This is a native bunchgrass found from Washington and Montana south to California and Colorado. The large bunches reach to 3 feet with numerous smooth leaves. This is a valuable range grass, palatable while green, and also curing well for fall and winter forage. It has potential for seeding on range lands.

Last update February 18, 1999 by ch

Meadow fescue

Gramineae *Festuca pratensis* Huds. (= *F. elatior* L.)

Source: Magness et al. 1971

This is a hardy perennial bunchgrass, introduced from England and adapted to cool climates. On rich soils it reaches up to 30 inches in height. Leaves are long and slender, bright green and succulent. It is now grown less than in the past for pasturage and hay because of the general superiority of tall fescue. It is not as heavy yielding nor as persistent as tall rescue.

Last update February 18, 1999 by ch

Sheep fescue

Gramineae, Poaceae *Festuca ovina* L.

Source: Magness et al. 1971

This is a bunchgrass that forms dense clumps, with numerous stiff, sharp, bluish grey leaves. It is cold and drought tolerant and is better than most grasses on sandy or gravelly soils in northern states. It is useful for grazing in early spring, but its greatest value is providing a durable turf on sandy or gravelly soils.

Field pea

Leguminosae *Pisum sativum* L.

Source: Magness et al. 1971

The term **field pea** designates peas used as forage for livestock rather than for human food. The plants are annuals, adapted to cool climates. They have weak, semi-vining stems. The leaves usually consist of 3 pairs of broad, ovate leaflets and terminate in a tendril. They are borne along the whole length of the stem. Seeds are usually near round, smooth, and produced several to a pod. Field peas are grown for livestock feed in northern states from New York west to Oregon, where they are seeded in early spring. In the South they are seeded in the fall for winter pasture and green manure. For harvesting dried peas, fields are mowed, the vines windrowed to dry, then threshed with combines. The dry beans are grown on about a quarter million acres. Straw after threshing, as well as the peas, are nutritious feeds.

Figwort

Scrophularia marilandica L.

Synonym.—*Scrophularia nodosa* var. *marilandica* A. Gray.

Other common names.—Maryland figwort, heal-all, pilewort, carpenter square.

Habitat and range.—This plant, often galled Maryland figwort, is found in woodlands from Maine to Kansas and south to Georgia and Tennessee.

Description.—The figwort is 3 to l0 feet high with 4-angled stems widely branched above and slender-stemmed, somewhat egg-shaped or lance-shaped sharply toothed leaves 3 to 9 inches long. The numerous small, greenish-purple flowers are produced from July to September in rather open panicles.

Part used.—The herb.

Figure 49.—Figwort (*Scrophularia marilandica*)

Meadow foxtail

Gramineae *Alopecurus pratensis* L.

Source: Magness et al. 1971

This grass is native to temperate Europe and Asia, and was introduced into the United States around the middle of the last century. It is a long-lived perennial, which forms a few short rootstocks and underground branches. It produces a medium dense sod. Leaves are medium in width, dark green and numerous. Stems generally reach about 3 feet. The species is especially adapted to cool moist climates, such as west of the Cascade Mountains in Oregon and Washington; but is useful in other northern states. It is especially useful as pasture, growing throughout a long season. In combination with legumes it is made into silage in the Pacific Northwest, but is rarely harvested for hay.

White Ash

Fraxinus americana L.

White ash

Figure 114.—White ash (*Fraxinus americana*)

Synonyms.— *Fraxinus alba* Marsh.; *F. acuminata* Lam.

Other common names.—Ash, American white ash, cane ash.

Habitat and range.—The white ash is native in rich woods, from Nova Scotia to Minnesota, south to Florida and Texas, but chiefly in the Northern States and Canada

Description.—This tree usually attains a height of from 60 to 80 feet, but occasionally reaches 120 feet. The leaves, which appear late in the spring, are about 12 inches long and consist of from five to nine leaflets from 3 to 5 inches long and about half as wide. The small, whitish-green flowers which appear from April to June are arranged in loose clusters, and the fruits which follow are in the form of clustered, winged seeds each of which is from 1 to 3 inches long, narrow, flat, and 1-seeded.

Another species.—The black ash (*Fraxinus nigra* Marsh., syn. *F. sambucifolia* Lam.) is also a native, inhabiting swamps and wet woods from Canada to Virginia and Arkansas. Other names applied to it are hoop ash, swamp ash, water ash and basket ash. It reaches a maximum height of 100 feet and has leaves about 16 inches long composed of 7 to 11 leaflets 3 to 6 inches long.

Part used.—The bark of the trunk and root of both species.

Galleta grass

Gramineae, Poaceae *Hilaria jamesii* (Torr.) Benth.

Tobosa grass

***H. mutica* (Buckl.) Benth.**

Source: Magness et al. 1971

Both of these native species are slightly spreading range grasses. Galleta grass occurs from Wyoming to California and West Texas while Tobosa is in West Texas and Arizona and south into Mexico. The bases of the stems of both are rhizome like. Stems may reach to 2 feet, with small, narrow leaves. Both are found under arid conditions and are highly drought resistant. They are moderately palatable while succulent, but not when dry.

Imbe

Guttiferae *Garcinia livingstonei* T. Anders.

Source: Magness et al. 1971

The Imbe is a small tree up to 20 feet, native to East Africa. Leaves are leathery, dark green, oblong, up to 6 inches in length. Fruits are up to 2 inches long, nearly as broad, and ripen in mid-summer. The skin is tender and encloses a thin, tart, watery pulp, with generally a single seed. There is no commercial production in the United States, but occasional trees may be found in tropical areas.

Huckleberry

Ericaceae *Gaylussacia* sp.

Source: Magness et al. 1971

In the United States, the name huckleberry is often used for blueberry, which see. While the two fruits are similar in appearance and flavor, the huckleberry which is a drupe has a 10-celled ovary, each cell (drupelet) normally containing a seed large enough to be conspicuously noticeable when the whole fruit is eaten. Blueberries, in contrast, contain many seeds so small as not to be noticeable when the fruit which is a berry is consumed. Only blueberries are a cultivated crop, but quantities of huckleberries are harvested from native plants. The huckleberry plant is a shrub, to 6 feet, with small, entire oval leaves. Fruits are borne in small clusters. Individual fruits are generally one-third inch or less in diameter, mainly blue to black in color, sweet or slightly tart when ripe. Several species, mainly in Eastern United States, produce fruits valued locally.

Genipa americana L.

Rubiaceae

Genipap, Genip, Genipe, Genipop, Jagua, Marmalade box

GERANIUM

Family: Geraniaceae, (*Pelargonium graveolens* L'Her. ex Ait.)

Source: Simon, J.E., A.F. Chadwick and L.E. Craker. 1984. Herbs: An Indexed Bibliography. 1971-1980. The Scientific Literature on Selected Herbs, and Aromatic and Medicinal Plants of the Temperate Zone. Archon Books, 770 pp., Hamden, CT.

Rose geranium, *Pelargonium graveolens* L'Her. ex Ait., is one of the many fragrant species of *Pelargonium* used as a source of geranium oil. The woody, perennial herb is native to South Africa and is produced in Egypt, France, the People's Republic of China, Algeria, South Africa, Morocco, and Spain. Reaching a height of one meter, the plant has pubescent, fragrant, green, deeply lobed leaves and rose-colored flowers.

The geranium flourishes in the full sun of temperate and subtropical climates. Best growth is obtained on well-drained, fertile soils and under a high relative humidity. The species are cold sensitive but tolerant of drought.

The essential oil accumulates in small glands found in the foliage and flowers. Harvesting, usually done by hand two or three times annually, begins as the plant starts flowering. The herb is cut in the morning in sunny, dry weather. Distillation begins after a few hours of field drying.

There are several types of geranium oil, the main ones being Reunion or Bourbon, Algerian, Moroccan, and French. The oils are composed chiefly of geraniol, citronellol, linalool, citronellyl formate, and several other compounds (7.5-124, 8.2-13, 8.2-33, 14.1-9). Reunion oil is very rich in citronellol and has a heavy rose and minty odor. Algerian oil has a delicate odor. Moroccan oil is similar to Algerian oil. French oil is thought to possess the finest rose-like odor. The concrete and absolute of geranium are also available commercially.

The oil of geranium, widely used in perfumery and cosmetics, is stable and blends well with other fragrances. Dried leaves are used in sachets and potpourris. Leaves of geranium are also used in herbal teas and the oil is used in baked goods and fruit desserts. The geranium of florists comes from many annual and perennial geranium species that vary in fragrance, growth habit and leaf and flower color. The scented geraniums are extensively used in flower gardens and as potted herbs.

As a medicinal plant, geranium has traditionally been considered an astringent and used as a folk remedy in the treatment of ulcers (11.1-50). A terpine hydrate synthesized from geraniol is known to be, an effective expectorant (11.1-96). Leaves are reported to have antifungal activity (7.5-124). Scented geranium and oil of geranium are reported to cause contact dermititis (8.2-79, 11.1-96). Geranium is reported to repel insects because of its citronellol content.

Several forms, varieties, and hybrids of geranium exist. Rose-scented geranium, *Pelargonium capitatum* (L.) L'Her. ex Ait.; nutmeg geranium, Pelargonium fragrans Willd.; apple geranium, *Pelareonium odoratissimum* (L.) L'Her. ex Ait. and crowfoot geranium *Pelargonium radens* H. E. Moore, represent the wide diversity of plants that contribute to the production of geranium oil. *Geranium macrorrhizum* L., an aromatic plant, and wild geranium, *Geranium maculatum*, are members of the Geraneaceae family and should not be confused with the scented geraniums. Although used in flavoring and perfumery, East Indian geranium is actually *Cymbopogon martini* Stapf., of the Poaceae family.

Pelargonium species are generally recognized as safe for human consumption as natural seasonings/flavorings and as plant extracts/essential oils (21 CFR sections 182.10, 182.20 [1982].

[Note: References listed above in parentheses can be found in full in the original reference].

Aromatic and Medicinal Plants Index | Purdue Guide to Medicinal and Aromatic Plants

Last modified 6-Dec-1997

Wild Geranium

Geranium maculatum L.

Figure 118.—Wild geranium (*Geranium maculatum*)

Other common names.—Crane's-bill, spotted crane's-bill, wild crane's-bill, stork's-bill, spotted geranium, alumroot, alum-bloom, chocolate-flower, crowfoot, dove's-foot, old-maid's-nightcap, shameface

Habitat and range.—Wild geranium flourishes in low grounds and open woods from Newfoundland to Manitoba and south to Georgia and Missouri.

Description.—This plant, although generally only about a foot in height will sometimes reach a height of 2 feet. It is erect, usually unbranched, and hairy. The leaves, which are 3 to 6 inches wide, are deeply parted into three or five divisions, each of which is again cleft and toothed. The rose-purple, pale or violet-purple flowers, which appear from April to June, are borne in loose clusters and are from 1 to 1 1/2 inches wide. The fruit capsule, which springs open when ripe, consists of five cells each containing one seed. The rootstock is 2 to 4 inches long, thick, with numerous branches and with sears showing the remains of stems of previous years. When dry it has a somewhat purplish color internally.

Part used.—The root, collected just before the flowering period.

Gerbera Daisies: A Potential Field-produced Cut Flower Crop for Coastal South Carolina

Robert J. Dufault, Tyron Phillips, and John W. Kelly

INTRODUCTION

Need for Alternative Crops

Historically, the coastal area of South Carolina has been a region of great agricultural importance in the Southeast. Dating back to the seventeenth century, many crops, once considered alternative crops or new crops were introduced and became strong industries. Rice, then indigo, and finally sea island cotton were important crops in the region for two centuries. Vegetable production supplanted cotton production by the turn of the twentieth century. During the last eighty years, crops such as beans, lettuce, carrots, cabbage, greens, and potatoes were considered major crops; however, through a variety of reasons, competition eroded these markets. Presently, fresh market tomatoes are the major vegetable produced in coastal South Carolina, but the future of this industry is threatened by strong competition from Florida's growers, who are extending their production periods.

Potential of Field Cut Flowers

The search for new crops to supplement the income from traditional crops has followed many routes. Cut flowers are one of the alternatives being considered. Presently, a few growers in South Carolina produce snapdragons, gladiola, daylilies, and statice. Most of these flowers are sold directed to retail florists. Surveys of local retail and wholesale florists in Columbia, South Carolina have indicated that there is potential for local growers to produce and sell more diverse types of cut flowers. Barberton or Transvaal daisies, or simply Gerbera daisies (*Gerbera jamesonii* Bolus) are one of the top cut flower crops in Europe and in recent years have been steadily exported to the United States from the Netherlands, France, Italy, Japan, India, Australia, and New Zealand (Tjia 1984). Gerbera daisies are produced also in South America (Colombia), but the majority of these are exported to Europe and Japan (Tjia and Rogers 1982).

Gerbera daisies are a high value cut flower crop with retail prices as high as $3.50/stem. Growers could sell Gerbera cut flowers to a wholesaler for 25 to 40 cents/stem who would, in turn, sell the same stems to a retail florist for 40 to 70 cents/stem. Demand and price paid for Gerbera cutflowers is highest from Valentine's Day to Mother's Day.

Most gerbera cut flowers are produced in some form of protected structure. In the Netherlands, Gerbera cut flowers are produced on raised beds in heated greenhouses to protect from severe winter weather. Domestically, Gerbera daisies are produced in Florida in sawtooth or saran houses (Behnke 1984). Shade cloth is needed to reduce temperatures and to enhance stem length (Auman 1980). While some production is in open fields, the majority is produced under some permanent protective structure (B. Tjia, personal communication).

The coastal area of South Carolina has many aspects about its geography and climate that can be considered favorable to the production of field gerbera cut flower production. The area is an 8 to 9 on the hardiness zone. The summers are sub-tropical with sub-temperate winters. However, to capture the early Valentine's Day market demand, some form of protection is needed. The region has ample water, warmth, and productive soils unusually high in phosphate. Gerbera daisies are a popular bedding plant in the home landscape and over-winter without plant loss. They are one of the earliest to flower in spring, are extremely heat tolerant blooming through the intense heat and humidity of the summer months, and will bloom continuously to late November. As bedding plants, they are considered "easy" to grow. Geographical benefits include close proximity to the large metropolitan areas of Charleston and Columbia, South Carolina and Atlanta and Savannah, Georgia, and within easy reach of metropolitan areas north or south along the eastern corridor. Recently, local "pick-your own," vegetable farms have diversified their product lines and sell annual cut flowers, such as zinnia, marigold, and cosmos with great success. Customers are drawn to these stands by the splashes of bright colors of cutflowers. Perennial cut flowers, such as Gerbera daisies, could be a welcome addition.

FIELD STUDIES ON GERBERA DAISY CUT FLOWER PRODUCTION

Population and Fertility Research

Potential factors working against the success of this new crop are uncertainties of the cultural practices needed to produce high quality gerbera cut flowers in open fields. The basic fertility and population considerations to produce quality cuts are unknown and awareness of pest problems needs close scrutiny The floral industry has defined the level of quality the grower needs to satisfy. Florists demand large, showy blooms preferably 7.5 cm in diameter or greater. The many different types of gerbera flower forms include singles, doubles, crested doubles, full-crested doubles, and quilled types (Clay 1983). Florists seldom use singles in arrangements, preferring the fancier flower types. Stems should be sturdy and at least 30 cm, but preferably 60 cm in length. Blooms must be insect- and disease-free. Work was initiated in 1987 at Clemson's Coastal Research Center in Charleston to determine the appropriate cultural practices to produce quality cut flowers in unprotected culture in the open field (Fig. 1).

A two-year study evaluated the influence of nitrogen (N) and potassium (K) fertility and plant populations on quality cutflower production. Three levels of N (55, 110, and 220 kg/ha) and plant populations of 24,000, 36,000, and 72,000 plants/ha were factorially combined to produce 27 unique cultural systems. In the first year of production, we found that populations of 72,000 plants/ha can be used to produce cut flowers without loss of flower size and quality. At least 110 kg N/ha, was needed to enhance high yields (Table 1). Increasing the N rate to 220 kg/ha increased cull production with negligible increases in marketable yields. Nitrogen rate did not affect flower size or quality. At least 220 kg K/ha is needed to increase marketable yield, individual flower fresh weight and vase life and to decrease cull flower production.

Marketable and cull yield also increased with N rate applied in the second year (Table 1). In contrast to the first year's work, production was highest with 220 kg N/ha while K had no effect on yield. High populations of 72,000 plants/ha increased marketable yields. Levels of N, K or plant populations had no effect on flower diameter, stem length, flower fresh weight or overall quality. To obtain high yields of marketable quality, fertility regimes of 220 kg N/ha with at least 55 kg K/ha are needed. High plant populations of 72,000 plants/ha win maximize flower yields without adverse effect on flower quality and production.

Research To Improve Stem Length and Earliness

Short stem length was a persistent problem in the fertility/population experiments. Stem lengths averages about 31 cm and 34 cm in 1987, and 34 cm in 1988. Fertility and plant spacing did not affect stem length. Research is ongoing to study the utility of shade cloth of 30, 47, 63 or 80% light exclusion to induce greater stem length. Portable shade cloth houses are placed over the beds during the growing season. The benefits to production and economics of utilizing shade cloth remain to be determined.

Normally in Charleston, gerberas bloom in early April. The use of row covers could increase early production to mid-February, and are currently being investigated. Although all row cover materials tested resulted in earlier production in January, 1989, the lengthening stems were abraded by the row cover materials and seriously damaged. Better designs combining row covers with higher clearance tunnels are needed.

POTENTIAL OF GERBERA AS AN ALTERNATIVE CROP

Thrip-induced petal striations and streaks are the major hindrance to quality flower production in coastal South Carolina. Various systemic and non-systemic insecticides evaluated were ineffective in controlling thrips and these compounds are not yet labeled for use with these crops. Before this new crop can be grown commercially, entomological studies are needed to learn how to control thrips.

The success of this crop in the market place will depend ultimately on the aggressiveness of the grower to pursue retail and wholesale floral markets. Quality must be demonstrated and price set to undersell the competition. Only a limited number of Gerbera daisies can be absorbed by local market outlets. Retailing through "pick-your-own" farmstands and farmers markets may be the best ways for the small grower to become familiar with growing the crop, developing a quality product, and establishing a good reputation in the market.

Floral trade experts expect that the boom in flower use by Americans will continue to increase. Americans spent about $21 per capita in 1986 for cut flowers (Levin 1987). Although our use of flowers still lags behind the Europeans, the trend of buying flowers for the home is moving the country closer to the European tradition. We expect that field-production of cut flowers will increase significantly in the coming years.

Prosopis cineraria (L.) Druce

Syn.: *Prosopis spicigera* L.
Mimosaceae
Ghaf (Arabic), Jand (Punjab), Jandi (Pakistan), Shum (India)

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

According to Burkart (1976) *Prosopis cineraria* is not used commercially. During India's Rajputana famine (1868–69), many lives were spared, using the sweetish bark as a food. It was ground into flour and made into cakes. Wood used for boat frames, houses, posts, and tool handles; the poor form of unimproved trees limits use as timber. Containing 31% soluble potassium salts, the wood ash may serve as a potash source. Pods and lopping provide valuable fodder during the dry season. According to the NAS (1980a), it "does not compete for moisture with crop plants, which may be grown close to its trunk." Pakistanis and Indians believe, quite properly, that it increases fertility under its canopy. Bark and leaf galls used for tanning. The gum exuding from the trunk is suggestive of gum arabic.

Folk Medicine

Reported to be astringent, demulcent, and pectoral, ghaf is a folk remedy for various ailments. In India, the flowers are mixed with sugar and administered to prevent miscarriage. In Las Bela, India, the ashes are rubbed over the skin to remove hair (perhaps *Leucaena* ashes should be tried as well). The bark, considered anthelmintic, refrigerant, and tonic, is used for asthma, bronchitis, dysentery, leucoderma, leprosy, muscle tremors, piles, and wandering of the mind. Smoke from the leaves is suggested for eye troubles, but the fruit is said to be indigestible, inducing biliousness, and destroying nails and hair. Punjabis consider the pod astringent. Central Province Indians use bark for rheumatism. Although recommended for scorpion sting and snakebite, the plant has not proved out (Kirtikar and Basu, 1975).

Chemistry

The heartwood, contains sugars, five flavonones, fatty acids, and tannins (Burkart, 1976). Fresh leaves (ZMB) contain 15.3% CP, 17.5% CF, 10.0% ash, 3.2% EE, 54.0% NFE, 2.65% Ca, and 0.24% P (Gohl, 1981). Wealth of India reports that leaves contain 2.9% N, 0.4% P_2O_5, 1.4% K_2O, and 2.8% CaO. The flavone glycoside patulitrin has been isolated from the flowers (C.S.I.R., 1948–1976). A novel variant on the piperidine-3-ol alkaloid recently reported is spicigerine (Jewers et al., 1976).

Description

Tree to 6.5 m high; cortex cinereous; prickles internodal, scattered, straight, somewhat acroscopic, conical with broad bases. Taproot to more than 3 m long. Leaves 1–3-jugate, glabrous or puberulous; petiole and rachis 0.5–4 cm long, the pinnae 2–7 cm long; leaflets 7–14-jugate, ovate, straight to subfalcate, without nerves (or 2–4-nerved at base, the midrib excentric), mucronate, 4–15 mm long x 2–4.5 mm broad, grayish when dry; stipules foliaceous, deciduous. Racemes spiciform, 5–13 cm long, several together, subpaniculate; peduncle with amplexicaul bract (or 2 bracts united), this caducous and leaving an oblique scar, 1.5–2 mm long; bractlets ovate, sessile, 0.5–0.8 mm long, caducous; pedicels 0.5 mm, to 1.5 mm long when mature; flowers yellow, glabrous; calyx truncate, 0.8–1.2 mm long; corolla 3.5 mm long, glabrous, the petals rolled back in age; anthers 0.8–1 mm long; pistil glabrous. Fruit slender, elongate, 8–19 cm long (including the stipe 0.8–2 cm), subcylindric-torulose, 4–7 mm in diameter, glabrous; pericarp thin, brittle; endocarp segments thin, longitudinal, little developed; seeds distant, longitudinal, ovate, 6 mm long, the tegument with open horse-shoe fissural line on faces (Burkart, 1976), 10–15 in a pod, brown (C.S.I.R., 1948–1976).

Germplasm

Reported from the Hindustani Center of Diversity, ghaf, or cvs thereof, is reported to tolerate alkalinity, drought, grazing, heat, high pH, poor soil, sand, and salt. Young seedlings are sensitive to frost (C.S.I.R., 1948–1976).

Distribution

In dry and arid regions of northwestern India in Punjab, West Rajasthan, Gujarat, Uttar Pradesh, in dry parts of central and southern India, extending into Pakistan, Afghanistan, Iran, and Arabia. Usually at low elevations. Introduced in Abu Dhabi, where plantings totaling 2,000 ha have been made on flat, silty, gravelly plains and in shifting sand dunes (NAS, 1980a).

Ecology

Withstands slight frost (-6°C minimum) and high temperatures (40–50°C maximum shade). Sometimes gregarious but scattered in open dry forest. Seems to require light. Our computer entries for *Prosopis* spp. are unreliable, partly due to past taxonomic confusions. I estimate this species to range from Tropical Thorn to Moist through Subtropical Thorn to Moist Forest Life Zones. I estimate it tolerates annual precipitation of 1 to 20 dm and pH of 6.5–9.8. The chief Indian tree species in the Punjab, where rainfall is less than 750 mm.

Cultivation

Reproduces freely by root suckers and establishes well from seed, which remain viable for decades. Seeds, which should be soaked for 24 hours, may be processed and planted like *P. alba*. They retain their viability for at least one year. An initial spacing of 2 x 2 m is recommended. Should be weeded until well established.

Harvesting

Tree coppices readily.

Yields and Economics

Standing crops yield 7–70 m^3 fuel/ha, averaging 21 m^3 stacked. Annual yields of stacked firewood approach 3 m^3/ha. The heartwood is very hard and heavy (769–945 kg cu m).

Energy

In the Punjab, its rather scanty, purplish brown heartwood is preferred to other kinds for firewood (Burkart, 1976). It is an excellent fuel, also giving high-quality charcoal (5,000 kcal/kg). According to the Wealth of India, the calorific value of the sapwood is 5,003 kcal (9007 BTU) (C.S.I.R., 1948–1976).

Biotic Factors

NAS (1980a) reports that "one fungus and five insect species are known to attack the tree." Species of Chrysobothris and Sinoxylon bore into the dead wood, causing wood rot. Felker et al. (1981) review the pest infestations of their *Prosopis* plantings with suggestions for their control. Browne (1968) lists the following: Angiospermae—*Cuscuta reflexs;* Coleoptera—*Caryedon gonagra, celosterna scabrator*; Hemiptra—*Drosicha stebbingi, Laccifer lacca, Oxyrhachia tarandus, Perisopneumon tamarinda;* and Orthoptera— *Schistocerca gregaria.*

Salsola kali L.

Chenopodiaceae
Russian thistle, Prickly saltwort, Tumbleweed, Glasswort

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Young plants serve as useful fodder, as long as they are not too high in nitrites or oxalic acids. As a low-water-use plant, germinating quickly on minimally disturbed soils, and relatively free of diseases and parasites, this has been suggested as a fuel source for arid lands (Foster et al., 1980). This is one of several plants burned to make soap, even in Biblical times, at least so we read in WSSA. Soap made in this fashion is still traded at Joppa and other Mediterranean ports [WSSA Newsletter 9(4): 12. 1981]. On account of its high alkali content, the plant has also been used in making glass (Watt and Breyer-Brandwijk, 1962). Salsolin has been used to regulate the blood pressure, said to resemble papaverine in its effect on vasoconstriction, hydrastine in its effect on the smooth muscles of the uterus (List and Horhammer, 1969–1979).

Folk Medicine

According to Hartwell (1967–1971), the plants are used in folk remedies for that cancerous condition he terms superfluous flesh. Reported to be cathartic, diuretic, emmenagogue, poisonous, stimulant, and vermifuge, Russian thistle is a folk remedy for dropsy and excrescences (Duke and Wain, 1981). Navaho used a decoction of the ashes, both internally and externally for influenza and smallpox (Duke, 1983c).

Chemistry

Of 21 samples, the average DM content was 39.4% (20.0–80.2). On a Zero Moisture Basis (ZMB), CP, ran 4.9–25.0% (mean of 31 = 12.3), EE 0.6–3.8 (mean of 23 = 1.8), CF 20.2–43.1% (mean of 21 = 31.7), ash, 5.4–22.8% (mean of 30 = 15.2), and the NFE averaged 39.0%. Ca ranged from 1.6–4.14 (mean of 48 = 2.47%), P from 0.04–0.27 (mean of 48 = 0.17%), K from 4.63–6.83% (mean of 6 = 6.46%), Mg from 0.60–0.93 (mean of 17 = 0.81%), with ca 19 mg/kg Cu, 33 mg/kg Mn, 0–8 mg/kg carotene (Miller, 1958). Seeds contain 40.5% protein, 27.0% fat, on a ZMB (Duke and Atchley, 1983). Fruiting plants may contain 0.2% alkaloids, among them salsolidine and salsoline. Hager's Handbuch reports the fatty oils from the plant contain linolenic-, oleic-, arachidic-, palmitic-, and stearic-acids, along with glucose, arabinose, fructose, and rhamnose, with eicosanol and β-sitosterol. The ash contains ca 20% K, 18% Ca, 3% Mg, 1.5% Al, 1.5% Fe, 6% phosphate, 6% sulfate, 40% carbonate, and 2% chloride (List and Horhammer, 1969–1979).

Toxicity

The plant can contain as much as 5% oxalic acid. This oxalic acid, or excess of KNO_3 may lie behind reports of toxicity to grazing animals.

Description

Annual herb with spreading taproot; stems bushy, much-branched, 1.5–12 dm tall, 3–15 dm in diameter, rigid, spiny, spherical, often reddish in age, young stems and leaves green and succulent; leaves alternate, the first-formed fleshy, cylindrical or awl-shaped, 0.5 mm broad, 1.2–6.5 cm long, apically pointed, the latter-formed shorter, stiff, dilated and thickened at the base, ending in a hard sharp spine. Flowers small, greenish, mostly solitary in the axils; petals none; sepals 5, papery and persistent; stamens 5; pistil 1, bracts at the base of each flower 2, rigid, spine-tipped; fruit surrounded by the 5 enlarged sepals, each developing a fan-shaped, strongly veined wing on its back, 3–9 mm broad. Seeds numerous (to one million per plant), top-shaped, ca 2 mm broad, with a yellowish coiled embryo, visible through the thin gray wall (Reed, 1970).

Germplasm

Reported from several arid Mediterranean Centers of Diversity, Russian thistle, or cvs thereof, is reported to tolerate drought, grazing, heat, and poor soils. I predict it will also tolerate salinity and high pH, as do so many desert xerophytes. ($2n = 36$)

Distribution

Disturbed areas, roadsides, ditchbanks, fallow abandoned grain-fields, overgrazed ranges, and pastures. Common to abundant in Western and parts of the Central States of the US, occasional along the eastern and southern coasts, where it is spreading rapidly (Reed, 1970). Treated as a serious weed in Afghanistan and Argentina, a principal weed in Canada and Hungary, a common weed in Iran, Italy, Morocco, South Africa, and the United States. Listed also as weed in Australia, Chile, China, Egypt, Greece, Hawaii, Indonesia, Iran, Japan, Lebanon, Mexico, Norway, New Zealand, Pakistan, Poland, Turkey, and the USSR (Holm et al., 1977).

Ecology

Estimated to range from Cool Temperate Desert to Steppe to Subtropical Very Dry to Thorn Forest Life Zones, Russian thistle is reported to tolerate annual precipitation of 2.6 to 9.7 dm (mean of 4 cases = 4.9), annual temperature of 9.2 to 23.8°C (mean of 4 cases = 15.3), and pH of 7.0 to 7.9 (mean of 2 cases = 7.4) (Duke, 1978, 1979).

Cultivation

A self seeding annual, producing up to a million seed a plant, the Russian thistle doesn't really need to be cultivated, except perhaps as a desert fuel candidate.

Harvesting

Spread of the weed is encouraged by the long-viable seed. Harvesting of the tumbleweed and processing it for fuel is treated in various papers by Karpiscak and/or Foster.

Yields and Economics

Productivity of natural stands in Avra Valley, ca 32 km northwest of Tucson, averages more than 3 MT/ha. Hence this weed has been suggested as desert fuel crop for 240,000 ha of arid or fallow land retired as the cost of irrigation increases (Foster, Rawles, and Karpiscak, 1980). With its C4 photophysiology, it has a high water use efficiency. Currently, this is an economic negative. Tumbleweeds block irrigation canals. They are a traffic hazard which cost the California transportation department hundreds of thousands of dollars to eliminate (Anon., 1982a). It costs about $250 a hectare to haul away the brush, while application of an herbicide (e.g. Brominal) costs closer to $100.

Energy

According to the phytomass files (Duke, 1981b), annual productivity ranges around 3 MT/ha but yields of ca 6–10 MT/ha forage are reported for *Salsola orientalis* (with Eurotia and Kochia) in Kazakhstan (USSR) (Pryanishikov and Alimaev, 1977. Proc. 13th Internat. Grassland Cong. Leipzig) [CAB V81(10)]. In dry regimes, *Salsola kali* has higher biomass in mixed than in monoculture (Allen, 1982). Karpiscak et al (1980) report on the feasibility of agricultural production as a source of burnable biomass. Foster et al. (1980) discuss the processing into artificial fireplace logs whose economic potential is substantial. Energy content in field-dried tumbleweed ranges from 6,500–6,800 Btu/lb cf 5,580–7,920 for lignite. Wild stands yield 3–10 MT/ha; irrigated plots up to 15 MT/ha. The value of the fireplace logs made from compressed tumbleweed is $14 to $20 per million Btu. It costs $4.33–6.40 to prepare the product (Foster et al, 1983). The most common means of eradication is by burning, which only perpetuates the problem by releasing up to 1,000,000 fire-resistant seeds per plant (Anon., 1982a).

Biotic Factors

Agriculture Handbook No. 165 lists the following as affecting this species: *Melanospora townei* (on stems), *Phymatotrichum omnivorum* (root rot), *Pleospora lecanora* (on stems), *Puccinia aristidae* (rust), *Pyrenophora salsolae* (on stems), *Pythium deparyanum* (root rot), and curly top virus *Ruga verrucosans*. Golden (p.c. 1984) lists the "false root-knot" nematode, *Nacobbus aberrans*.

Gleditsia triacanthos L.

Caesalpiniaceae
Honeylocust

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Widely introduced as a fast-growing tree for fuel and fodder and fence posts, for ornament, shade and soil reclamation. The wood is said to be coarse-grained, durable, hard, and resistant to soil decay. Hence it is used for fence posts, railroad ties and tubs for wheels. South Africans sometimes plant orchards of the tree for fodder. The gum from the seeds has been suggested as an emulsifying substitute for acacia and tragacanth. Flowers very attractive to bees. The pulp has always attracted the sweet tooth of animal and man alike, when better sweets were not available. A potable or energy alcohol can be made by fermenting the pulp. Seeds have been roasted and used as a coffee substitute. Wood is hard, coarse grained, reddish-brown and takes a high polish; the wood resists decay and makes good fence posts. Lumber is used for various purposes, but the chief use is as an ornamental. The pods are readily eaten by cattle, goats, deer, squirrel, rabbits, quail, and starlings (Brown and Brown, 1972).

Folk Medicine

Sokoloff et al. (1964) note that recently, Soviet investigators have been studying the biological factors present in the fruit and leaves of *Gleditsia triacanthos.* The alcoholic extract of the fruits of the Kirgis honey locust, after elimination of tannin, considerably retarded the growth, up to 63% of Ehrlich mouse carcinoma. However, the cytotoxicity of the extract was quite high and the animals, besides losing weight, showed dystrophic changes in their liver and spleen. The alcoholic extract of the fruit exerted moderate oncostatic activity against sarcoma 180 and Ehrlich carcinoma at the total dose 350 mg/kg/body weight/mouse. Weight loss was considerable. Epicatechol-3-D-glucoside dihydride, isolated from the flowers, exhibited no oncostatic or cytotoxic activity. The Pigment tentatively identified as dihydroxy-4-methoxyisoflavone, isolated from the fruit, exerted considerable oncostatic activity (and cytotoxicity). Triacanthine from the leaves was highly toxic (LD_{50} ca 35 mg/kg) and of questionable oncostatic activity (Sokoloff et al., 1964). In Lesotho, fruit pulp is used for catarrh of of the lung. Powdered seed used as a snuff for head cold. Some people, probably having seen the erroneous report of cocaine in the leaves, state that "ingestion of a suitable preparation of the leaf increases the capacity for muscular work and delays the onset of fatigue." Reported to be anodyne, mydriatic, narcotic, and experimentally oxytocic (Duke and Wain, 1981), honeylocust pods are a folk remedy for dyspepsia and measles among the Cherokee. The bark tea is used for whooping cough. Delaware Indians used the bark for blood disorders and coughs, the Fox for colds, fevers, measles, and smallpox. Chinese probed tumors and abscesses with the thorns of *Gleditsia sinensis*, considering them counterirritant.

Chemistry

Per 100 g, the fruit is reported to contain (ZMB): 23.1 g protein, 4.6 g fat, 66.9 g total carbohydrate, 12.7 fiber, 5.4 g ash. The seed is said to contain 10.6 g protein, 0.8 g fat, 84.7 g total carbohydrate, 21.1 g fiber, 3.9 g ash, 280 mg Ca and 320 mg P. Scanlon (1980), interested in the potential of honeylocust for alcohol production, presents the following analytical data. Differences in sugar content are possible in trees of the same clone grown in different locations. 'Millwood' pods from trees grown in Beltsville, Maryland, contained 21.07% total sugars, while 'Millwood' at Auburn, Alabama, contained 36.8%. Small differences in sugars were found in pods from the same clonal trees collected in different years.

Constituents of 'Millwood'	Whole pods	Pods without seeds	Seeds only
Ash	3.75	3.82	10.23
Crude fat (ether extract)	0.81	0.52	3.06
Crude protein (%N x 6.25)	10.15	8.21	28.74
Crude fiber	14.19	13.81	11.02

Nitrogen-free extract	71.10	73.64	46.95
Reducing sugars (glucose)	2.86	3.32	
Nonreducing sugars (sucrose)	29.12	32.22	
Total sugars	31.98	35.54	

Air-dried leaf yields 0.5% of an alkaloid triacanthine $C_8H_{10}N_4$ which in intravenous doses of 0.1 mg/kg, depresses the action of the cat heart, the intensity apparently depending on the intensity of effect on the vasomotor centre (145). Heart-wood contains 4–4.8% tannin and also fustin and fisetin (Watt and Breyer-Brandwijk, 1962). The alkaloid gleditschine is said to produce stupor and loss of reflex activity in a frog. Stenocarpine has been used for local anesthesia (Grieve 1931). "It also contains cocaine" (Grieve 1931). To the best of my knowledge it does not contain cocaine!

Description

Tree 20–30 m tall with trunk 3–6 dm in diameter, occasionally reaching a maximum of 50 m tall, diameter to 1.5 m; bark with many large plates, loose at edges, grayish-brown. Twigs brown, glabrous; buds small, glabrous, superposed, the upper one producing a thorn or an inflorescence. Thorns axillary, lustrous, reddish-brown, ca 5–8 cm long, with 2 short branches near base, those on trunk often longer and more branched, with new ones produced for many years. Leaves 1.6–2 dm long; if bipinnate, composed of 4–7 pairs of pinnae, each pinna 18–28 leaflets, or the ultimate sections of the leaf pinnate. Leaflets oval to ovate-oblong, 1.5–3 cm long, 1.25 cm wide, dark green and glossy above, yellowish-green and essentially glabrous beneath; margins nearly entire, obtuse at both ends. Racemes 5–12 cm long, flowers about 5 mm broad, greenish. Pod dark brown 2–4 dm long, 2.5–3.5 cm wide, about 1 cm thick, smooth and shining. Space between the seeds filled with sweet edible pulp.

Germplasm

Reported from the North American Center of Diversity, honeylocust or cvs thereof is reported to tolerate drought, frost, pests, poor soil and slope. Germplasm is covered rather thoroughly in the SERI symposium on Tree Crops for Energy Co-production on Farms, especially the papers by McDaniel (1980) and Scanlon (1980). 'Moraine' and 'sunburst' locusts are nursery selections of the unarmed types.

Distribution

Native to the central United States, now naturalized east of the Appalachian Mountains from South Carolina to New England. Also introduced, established and possibly spreading, sometimes as a weed tree in India, New Zealand and South Africa.

Ecology

Ranging from Warm Temperate Dry to Moist through Cool Temperate Dry to Moist Forest Life Zones, honeylocust is speculated to tolerate annual precipitation of 6 to 15 dm, annual temperature of 10 to 21°C, and pH of 6 to 8.

Cultivation

Pretreated seeds (hot water or sulfuric acid) are drilled in rows 15–25 cm apart and covered with 1–2 cm soil with 30–40 seed per linear meter. Seedlings reach suitable size for outplanting in one year. Clonal reproduction of select germplasm is often recommended. ($2n = 28$)

Harvesting

There is a trend toward biennial production in the cultivars, a hectare of Millwood yielding ca 8000 kg/ha in 1946, but only 550 kg/ha in 1947. Harvesting of pods is rather difficult, especially in thorny cvs.

Yields and Economics

'Calhoun' 3 yrs old yielded ca 0.5 kg/tree, 4-yr-olds ca 2 kg/tree, and 5-yr-olds ca 12 kg. 'Millwood 3-yr-olds yielded ca 0.6 kg/tree, 4-yr-olds ca 2 kg/tree, and 5-yr-olds ca 27 kg/ha. With such low yields (Scanlon, 1980) it is difficult to see how we could get 50 barrels of ethanol per ha. Older 'Millwoods' averaged 33 kg which would give only 3,300 kg/ha if spaced at 100 trees/ha. In Alabama, nearly 6.5 MT *Lespedeza sericea* hay was produced annually in the shade of honeylocust spaced at ca 85 trees/ha.

Energy

Freedman (1980) cited figures suggesting yields of only 3 MT/ha which would yield only ca 5 barrels ethanol. The wood has been described as good fuel wood (C.S.I.R., 1948–1976). Williams (1980) ranks this as a highly feasible (high yield, low maintenance) woody perennial for ethanol production in Applachia, along with blackberry, blueberry, cranberry, elderberry, hawthorn, mulberry, persimmon, raspberry and serviceberry. He estimated yields at ca 10–58 barrels alcohol per ha, much higher than is consonant with fruit dry weights of 3.3 MT/ha/yr, which is closer to the lower barrel figure (Scanlon, 1980; Williams, 1980). Avgerinos and Wang (1980) were more pessimistic about honeylocust than mesquite pods for alcohol production.

Biotic Factors

Allen and Allen (1981) report the invasion of honeylocust root hairs by rhizobia from *Erythrina, Glycine, Leucaena, Lupinus, Pisum,* and *Vigna* species. The infection threads did not penetrate beyond the epidermal wall. Disk assay tests using aqueous root extracts showed the presence of antirhizobial substances that were suggestive of flavones in other tests. Nodulation was not inhibited or diminished on diverse species of other leguminous genera grown in association with honeylocust. It was concluded that the nodule-inhibitory principle was root-contained, or nonfunctional, if exuded into the rhizosphere (Allen and Allen 1981). In the middle Atlantic states, the mimosa webworm is beginning to cause problems. Grazing animals may damage young plants, while other animals and birds may eat the pods. Agriculture Handbook 165 lists quite a few diseases: *Aglaospora anomia, Agrobacterium rhizogenes, B. ribis, Cercospora condensata, C. olivacea, Curcurbitaria elongata, C. recuperata, Cytospora gleditschiae, Daelalea ambigua, D. elegans, Dothiorella gleditschiae, Eutypella fraxinicola, Fomes* spp., *F. applanatus, F. connatus, F. igiarius* var. *laevigatus, F. marmoratus, F. meliae, Ganoderma curtisii, G. lucidum, Glomerella cingulata, Haplosporella gleditschiae, H. gleditschiicola, Hendersonia* sp., *Libertella gleditschiae, Linospora gleditsiae, Macrophoma mamillaris, Melasmia hypophila, Microsphaera alni, M. ravenelii, Mycosphaerella* sp., *Nectria cinnabarina, Parodiella perisporioides, Phoradendron flavescens Phymatotrichum omnivorum Physalospora obtusa, P. rhodina Phytophthora citrophthora, Polyporus* spp., *P. adustus, P. Albus, P. arcularius, P. hydnoides, P. pargamenus, P. pulchellus, P. sulphureus, P. supinus, P. tulipiferus, P. versicolor, Poria ambigua, Ravenelia opaca, Schizophyllum commune, Septobasidium curtisii, Sphaeropsis gleditschiae, S. gleditschiicola, Sphaeropsis mamillaris, S. triacanthi, Thyronectria austro-americana, Xylaria mali* and *Chlorogenus robiniae.* Nematodes of the genus Meloidogyne may be present.

Last update Wednesday, January 7, 1998 by aw

Gliricidia sepium (Jacq.) Steud.

Fabaceae
Madre de cacao

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

According to the National Academy of Sciences (1980a), the leaves contain over 20% crude protein and are nutritious for cattle though TOXIC to most other animals including horses. The tree is widely planted as shade for chocolate, coffee, tea, and vanilla. There are few "living fence" species that strike root from cuttings more readily, also widely planted as a hedge and/or windbreak. Tilth and fertility of the soil beneath the trees are greatly improved from the leaf- and flower-fall. The timber is said to finish smoothly and be used for furniture, agricultural instruments, posts, railroad ties, and heavy construction. Flowers are a good source of forage for bees. Flowers are consumed by Mexican rural inhabitants who use the pods for rat poison. In the Philippines, the foetid leaves are crushed and rubbed onto cattle. In Indonesia, the tree is planted as a firebreak. This and other fast-growing leguminous trees have the vigor to outgrow or compete with the Imperata grass. In the shade of *Gliricida*, the grass finally dies, leaving nothing that can sustain a grass fire (NAS, 1980a).

Folk Medicine

Reported to be expectorant, insecticidal, rodenticidal, sedative, suppurative, Madre de Cacao is a folk remedy for alopecia, boils, bruises, burns, colds, cough, debility, eruptions, erysipelas, fever, fractures, gangrene, head-ache, itch, prickly heat, rheumatism, skin, sore, tumors, ulcers, urticaria, and wounds (Duke and Wain, 1981).

Chemistry

According to Roskoski et al. (1980), studying Mexican material, the seeds contain 11.93% humidity, 1.90% ash, 33.00% CP, 16.50% CF EE, 9.07% CF, 27.60% carbohydrates with a 52.42% in vitro digestibility. The foliage contains 11.96% humidity, 12.09% ash, 19.92% CP, 2.34% crude fat, 11.04% CF, 42.65% carbohydrates, and 69.69% in vitro digestibility. Low levels of alkaloids were found in the seed and saponins in the foliage, but the plant is still used for forage. Allen and Allen (1981) cite data suggesting that fallen leaves emit the new-mown-hay odor, because of the occurrence of coumarin compounds.

Description

Smooth deciduous tree to 10 m tall, 20–30 cm DBH. Leaves alternate, pinnately compound, 15–30 cm long, the 9–13 leaflets 3–6 cm long, opposite, oblong-ovate, bluntly pointed at the tip, rounded at the base, entire. Flowers on numerous lateral racemes, often on leafless branches, the clusters 5–125 cm long; flowers pinkish, ca 2 cm long; stamens 10, 9 united in a tube, one separate, white. Pods yellow-green when immature, turning blackish 10–14 cm long, 1–2 cm broad, with 3–8 elliptic, flat, shiny, blackish seed (ca 4,400/kg).

Germplasm

Reported from the American Center of Diversity, Madre de Cacao, or cvs thereof, is reported to tolerate drought, limestone, slope, and weeds. ($2n = 20$)

Distribution

Native from Mexico to Colombia, Venezuela, and the Guianas, widely introduced and naturalized throughout the tropics.

Ecology

Ranging from Subtropical Thorn to Wet through Tropical Thorn to Wet Forest Life Zones, Madre de Cacao is reported to tolerate annual precipitation of 4.8 to 41.0 dm (mean of 79 cases = 16.2), annual temperature of 21.3 to 28.5°C (mean of 61 cases = 25.3), and pH of 4.3 to 5.0 (mean of 2 cases = 4.6) (Duke, 1978, 1979).

Cultivation

Soak seeds 24 hours in lukewarm water and sow directly in potting soil in prepared pots (10 x 15 mm) wrapped in polyethylene. Move to shade for three weeks after germination, watering as needed. Use insecticide/fungicide once a month or as needed. Hardened 2–3 month old seedlings may be outplanted, avoiding midday heat, at the beginning of the rainy season (Fabian, 1981). Roskoski et al. (1980) note that the tree is easily propagated from seeds (which require no special treatment) or cuttings. Cuttings are used to make living fences throughout the tropics.

Harvesting

Living fences may be lopped for fuel or fodder as needed.

Yields and Economics

In Sri Lankan tea plantations, an average tree gave 64 kg green loppings per year (Allen and Allen, 1981). Studying Mexican material, Roskoski et al (1980) concluded that there were 44.1 (± 14.9) moles N_2 fixed per gram of nodule per hour in one assay, 11.7 ± 2.6 in another. One stand was fixing N at the rate of 13 kg/ha/yr.

Energy

Wood coppiced from living fences of *Gliricidia sepium* is burned for fuel by the rural population of Veracruz, Mexico. Annual productivity has not yet been determined here. The calorific value of the wood is 4,900 kcal/kg.

Biotic Factors

In Puerto Rico, the foliage is often attacked by aphids that secrete a sweet honeydew which attracts ants, causing the leaves to fall. On the other hand, the wood is said to be highly resistant to termites and decay.

Glory Lily or Kalihari (*Gloriosa superba* L.)

Contributor: Pankaj Oudhia

Copyright (c) 2002. All Rights Reserved. Quotation from this document should cite and acknowledge the contributor.

Common (Indian) Names:
Hindi: Kalihari, Kathari, Kulhari, Languli
Gujerati: Dudhio Vacchonag
Canarase: Akkitang hall, Huliyuguru, Nangulika, Sivasaktibalb
Marathi: Indai, Karianag, Khadyanag
Sanskrit: Agnimukhi, Garbhapatani, Kalikari

Family: Liliaceae

Habitat: Common in forests. Under cultivation in fairly large areas of India.

Botany: Herbaceous, tall, stout climbing herb. Root-stock of arched, solid, fleshy-white cylindric tubers. Leaves sessile. Ovate lanceolate, tip ending in a tendril-like spiral. Flowers large solitary, axillary, changing colors from greenish yellow, orange, scarlet and crimson from blooming to fading. Fruits cupsule. Flowering time July in October to Indian conditions.

Related Species: Six tuberous-rooted species in tropical Africa and Asia have been reported. Difference between two major varieties *G. superba* and *G. rothschildiana* are given in Table 1.

Table 1. Comparison of *Gloriosa superba* and *G. rothschildiana*

Particulars	*Gloriosa superba*	*Gloriasa rothschildiana*
Height	Climbing 1.5 m or more	Tall climbing
Leaves	Long-lanceolate to narrowly ovate-lanceolate	Broad lanceolate to broadly ovate lanceolate
Leaf length	10.2-12.7 cm	12.7–17.8 cm
Leaf width	1.3–2.5 cm	3.8–5.1 cm
Flowers	linear to narrow lanceolate	oblong-lanceolate to ovate-lanceolate
Flower length	5.1–7.6 cm	5.1–7.6 cm
Flower color	Yellow changing to red	Whitish and yellow at the base, crimson and more or less margined above
Origin	Tropical Africa and Asia	Tropical Africa

Useful Parts: Tubers, leaves, and flowers.

Medicinal Properties and Uses: In Ayurveda and Yunani systems of medicine it is a reputed medicine. According to Ayurveda, tuber is pungent, bitter, acrid, heating, anthemirtic, laxative, alexiteric, abortifacient, and useful in ulcers, leprosy, piles, iflommations, abdominal pains, itching and thirst.

Chemical Constituents: Seed contain high level of colchicines. Cornigerine, 3-demethyl-N-formyl-N-deacetyl-β-lumicolchicine, 3-demethyl-γ-lumicolchicine, 3-demethyl colchicines have been isolated from plant. β-sitosterol, its glucoside, a long chain fatty acid, β and γ-lumiccolchicines from fresh tubers and luteolin, colchicines, N-formyldeacetylcolchicines and glucosides of 3-demethylcolchicine have been isolated from flowers.

Cultivation: Kalihari is under cultivation in many states of India particularly in South India.

Propagation: From its 'V' shaped tubers.

Spacing: 60 × 45 cm.

Season: Kharif (June-July in Indian conditions)

Manures and Fertilizers: In general, it is raised under organic farming. Initially before sowing 15–20 tonnes of farm yard manure is applied.

Insects & Diseases: No insect or disease have been reported in Indian conditions.

Maturity: 170–180 days after sowing.

Yield: 200 kg seed and 150 kg pericarp.

Glycycrhiza glabra L.

Fabaceae (Leguminosae)

American licorice, Licorice, Licorice root, Wild licorice

We have information from several sources:

Simon, J.E., A.F. Chadwick and L.E. Craker. 1984. Herbs: An Indexed Bibliography. 1971–1980.

Magness, J.R., G.M. Markle, C.C. Compton. 1971. Food and feed crops of the United States.

Gmelina arborea Roxb

Verbenaceae
Gmelina, White teak

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

The wood is one of the best timbers of the tropics, useful for particle board, plywood core stock, pit props, matches, and saw timber for light construction, furniture, general carpentry, and packing. Also used in carriages, carvings, musical instruments, and ornamental work. Graveyard tests indicate that the untreated timber may last 15 years in contact with the soil. With pulping properties superior to most hardwood pulps, gmelina has been planted by the millions, e.g. in the Rio Jari region of Brazil to feed a 750 MT/day kraft pulp mill. In Gambia there are dual purpose plantings, for firewood and for honey. It is often planted as an ornamental avenue shade tree. The wood makes a fairly good charcoal. According to Little (1983), the leaves are harvested for fodder for animals and silkworms; the bittersweet fruits were once consumed by humans.

Folk Medicine

According to Hartwell (1967–1971), the root decoction is used in folk remedies for abdominal tumors in India. Reported to be anodyne, demulcent, lactagogue, refrigerant, stomachic, and tonic, gmelina is a folk remedy for anasarca, anthrax, bilious disorder, bites, blood disorders, cholera, colic, convulsions, delirium, diarrhea, dropsy, dyspepsia, epilepsy, fever, gout, ,gravel, headache, hemorrhage, intoxication, madness, phthisis, ratbites, rheumatism, rinderpest, septicemia, smallpox, snakebite, sores, sorethroat, splenitis, stomachic, swelling, and urticaria (Duke and Wain, 1981). Deeming the fruits alterative, aphrodisiac, astringent, diuretic, and tonic, Ayurvedics prescribe them for alopecia, anemia, consumption, leprosy, strangury, thirst, and vaginal discharges; the flowers for blood disorders and leprosy; the root, deemed anthelmintic, apertif, laxative, and stomachic, for abdominal pains, burning sensations, fever, hallucinations, piles, thirst and urinary discharges (Duke, 1984 in ed.).

Chemistry

The drupes are reported to contain butyric acid traces of tartaric acid and resinous and saccharine matter, the latter two also in the roots, which contain traces of benzoic acid.

Description

Deciduous tree 12–30 m high and 60–100 cm in diameter. Bark light gray or gray-yellow, smooth, thin, somewhat corking, becoming brown and rough; twigs stout, often slightly 4-angled. Leaves opposite, broadly ovate, 10–20 cm long, 7–13 cm wide; base with 2–4 glands beneath, acuminate, entire, with 3 or 5 main veins from near base and 2–5 pairs of side veins, underneath velvety with yellow-brown hairs. Petiole 5–12 cm long, hairy. Cymes paniculate at ends of twigs, 15–30 cm long, branched, densely hairy. Flowers many, short-stalked, nodding, 4 cm long, densely hairy. Calyx bell-shaped, 5 mm long, 5-toothed; corolla bright orange-yellow or brownish-yellow, with short narrow tube, 2-lipped; stamens 4 in 2 pairs inserted near base of tube. Pistil with elliptical 4-celled ovary having 1 ovule in each cell. Stigma often slightly 2–4-forked. Drupes ovate or pyriform, 2–2.5 cm long, smooth, becoming orange-yellow, pulpy, with large egg-shaped stone, having 1–4 cells. Seeds 1–4 (Little, 1983).

Germplasm

Reported to tolerate disease, drought, fire, heat, laterite, light frosts, and slope. Although casting a dense shade itself, it is intolerant of shade as a seedling (Little, 1983).($2n = 36, 38$)

Distribution

Native to tropical moist forest from India, Burma, and Sri Lanka to southern China, Gmelina is widely introduced, e.g. in Brazil, Gambia, Honduras, Ivory Coast, Malaysia, Malawi, Nigeria, Panama, Philippines, and Sierra Leone.

Ecology

Estimated to range from Tropical Very Dry to Wet through Subtropical Very Dry to Wet Forest Life Zones, gmelina is reported or estimated to tolerate annual precipitation of 7 to 45 dm (NAS, 1980a), annual temperature of 20 to 26°C, and pH of 6 to 8. It can tolerate a 6–7-month dry season. Grows on many soils, acidic laterites to calcareous loams, doing poorly on thin or poor soils with hardpan, dry sands, or heavily leached acidic soils, well-drained basic alluviums.

Cultivation

Seeds, retaining their viability for only about 12 months, will benefit from soaking if rain or irrigation is not expected. Direct seeding is cheap but tubed seedlings are also outplanted, sometimes intercropped with beans, cashew, corn, peanuts, and tobacco. For fuelwood, spacing at 2 x 2 m is recommended, wider spacings for timber plantations. For the first year or so, weeding is necessary, but the canopy is soon dense, like the litter layer, quickly arresting the weed growth.

Harvesting

Trees coppice well, with 5-year coppice rotations for fuel, longer rotations for timber.

Yields and Economics

The NAS (1980a) reports annual increments; >30 m^3/ha, on fertile sites. Rotations of 5–8 years may produce 20–35 m^3. Occasionally trees may start dying out at only 10 years age.

Energy

Destructive distillation of the wood yields 31.8% charcoal, 47.1% total distillate, 37.1% pyroligneous acid, 10.0% tar, 2.4% pitch, and losses, 4.47% acids, 3.42% esters, 2.38% acetone, and 1.28% methanol on a dry weight basis. The non-condensable gases (1.88 ft^3/lb) contain 59% CO_2, 31.75% CO, 4.5% methane, 4.15% H, and 0.6% unsaturated hydrocarbons. Many of these have energetic potential (C.S.I.R., 1948–1976). Reynolds and Lawson (1978) concluded that the heating value of Gmelina wood was less than that from the local eucalypts. Although the calorific values of the samples studied were almost identical (4.53 mcal/kg and 4.54 respectively), the DM contents were 45 and 56%. The fresh weight of Gmelina firewood brought in cubic-meter lots was significantly correlated with butt size. The NAS (1980a) suggests 4.8 mcal/kg for the sapwood, spec. grav. 0.42–0.64. The charcoal burns well, without smoke, leaving a lot of ash. The Wealth of India (C.S.I.R., 1948–1976) puts the calorific value at 4.763 mcal (8,547 BTU) with silica free ash of 1.54%. In a 10-year-old Philippine stand, the aboveground biomass was 127 MT/ha, leaf biomass was 1.4 MT, leaf litter ca 5.2 MT, constituting ca 62% of the total litter. Annual productivity was 18 MT/ha. Annual stem increment was about 10 MT/ha or 30 M^3/ha, little influenced by the age of the stand over the first 15 years (Kawahara et al., 1981). Akachuku's data (1981) show annual yields of 20–50 m^3/ha/yr but he cites other studies on poor sandy soil yielding only 7, on laterites only 18; on the best of savanna sites 25, on rainforest sites 31–36, on Malaysia sites 28–38, and on Philippine sites 36 m^3. MAI in 7-year trees was 32 m^3 (15 MT) to 47 m^3 (23 MT)/ha (Akachuku, 1981).

Biotic Factors

Cattle may eat the foliage and bark; seeds and foliage are consumed avidly by rabbits and deer. In Latin America, the leaves are gathered by the leaf-cutter ants. In India, other insects may defoliate the plant. Calopepla may defoliate, while the borers, Dihamnus and Alicide, may damage the trees. The "machete disease", *Ceratocystis fimbriata,* is sometimes severe in moister climates. *Poria rhizomorpha* may cause stem and root diseases in wet situations with heavy soils. Browne (1968) lists the following as affecting *Gmelina arborea:* (Fungi) *Armillaria mellea, Cercospora ranjita, Fomes roseus, Polyporus baudni, Poria rhizomorpha, Sclerotinia rolfsii, Trametes straminea.* (Angiospermae) *Tapinanthus* sp. (Mollusca) *Limicolaria aurora.* (Myriapoda) *Odontopyge* sp. (Coleoptera) *Alcidodes ludificator, Apion angulicolle, A. armipes, Apophyllia chloroptera, A. sulcata, Calopepla leayana, Dihammus cervinus, Empecamenta calabarica, Lagria villosa, Lixus camerunus, L. spinimanus, Macrocoma candens, podagrica dilecta, Prioptera punctipennis, Xyleborus fornicatus.* (Hemiptera) *Agaeus pavimentatus, Anoplocnemis tristator, Chunrocerus niveosparsus, Dysdercus superstitiosus, Tingis beesoni, Trioza fletcheri.* (Isoptera) *Coptotermes curvignathus, C. niger, Macrotermes goliath.* (Lepidoptera) *Acrocercops telestis, Endoclita undulifer, Eupterote geminata, E. undata, Evergestis aureolalis, Gonodontis clelia, Indarbela quadrinotata, Metanastria hyrtaca, Phostria caniusalis, Psilogramma menephron, Sahyadrassus malabaricus, Selepa celtis, Xyleutes ceramica.* (Orthoptera) *Heteropternis thoracica, Kraussaria angulifera, Phaneroptera nana, Phymateus viridipes, Zonocerus elegans.* (Mammalia) *Axis axis, Strepsiceros strepsiceros, Sylvicarpa grimmia, Thryonomys swinderianus, Tragelaphus scriptus.*

Sweet Cudweed

Gnaphalium obtusifolium L.

Synonym.—*Gnaphalium polycephalum* Michx.

Sweet cudweed

Figure 103.—Sweet cudweed (*Gnaphalium obtusifolium*)

Other common names.—Fragrant life everSievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Lasting, sweet balsam, white balsam, feather-weed, rabbit-tobacco.

Habitat and range.—This plant grows in dry, mostly open places from Nova Scotia to Manitoba and south to Florida, Kansas, and Texas.

Description.—Sweet cudweed, which is better known in the drug market as life everSievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Lasting, is a fragrant herb 1 to 3 feet high, white-woolly nearly throughout, with an erect stem, simple or branched above. The leaves are narrow, one-sixth to one-third of an inch wide, and 1 to 3 inches long dark green above and densely white-woolly underneath. The flowers, produce] about August to September, are borne in numerous barely crowded heads consisting of one to five individual flowers.

Part used.—The herb.

Golden Groundsel

Senecio aureus L.

Other common names.—Life root, golden ragwort, swamp squawweed, coughweed, grundy-swallow.

Golden groundsel

Figure 55.—Golden groundsel (*Senecio aureus*)

Habitat and range.—Golden groundsel is found in swamps and meadows from Newfoundland to Ontario, and Missouri, Florida, and Texas.

Description.—This plant is a smooth herb with rather slender, solitary or tufted stems one-half to 2 1/2 feet high. The basal leaves, which are 1 to 6 inches long, are heart-shaped or kidney-shaped with long stems and often purplish beneath. The lower stem leaves are lance-shaped and deeply out and the upper most small and clasping. The flower heads, from two-thirds of an inch to about 1 inch broad, consisting of disk and deep yellow ray flowers, are borne several in a flat-topped open cluster during the early summer.

Part used.—The herb and the root.

Gourds

Sing kwa, Luffa, Dishcloth gourd, Strainer vine, Chinese okra, Vegetable sponge, California okra

Cucurbitaceae *Luffa acutangula* (L.) Roxb., *L. cylindrica* (L.) Roem, *Lagenaria* sp.

Source: Magness et al. 1971

Plants are running vines, similar to cucumber and melon. Leaves are rounded. Fruits are strongly ribbed, elongated, pyriform or cylindrical in shape, 1 foot or more in length, gourd-like. Sometimes young fruits are consumed as cooked vegetables. When ripe shell is hard and interior is fibrous, sponge-like, and inedible.

Season, seeding to harvest as vegetable: 3 or 4 months.

Production in U.S.: No data. Very limited.

Use: Immature fruits as cooked vegetable.

Part of plant consumed: All of young fruits.

Grape, American

Slip skin grape

Vitaceae *Vitis* sp., mostly *V. labrusca* L.

Source: Magness et al. 1971

These are grape varieties developed in whole or in part from species indigenous in this country. They are hardier and more disease resistant than the Old World grape, and are grown at least in home gardens in all mainland states except Alaska. Plants are perennial and long-lived vines, in commerce supported on trellises. Fruit is produced in bunches. Individual berries, from 0.5 inch to near 1 inch diameter, vary in shape from oval to slightly oblate and in color from green to red or black. Skin is thin and waxy, and separates readily from pulp, hence the name "slip skin." Fruits generally contain contain 2 to 4 seeds.

Season, bloom to harvest: 3 to 5 months.

Production in U.S.: About 300,000 tons commercially; extensively grown in home plantings.

Use: Fresh, juice, wine, jelly and jam.

Part of fruit consumed: Generally pulp only, but skin included by some people when eating fresh, or is separated from the pulp in the mouth.

Last update February 18, 1999 by ch

Grape seed oil

Vitaceae *Vitis* sp.

Source: Magness et al. 1971

Large quantities of grape seeds are available from grapes processed for wine, seeded raisins and grape juice. The seeds, up to 0.5 inch long, are enclosed near the center of the fleshy pulp. They contain about 12 percent of a drying oil. The oil is obtained by expression or with solvents. The oil, after refining, is used mainly for edible purposes. Oil from raisin grape seed is used for coating the raisins to improve appearance and keep them pliable. Grape seed oil is also used in industry.

Garlic, Great-headed

Elephant garlic

Amaryllidaceae *Allium ampeloprasum* L. (Great-headed garlic group)

Source: Magness et al. 1971

Plants have appearance of very robust garlic plants. Great-headed garlic forms large flower heads which usually lack bulblets. It may produce a cluster of several cloves similar to garlic, or a single massive bulb, with small bulblets around its main bulb. The bulb flavor is intermediate between onion and garlic. Cultural practices are similar to those for garlic. The bulbs are developed entirely underground. Great-headed garlic is grown in many home gardens, but rarely as a commercial crop.

Season, setting to harvest: About 8 months.

Production in U.S.: No data separate from garlic. Mainly in home gardens.

Use: Culinary, and as part of stews and soups.

Part of plant consumed: Bulb only. Last update February 18, 1999 by ch

Green needlegrass

Feather bunchgrass

Gramineae *Stipa viridula* Trin.

Source: Magness et al. 1971

This native bunchgrass is most abundant on the upland prairie and ranges of the Northern Plains. It frequently invades abandoned cropland. It grows on most soil types but thrives best on sandy soils. It grows up to 3 feet. Leaves are mostly basal, up to 12 inches long and 0.5 inch wide. Seed spikes have bent awns about an inch long but are less troublesome to livestock than those of Needle-and-thread grass. Growth starts early in the spring and continues through summer when moisture is available. The grass is palatable and nutritious and makes excellent hay. It also cures well on the ground so is useful for winter grazing. It is useful for revegetation as seedlings are vigorous and drought resistant. Seed of some improved varieties is available.

Gum Plant

Grindelia robusta Nutt.; (2) *G. squarrosa* (Pursh) Dunal.

Other common names.—(2) Broad-leafed gum plant, scaly grindelia.

Figure 59.—Broad-leafed gum plant (*Grindelia squarrosa*)

Habitat and range.—The gum plant (*Grindelia robusta*) grows in California, while the broad-leafed gum plant (*G. squarrosa*) is more widely distributed, being of common occurrence on the plains and prairies from Saskatchewan to Minnesota and south to Texas and Mexico.

Description.—The name " gum plant " is applied especially to Grindelia robusta on account of the fact that the entire plant is covered with a resinous substance, giving it a gummy, varnished appearance. It is an erect herb with a round, smooth stem about 1 1/2 feet in height. The leaves, about 1 inch in length, are green, leathery, rather rigid, and covered with resin. The plant branches freely near the top, each branch terminating in a yellow flower about three-fourths of an inch in diameter.

The broad-leafed gum plant, *Grindelia squarrosa*, is similar to *G. robusta*, except that it is smaller and less gummy in appearance. The leaves are much smaller and thinner and less rigid.

Part used.—The leaves and flowering tops of both species, collected when the plants are in full bloom.

Ground-Ivy

Nepeta hederacea (L.) Trev.

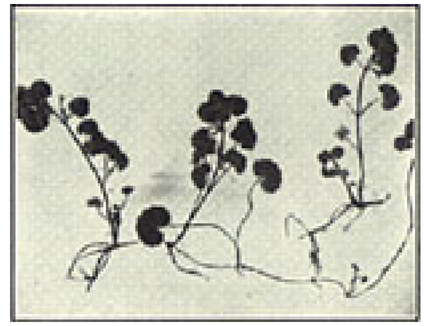

Figure 58.—Ground-ivy (*Nepeta hederacea*)

Synonym.—*Nepeta glechoma* Benth.; *Glecoma hederacea* L.

Other common names.—Field balm, gill-over-the-ground, gill, creeping Charlie, robin-runs-away, cat's-foot.

Habitat and range.—Ground-ivy is found in dams and shady places, especially in thickets, from Newfoundland and Ontario to Georgia, Tennessee, Kansas, and Colorado.

Description.—This small herb has numerous creeping, leafy, hairy stems sometimes 18 inches long, commonly branching at the base. The opposite leaves are round kidney-shaped, bluntly toothed, green on both sides, and one-half to 1 1/2 inches in diameter. The stems of the lower leaves are commonly longer than the leaves. The blue and white tube-shaped flowers are borne, few in a cluster, in the axils of the leaves from March to May.

Part used.—The herb.

Pithecellobium dulce (Roxb.) Benth.

Mimosaceae
Guamachil, Manila tamarind

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Often planted for living fence or thorny hedge, eventually nearly impenetrable, guamachil furnishes food, forage, and firewood, while fixing a little nitrogen. The pods, harvested in Mexico, Cuba, and Thailand, and customarily sold on roadside stands, contain a thick sweetish, but also acidic pulp, eaten raw or made into a drink similar to lemonade. Pods are devoured by livestock of all kinds; the leaves are browsed by horses, cattle, goats, and sheep; and hedge clippings are often gathered for animal feed. The plants withstand heavy browsing. The seeds contain a greenish oil (20%), which, after refining and bleaching, can be used for food or in making soap. The presscake, rich in protein (30%), may be used as stockfeed. Bark used as a fish poison in the Philippines (Perry, 1980). Known in the Philippines as "Kamachil", the wood, malodorous when cut, is used for boxes, crates, fuel, and wagon wheels. The gum exuding from the trunk can be used for mucilage, the tannin for tanning. The bark is harvested for tanning in Mexico. Tree seems promising for the cultivation of the lac insect. Flowers make good honey.

Folk Medicine

Reported to be abortifacient, anodyne, astringent, larvicidal, guamachil is a folk remedy for convulsions, dysentery, dyspepsia, earache, leprosy, peptic ulcers, sores, toothache, and venereal disease (Duke and Wain, 1981). The bark of *P. avaremotem*, the "avaremo-temo" from Brazil, is a folk cancer elixir (Hartwell, 1967–1971).

Chemistry

The fruit, more probably the aril, is reported to contain, per 100 g, 78 calories, 77.8% water, 3.0% protein, 0.4% fat, 18.2% total carbohydrate, 1.2% fiber, 0.6% ash, 13 mg Ca, 42 mg P, 0.5 mg Fe, 19 mg Na, 222 mg K, 15 mg β-carotene equivalent, 0.24 mg thiamine, 0.10 mg riboflavin, 0.60 mg niacin, and 133 mg ascorbic acid. The essential amino acids in the aril are 143 mg/100 g valine, 178 lysine, 41 phenylalanine, and 26 tryptophan. An Indian aril (60% of the pod) contained 21.0 mg Ca/100 g, 40.0 Mg, 58.0 P, 1.1 Fe, 3.7 Na, 377 K, 0.6 Cu, and 109 S. As calcium pectate, pectin occurs as 0.96% of the sugars (mostly glucose) analysis of the aril (C.S.I.R., 1948–1976). The whole fruit, with husk and seeds (58% refuse) contains 33 calories, 32.7% moisture, 1.3 g protein, 0.2 g fat, 7.6 g total carbohydrate, 0.5 g fiber, 0.2 g ash, 5 mg Ca, 18 mg P, 0.2 mg Fe, 8 mg Na, 93 mg K, 5 mcg β-carotene equivalent, 0.10 mg thiamine, 0.4 mg riboflavin, 0.2 mg niacin, and 56 mg ascorbic acid (Leung et al, 1972). Per 100 g, the seed is reported to contain 13.5 g H_2O, 17.7 g protein, 17.1 g fat, 41.4 g starch, 7.8 g fiber, 2.6 g ash. On alcoholic extraction, the seeds yield a saponin, a sterol glucoside, a flavone, and lecithin. The fatty acid composition of the seed is 24.3% saturated acids, 51.1% oleic, and 24.0% linoleic. Hager's Handbook (List and Horhammer, 1969–1979) reports 0.3% caprylic, 0.3% caprinic, 0.3% lauric, 0.8% myristic, 12.1% palmitic, 6.9% stearic, 3.1% arachidic, 13.1% behenic, 4.9% lignoceric, 32.2% oleic, and 26.0% linoleic acids in the fatty acids. Further listed is a saponin containing oleanolic- and echinocytic acids, with the sugar sequence xylose, arabinose, and glucose; also pithogenin, ($C_{28}H_{44}O_4$), hederagenin and sodium nimbinate (which latter two are said to be antiarthritic and antiedemic in rats). Wax, hexacosanol, L-proline, L-leucine, L-valine, and asparagine, are also reported from the fruit, leucoro-binetinidin, leucofisetinidin, and melacacidin from the wood. After extraction of ca 20% edible oil, the seed cake, with 29.7% protein, can be used as animal feed. Bark contains up to 37% of a catechol type tannin. Bark also yields a yellow dye and 1.5% pectin. It is said to cause dermititis and eye inflammation. According to Roskoski et al (1980), studying Mexican material, the seeds contain 14.00% humidity, 2.66% ash, 25.69% CP, 8.12% EE, 22.16% CF, 26.97% carbohydrates with a 80.84% in vitro digestibility. The foliage contains 6.46% humidity, 15.34% ash, 17.17% CP, 6.83% EE, 30–95% CF, 23.25% carbohydrates, and 71.46% in vitro digestibility. For comparison, the Wealth of India reports (ZMB): 29.0% CP, 4.4% EE, 17.5% fiber, 43.6% NFE, 5.6% ash, 1.14% Ca, and 0.35% P. The manurial value of dry leaves is 4.91% N, 0.78% P2O5, 1.04% CaO, and 2.67% K_2O. The antitumor compound, β-sitosterol (perhaps ubiquitous), and campesterol, stigmasterol, and α-spinasterol occur in the heartwood (C.S.I.R., 1948–1976).

Description

A large, nearly evergreen tree that grows up to 20 m or more in height, Manila tamarind has a broad crown (to 30 m across) and a short bole (to 1 m thick). At the base of each leaf is normally found a pair of short, sharp spines, though some specimens are spineless. (NAS, 1980a).

Germplasm

Reported from the American Center of Diversity, guamachil, or cvs thereof is reported to tolerate drought, heat, poor soil, salt, sand, and shade. ($2n = 26$).

Distribution

Native to Mexico through Central America to Colombia and Venezuela. Introduced in southern Florida, Cuba, Jamaica, Puerto Rico, and St. Croix. Widely planted and naturalized in tropical regions, including the Old World (Little and Wadsworth, 1964). Listed as a common weed in Hawaii.

Ecology

Ranging from Tropical Desert (along water courses) to Moist through Subtropical Desert to Moist Forest Life Zones, guamachil is reported to tolerate annual precipitation of 1.4 to 22.0 dm (mean of 43 cases = 14.7), annual temperature of 18.0 to 27.9°C (mean of 37 cases = 25.4), and pH up to 8.3 (Duke, 1978, 1979). Occurs up to 1,800 m in Mexico and 1,500 m in Burundi. Suitable for most dry regions, it is drought resistant, in low rainfall areas developing an extensive root system. In Burundi it grows well at 800 m elevation and 600 mm, spread evenly year-round. In southern Florida rainfall averages 1,650 mm or more. It has great adaptability and grows on most soil types, including clay, oolitic limestone, and rather barren sands. It can also be found in wet sands that have a brackish water table (NAS, 1980a).

Cultivation

Reproduces easily by seeds or cuttings. For hedges, seeds may be sown in site, spaced 15 cm apart in two rows 30 cm apart.

Harvesting

Cut as needed for fuel, the tree has a fast rate of growth, coppices vigorously and can withstand "any amount of pruning, lopping, or browsing by animals." (C.S.I.R., 1948–1976).

Yields and Economics

In favorable soils and climates, the Manila tamarind may reach a height of 10 m in 5 or 6 years (NAS, 1980a). With no specific data available, I project that well established trees would produce forage somewhere between 6–20 MT/ha/yr, the 6 projected for *Prosopis tamarugo* and the 20 for *Leucaena*, by Felker (1981). Pod yields, according to my visual estimation, should approach those of *Prosopis juliflora*, a rather productive legume.

Energy

The reddish-brown wood is usually hard, heavy, and strong, though it is also brittle and rather difficult to cut. It is used (in India, Africa, and America) as a fuel, but smokes condiserably and is not best quality. Calorific value, 5,200–5,600 kcal per kg. In parts of India it is used as fuel for brick kilns (NAS, 1980a).

Biotic Factors

Normally pest damage is insignificant; can become affected by leaf spot diseases, *Phyllosticta inga-dulcis* and *Colletotrichum* sp., and a number of defoliating and boring insect pests. It is a favorite host of the thornbug. (NAS, 1980a). The nematode *Meloidogyne* is reported as a pest in Florida, the twig blight *Phomopsis* sp., the leaf spot *Phyllosticta pithecolubis* in Texas and Puerto Rico, *Physalospora fusca* and *Physalospora rhodina* in Florida, the wood rot *Polyporus gilvus* in Hawaii. Since several rhizobial cultures from guamachil failed to nodulate on several other taxa, this species was considered highly selective. Other tests with Baptisia, Crotalaria, and Dalea incurred nodulation (Allen and Allen, 1981). Browne (1968) lists: Fungi. *Corticum salmonicolor, Phyllosticta ingae-dulcis.* Coleoptera. *Celosterna scabrator, Sternocera sternicornis*. Hemiptera. *Kerria lacca, Nipaecoccus vastator.* Lepidoptera. *Cryptophlebia illepida, Eucosma stereoma, Euproctis scintillans, Hypanartia hecabe, Macroplectra nararia*.

Gudmar or Merasingi (Gymnema sylvestre R. Br.)

Contributor: Pankaj Oudhia

English Name: Periploca of the woods, Small Indian ipecacuanha

Common (Indian) Name:
Hindi: Gudmar, Merasingi
Canarese: Sanngera, Sannagerse
Gujrati: Mardashingi
Marathi: Bediki, Kavali, Vakundi
Sanskrit: Mehashingi, Meshavalli, Vishani

Family: Asclepiadaceae

Botany: Much branched large woody climber, young stems are densely pubescent. Leaves - Opposite, Ovate, elliptic, base rounded or cordate . Flower - in Cymes; C. - Companulate; yellow, corona of 5 processes; Fruits - Follicle, lanceolate, usually single; Seeds - with thin marginal wing; flowering time in Indian conditions - April - May.

Habitat: In India naturally occur in monsoon forests.

Useful parts: Whole plant

Medicinal Properties: According to Ayurveda, it is bitter, acrid, cooling, tonic, alterative, anthelmintic, alexeritic. It cures eye complaints, burning sensation, biliousness, bronchitis, ulcers, asthma etc. The plant has been used to treat diabetes in India for 2,000 years by traditional medicinal practioners, but interest in its properties waned during the British colonial period when western rather than traditional therapy was official patronized by the government, as well as diminished with the advent of insulin. Leaves possess special feature. The leaves when chewed, have remarkable property of paralysing the taste glands for few hours against sweet and bitter taste.

Chemical Constituents: The leaves contain pentriacontane, hentriacontane, phytin, a and b chlorophylls, resin, tartaric acid, formic acid, butyric acid, mucilage, inositol, gymnemic acid and antheraquinone. The plant is reported to content alkaloids, betain, choline and trimethylamine in the leaves

Cultivation: Gymnema is under cultivation as medicinal crop in fairly large areas, in different parts of India. Standard cultivation practices for commercial cultivation has yet not been developed.

Witch-Hazel

Hamamelis virginiana L.

Witch-hazel

Figure 122.—Witch-hazel (*Hamamelis virginiana*)

Other common names.—Snapping hazel, winterbloom, wych-hazel, striped alder, spotted alder, tobacco wood.

Habitat and range.—The home of this native shrub is in low damp woods from New Brunswick to Minnesota and south to Florida and Texas

Description.—Witch-hazel, while it may grow to 25 feet in height, more frequently reaches a height of only 8 to 15 feet. It has a crooked stem and long forking branches with smooth, brown bark. The leaves are from 3 to 5 inches long, thick, and borne on short stalks. A peculiar feature of the plant is the lateness of the threadlike, yellow flowers, which do not appear until late in autumn or in early winter after the leaves have fallen. The seed capsule does not mature until the following season, when it bursts open, scattering the shining black, hard seeds with great force and to a considerable distance.

Part used.—The leaves, twigs, and bark, collected in autumn. These contain a volatile oil the distillation of which for the production of witch-hazel extract b; a well-developed industry in southern New England.*

*Information on the extraction of volatile oils from plants is contained in the following publication: Sievers, A.F. Methods of extracting volatile oils from plant material and the production of such oils in the United States. U.S. Dept. Agr. Tech. Bul. 16, 36 p. illus. 1928.

Pittosporum resiniferum Hemsl.

Pittosporaceae
Petroleum nut (English) Hanga (Philippine)

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Called petroleum nut because of the fancied resemblance of the odor of the fruit's oil to that of petroleum, the fruits, even green ones, burn brilliantly when ignited. Hence they are used like torch nuts or candlenuts for illumination in the bush. Dihydroterpene ($C_{10}H_{18}$) is used in perfumes and medicines. Heptane (C_7H_{16}) is a component of gasoline, and has been suggested as a possible component of paint and varnish (Anonymous, 1981c).

Folk Medicine

Fruit is used as a panacea by Philippine traditionalists, especially, however, for abdominal pain. The oleoresin is used to treat muscular pains and skin diseases (Perry, 1980). The nut decoction is used for colds. Crushed nuts are mixed with coconut oil as a relief for myalgia. Altschul (1973) quotes from a 1947 Sulit herbarium specimen, "Petroleum gas extracted from the fruit is medicinal for stomachache and cicitrizant."

Chemistry

The volatile oil of the fruit is reported to contain "dihydroterpene and heptane, which is a cardiac glycoside." (Perry, 1980). The Horticultural and Special Crops Laboratory at Peoria analyzed an accession of fruit, and identified, from its "squeezings", constituents passing through a gas chromatographic column, heptane (about 45% of the elutents) nonane, α-pinene or β-ocimene, β-pinene, myrcene, and unidentified materials. According to Nemethy and Calvin (1982) the essential oil (8-10% of fruit weight) contains myrcene (40%) and α-pinene (38%) in ± equal quantities (*P. undulatum's* contains mostly limonene). The two components n-heptane (5%) and n-nonane (7%) are minor components.

Description

Aromatic tree to 30 m tall, but probably smaller in its elfin forest habitat (perhaps even epiphytic); fruiting when only 6–12 m tall. Leaves aromatic, coriaceous, entire (possibly evergreen), thickest above the middle, pinnately nerved, with a short acumen at the tip. Flowers fragrant, white, clustered on the stems. Fruits average 25 mm in diameter (12–43). Each fruit has 5–72 seeds (average 31), the seeds ranging from 1–40 mm, averaging 3 mm. The seeds are about as close to hexahedral and prismatic as any I have seen, being quite angular, black to blackish gold, often still surrounded by a gummy or resinous endocarp.

Germplasm

The FORI Director in the Philippines is actively collecting superior germplasm in the high mountains of Bontoc and Benguet where they abound, especially in elfin forests.($2n = 24$)

Distribution

In the Philippines, petroleum nut is locally known in Benguet as apisang, abkol, abkel, and langis; in the Mountain Province, dael and dingo, and in Abra, sagaga. It abounds in Mt. Pulis, Ifugao, and is reported from the headwaters of the Agno and Chico River Basins. Also in the Bicol Provinces, Palawan, Hindoro, Nueva Ecija, and Laguna Provinces. It is being cultivated at FORI's Conifer Research Center, Baguio City.

Ecology

Petroleum nut is reported to range from 600–2,400 m elevation, usually in elfin or Benguet Pine Forest. Average of 7 climatic data sites where the *Pittosporum* grows, was close to 1,000 m, the range from ca 550 to 2,000 m. Whether or not it can stand frost, dry heat, and drought is questionable. Frequently, species of elfin forests have very narrow ecological amplitudes and do not thrive in other vegetation types. Results of transplants and trials are unavailable to me now. Reportedly seed were introduced once, at least to Hawaii. Thanks to Professors Ludivina S. de Padua, S.C. Hales, and Juan V. Pancho of the Philippines, we now have a fairly good idea of the ecosystematic amplitudes of the Pittosporum, an energy plant that has captured the imagination of many. Professor de Padua checked off all the climatic data points (from our climatic data base) at which *Pittosporum resiniferum* was growing, prior to its widespread introduction for potential energy studies elsewhere in the Philippines. Ranging from Tropical Dry to Moist through Subtropical Forest Life Zones, the petroleum nut grows where the annual precipitation ranges from 15 to more than 50 dm (mean of 36 cases = 27 dm), annual temperature from 18–28°C (mean of 17 cases = 26°C). Of 17 cases where both temperature and rainfall data were available to us, 13 would suggest Tropical Moist Forest Life Zone, three would suggest Tropical Dry, and one would suggest Subtropical Rain Forest Life Zones.

Cultivation

Seeds and cutting can be used to propagate the tree. Seeds may lose their vitality rather rapidly. According to Juan V. Pancho (personal communication, 1982), "from my experience, the seed lost its viability after one month storage."

Harvesting

Currently, seeds are harvested from the wild.

Yields and Economics

A single fruit yields 0.1–3.3 ml, averaging about 1.3 ml. In general, the bigger the fruit, the larger the seed, and the greater the oil content (Veracion and Costales, 1981). It is reported (Anonymous, 1981) that a single tree from Mount Mariveles, Bataan, yielded 15 kg green fruits, which yielded 80 cm^3 of oil. The residue, ground up and distilled with steam, yielded 73 cm^3 more. Another report gave 68 g per kg fresh nuts, suggesting about 1 kg oil per tree yielding 15 kg (Anonymous, 1981c). Currently seed are being sold at $2.00 per gram in 5-gram lots (ca 40 seed per g) by the FORI Seed Officer, Forest Research Institute, College, Laguna, Philippines.

Energy

The plant was discovered as a hydrocarbon source just after 1900, but based on the previous paragraph, it seems it would take 1,000 trees per ha to get one MT oil per hectare from the fruits. Perhaps the resin in the leaves, twigs, etc. would equal or exceed this; figures are not yet available. The oil derived from the fruits is quite sticky and rapidly turns resinous when laid thin. In an open dish, it burns strongly, although with a sooty flame (Anonymous, 1981). C.A. Arroyo (1981) notes that for home use as fuel, "the husk of African oil palm nuts could be much better than the petroleum nut that emits sooty smoke and strong smell." Recently, I heard rumors that President Marcos was encouraging each Philippine farmer to plant five trees in the hopes that they could obtain 300 liters of oil therefrom, per year. I saw nothing about this at the Philippine exhibit at the World's Fair in June 1982. However, if yields of 60 liters of oil per tree are possible, the tree should certainly be examined! In the January 1981 issue of Canopy, Generalao (1981) lists petroleum nut at the top of a long list of potential oil seeds including *Pongamia pinnata*, *Sterculia foetida, Terminalia catappa, Sindora supa, Calophyllum inophyllum, Canarium luzonicum*, *Aleurites moluccana*, *Aleurites trisperma, Mallotus philippensis*, *Barringtonia asiatica*, *Sindora inermis, Pithecellobium dulce, Tamarindus indica, Chisocheton cumingianus, Jatropha curcas*, and *Euphorbia philippensis* to help the Philippines solve their energy problem (importing 85%). Presidential Decree 1068 declares the imperative acceleration of research on energy alternatives. Speaking in that same issue of Canopy, an editorial notes that in 1978 FORI concluded the flammable element in petroleum nut is volatile, evaporating quickly like acetone. Some chemists believe admixing another element will stabilize the compound. One seed catalog (Anonymous, ca 1983) has very optimistic notes about the plant. "The Gasoline Tree produces masses of apricot-sized orange fruits which when cut and touched with a match leap into flame and burn steadily. The fruits contain 46% of gasoline type components (heptane,dihydroterpene, etc.), which are found in extensive networks of large resin canals. If planted the estimated yield would be about 45 tons of fruit or 2500 gallons of 'gasoline' per acre per year."

Biotic Factors

No data available.

Hardinggrass

Gramineae *Phalaris stenoptera* Hack.

Source: Magness et al. 1971

This is a cool-season grass, native to Africa, but brought to the United States from Australia in 1914. It is a long-lived bunchgrass with short, stout rhizomes. It is adapted to mild climates with winter rainfall and thrives best on heavy soils. It is the most widely adapted range grass in California but is grown only sparingly in other areas of the Southwest. Where adapted, forage yields are high and quality is good.

Hemlock

Tsuga canadensis (L.) Carr.

Synonym.—*Abies canadensis* Michx.

Other common names.—Hemlock spruce, weeping spruce, spruce pine, tanbark

Habitat and range. The hemlock tree is found in forests from Ontario south to Virginia and Alabama and west to Michigan and Wisconsin.

Description.—This tall forest tree, which at times attains a height of 110 feet and a trunk diameter of 4 feet, is well known throughout its range as a source of tanbark. Its lower branches are somewhat drooping, and the dense, rather delicate foliage is deep green above and silvery beneath. The flat, narrow leaves are from one-half to three-fourths of an inch long and less than one-twelfth of an inch wide. The hanging cones are as long as or slightly longer than the leaves.

Part used.—The bark.

HENNA

Family: Lythraceae, (*Lawsonia inermis* L.)

Source: Simon, J.E., A.F. Chadwick and L.E. Craker. 1984. Herbs: An Indexed Bibliography. 1971-1980. The Scientific Literature on Selected Herbs, and Aromatic and Medicinal Plants of the Temperate Zone. Archon Books, 770 pp., Hamden, CT.

Henna, *Lawsonia inermis* L., a perennial shrub native to northern Africa, Asia, and Australia, is naturalized and cultivated in the tropics of America, Egypt, India, and parts of the Middle East. Also known as El-Henna, Egyptian priest, and mignonette tree, the species is sometimes classified as *Lawsonia alba* Lam. or *Lawsonia ruba*. Reaching a height of up to 6 meters, the plant has fragrant white or rose-red flowers.

The reported life zone of henna is 19 to 27 degrees centigrade with an annual precipitation of 0.2 to 4.2 meters and a soil pH of 4.3 to 8.0 (4.1-31). Henna is planted today primarily as an ornamental hedge, but is probably best known for the dried, ground leaves (called henna) traditionally used to produce colorfast orange, red, and brown dyes. Dried, powdered leaves of henna contain about 0.5 to 1.5 percent lawsone, the chief constituent responsible for the dyeing properties of the plant (1.1-273, 14.1-35). Henna also contains mannite, tannic acid, mucilage, gallic acid, and napthaquinone (7.6-192).

The leaves of henna have been used in Asia since antiquity as a hair, nail, and skin dye. In the West and the Middle East, henna is used in hair shampoos, dyes, conditioners, and rinses. Henna dye products are mixed with indigo or other plant material to obtain a greater color range. Extracts of henna are also used to stain wood and to dye fabrics and textiles.

As a medicinal plant, henna has been used for astringent, antihemorrhagic, intestinal antineoplastic, cardio-inhibitory, hypotensive, and sedative effects (7.6-192, 11.1-154). It has also been used as a folk remedy against amoebiasis, headache, jaundice, and leprosy (11.1-154). Henna extracts show antibacterial, antifungal, and ultraviolet light screening activity (1.8-169, 7.2-21,14.1-21, 14.1-35). Henna has exhibited antifertility activity in animals and may induce menstruation (7.5-76, 11.1-154).

The dried leaf and petiole of henna are generally recognized as safe when used as a color additive for hair (21 CFR section 73.2190[1982]).

Liverleaf

(1) *Hepatica americana* Ker.; (2) *H. acutiloba* DC.

Other common names.—(1) Round-leaved hepatica, common liverleaf kidney liverleaf, liverwort (incorrect), noble liverwort, heart liverwort, three-leaved liverwort, liverweed, herb trinity, golden trefoil, ivy flower, mouse-ears, squirrel cup; (2) heart liverleaf, acute-lobed liverleaf, sharplobe liverleaf, sharplobe hepatica.

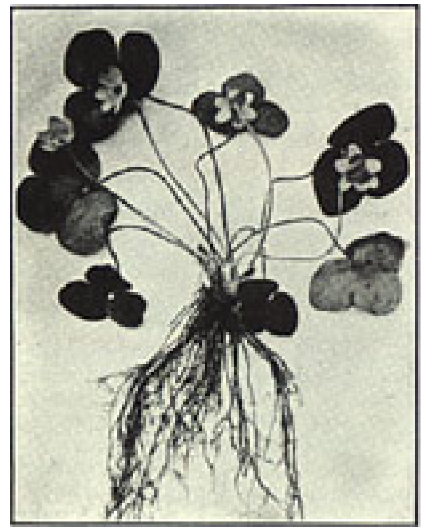

Figure 73.—Liverleaf (*Hepatica americana*)

Habitat and range.—The common liverleaf is found in woods from Nova Scotia to northern Florida and west to Iowa and Missouri, while the heart liverleaf occurs from Quebec to Ontario, south to Georgia (but rare near the coast), and west to Missouri and Minnesota.

Description.—The hepaticas are among the earliest of our spring flowers, blossoming about March and frequently sooner. They grow only about 4 to 6 inches in height, with leaves produced from the rootstocks on soft, hairy stalks spreading on the ground. The thick and leathery evergreen leaves are roundish or kidney-shaped. The bluish to purple or white flowers are about half an inch in diameter and are borne singly on slender, hairy stalks arising from the root.

The heart liverleaf is very similar to the common liverleaf, but has sharp leaf lobes while those of the common species are very blunt.

Part used.—The leaves of both species, collected in April.

Tyfon, or Holland Greens

Brassica rapa 'Tyfon'

Brassicaceae or Cruciferae

Source: *Cornucopia, a Source Book of Edible Plants,* by Stephen Facciola, 2nd ed., Kampong Publications, Vista, California. 1992.

Tyfon, or Holland greens is a hybrid between Chinese Cabbage (*Brassica rapa* Pekeninensis Group) and stubble turnip (*Brassica rapa* Rapifera Group). Tyfon is rapid growing and vigorous...extremely cold-hardy and also slow to bolt. Several foliage harvests can be made by repeated cuttings. Mild in flavor, Tyfon can be eaten fresh as a salad green, or as a cooked pot-herb, just as collard or mustard greens.

Amaranth, Chinese

Hon-toi-moi, Tampala, Chinese spinach

Amaranthaceae *Amaranthus tricolor* L.

Source: Magness et al. 1971

Several species of Amaranthus are cultivated in Southwest Asia and to a limited extent by Chinese gardeners in the U.S. Plants are annuals, grown from seed, and leaves and young stems are used as pot herbs. Mature plants are 1 to 3 feet tall, with leaves 6 inches long. For use as pot herbs, young plants may be pulled at 3 to 4 weeks; or the tops may be cut off at that stage, and a second crop will be produced from lateral growth. Plant growth and parts used are similar to spinach.

Season, seeding to harvest: 3 to 6 weeks. A second crop may be reduced.

Production in U.S.: No data. Mainly by Oriental gardeners for Chinese users.

Use: Cooked as a pot herb.

Part of plant consumed: Young stems and leaves.

Hophornbeam

Ostrya virginiana (Mill.) K. Koch.

Figure 64.—Hophornbeam (*Ostrya virginiana*)

Other common names.—Ironwood, deerwood, leverwood, black hazel, Indian cedar

Habitat and range.—The ironwood is common in rich woods in Canada and the eastern United States, and westward to Minnesota and Texas.

Description.—This slender tree sometimes attains a height of 50 feet in the western portion of its range, but farther eastward it usually grows only 15 to 20 feet high. The bark is finely furrowed in short lines lengthwise, and the wood is very hard and heavy. The leaves are from 2 1/2 to 4 inches long and about an inch or more wide, resembling the leaves of the sweet birch except that they are rough to the touch instead of smooth and shining. The green inconspicuous male and female flowers are produced from April to May. The male flowers are borne in cylindrical catkins from l 1/2 to 3 inches long and the female flowers in short catkins which mature in July and August into large fruiting cones which very much resemble hops.

Part used.—The bark and inner wood.

Hoptree

Ptelea trifoliata L.

Figure 65.—Hoptree (*Ptelea trifoliata*)

Other common names.—Waferash, ptelea, wingseed, shrubby trefoil, swamp dogwood, three-leaved hoptree, ague bark, prairie-grub, quinine tree, stinking ash, stinking prairie-bush, sang-tree, pickaway-anise.

Habitat and range.—This native shrub is found in shady woods from New York to Florida and west to Minnesota and Texas, occurring in greatest abundance west of the Alleghenies.

Description.—The hoptree is a shrub usually from 6 to 8 feet, sometimes 20 feet, in height, with leaves consisting of three dark green, shining leaflets 2 to 6 inches long. The leaves are glandular dotted and are borne on long stems, but the leaflets are stemless. The greenish-white flowers, produced in June, are borne in compound clusters at the end of the stems. Both leaves and flowers have an unpleasant odor. The flowers are followed by large clusters of winged, flat, roundish fruits each containing two seeds. They have a bitter taste.

Part used.—The bark of the root.

Barley

Gramineae Hordeum sp.

Source: Magness et al. 1971

Barley is the fourth most important grain crop in the United States. Acreage planted in 1966 and 1967 averaged about 10.6 million, with an average yield for the two years of 381.7 million bushels.

Barley is one of the most ancient of cultivated grains. Grains found in pits and pyramids in Egypt indicate that barley was cultivated there more than 5000 years ago. The most ancient glyph or pictograph found for barley is dated about 3000 B.C. Numerous references to barley and beer are found in the earliest Egyptian and Sumerian writings.

The origin of barley is still not known. There are differing views among researchers as to whether the original wild forms were indigenous to Eastern Asia, particulariy Tibet, or to the Near East or Eastern Mediterranean Area, or both. Possibly in a crop so long cultivated this can never be resolved with certainty. J. R. Harlan, in U.S.D.A. Handbook 338, Barley: Origin, Botany, Culture, Winterhardiness, Genetics, Utilization, Pests, summarizes the evidence for different viewpoints.

Species and Characteristics of Barley

Three species of *Hordeum* constitute the barleys under cultivation.

They are derived species, not known as such in nature. All have 14 cbromosomes in the diploid stage and inter-cross readily. They are characterized as follows:

Hordeum vulgare L. These are 6-rowed barleys with a tough rachis or spike stem. All florets are fertile and develop normal kernels. Within the species are two groups: (1) The typical group in which lateral kernels are only slightly smaller than the central one. (2) The intermediate group in which lateral kernels are distinctly smaller than central ones. This group may contain kinds with sterile or near sterile lateral spikelets. The two groups may overlap and are not fully distinct.

Hordeum distichon L. This species is the 2-rowed barleys with a tough rachis. The central spikelets all contain a fertile flower, while flowers in the lateral spikelets are either male or sexless. Two groups of varieties occur: (1) The typical 2-row group, with lateral flowers containing lemma, palea and reduced sexual parts. (2) The deficiens group, with lateral flowers containing no sexual parts.

Hordeum irregulare E. Aberg and Wiebe. This is an irregular barley with a tough rachis, but with lateral flowers reduced in some instances to a stem piece only; and others fertile, sterile or sexless. Central spikelets contain fertile flowers and set seeds.

A number of species of *Hordeum* are native in various parts of the world. Hitchcock (Manual of

Grasses of the United States, Ed. 2, U.S.D.A. Misc. Pub. 200, 1951) lists 11 species of barley grasses as occurring in the United States. None of the native species is in cultivation.

Barley plants are annual grasses which may be either winter annuals or spring annuals. Winter annuals require a period of exposure to cold in order to produce flowers and set seeds, thus are planted in the fall. They form a rosette type of growth in fall and winter, developing elongated stems and flower heads in early summer. If seeded in the spring they fail to produce seed heads. Winter varieties form branch stems or tillers at the base so several stems rise from a single plant. The winter varieties of barlev are more hardy than winter oats, but somewhat less hardy than winter wheat. Around a fourth of the barley grown in the United States is of winter varieties. Spring varieties do not require exposure to cold in order to devlop seed heads. Also, they do not have a typical rosette stage and so develop fewer tillers than winter varieties. They are the only kind adapted to areas with very cold winters. For best production they should be seeded as early as land can be worked in the spring.

The stems of both winter and spring varieties may vary in length from 1 to 4 feet, depending on variety and growing conditions. Stems are round, hollow between nodes, and develop 5 to 7 nodes below the head. At each node a clasping leaf develops. In most varieties the leaves are coated with a waxy chalklike deposit. The density of this varies, and in some varieties no waxiness is present and leaves are glossy. Shape and size of leaves varies with varietv, growing conditions, and position on the plant.

The spike, which contains the flowers and later the mature seeds, consists of spikelets attached to the central stem or rachis. Stem intervals between spikelets are 2 mm. or less in dense headed varieties and up to 4 to 5 mm. in lax or open headed kinds. Three spikelets develop at each node on the rachis. Barley varieties are classed as 2-row or 6-row. In 2-row varieties only the central spikelet develops a fertile flower and seed. In 6-row varieties all three of the spikelets at each node develop a seed.

Each spikelet has two glumes rising from near the base. These are linear to lanceolate and flat and terminate in an awn. The glumes minus the awn are about half the length of the kernel in most varieties, but this varies from less than half to equal to the kernel in length. Glumes may be covered with hairs, weakly haired or hairless. The awns on the glumes may be shorter than the giume, equal in length or longer. The glumes are removed in threshing.

The barley kernel consists of the caryopsis, or internal seed, the lemma and palea. In most barley varieties the lema and palea adhere to the caryopsis and are a part of the grain following threshing. However, naked or hutless varieties also occur. In these the caryopsis is free of the lemma and palea and threshes out free as in wheat. This type is grown mainly where barley is used for human food and is rarely found in the United States.

The lemmas in barley are usually awned. Awns vary from very short up to as much as 12 inches in length. Edges of awns may be rough or "barbed" (bearded) or nearly smooth. Awnless varieties are also known. In 6-row barley awns are usually more developed on the central spikelets than on the lateral ones.

The barley kernel is generally spindle shaped. In commercial varieties grown in the United States length ranges from 7 to 12 mm. Kernels from 2-rowed varieties are symmetrical. In 6-rowed varieties the third of the kernels from the central spikelets are symmetrical, but the two-thirds from lateral spikelets are twisted. The twist is most apparent at the attachment end, less conspicuous at the terminal. The dorsal surface of kernels is smooth, the ventral surface grooved.

The period from flowering until barley is ready for harvest may vary from 40 days to as long as 55 days, varying with varieties and climatic conditions.

Cultivated Variety Groups

Some 150 varieties of barley are cultivated in the United States, many on a minor scale. Varieties are constantly changing as new ones are devloped and tested while others pass out of cultivation. These varieties fall into four general groups, as follows:

Manchuria - OAC 21 - Aderbrucker Group- These are 6-rowed, awned, spring-type varieties with medium sized kernels. The type is believed to have come originally from Manchuria. Plants are tall with open or lax, nodding heads. They tend to shatter badly in dry climates. These are grown mainly in the upper Mississippi Valley and are extensively used for malting.

Coast Group. These varieties trace to North African ancestry and are grown in California and Arizona, also in the Inter-Mountain Region. They are 6-rowed, awned, with large kernels, and short to medium length stems. Spikes are medium to short, dense and generally held erect to semierect. They mature early and are not prone to shatter. They have a spring growth habit but may be fall or winter seeded in California and Arizona where winters are mild.

Tennessee Winter Group. Varieties of this group trace to the Balkan-Caucasus Region or Korea. They are 6-rowed, avrned, with mid-long lax spikes which tend to nod. Plants are medium tall, of winter habit. These varieties are fall seeded and are grown in the southeastern quarter of the United States.

Two-rowed Group. This group includes types tracing to Europe and Turkey--the Turkish type being adapted to areas with marginal rainfall. Varieties in this group are grown principally in the Pacific and InterMountain States and to some extent in the Northern Great Plains. Varieties are mainly spring type though 2-rowed winter varieties are known. Some varieties are used mainly for malting, others for feed.

Uses of Barley

Half or more of the barley grown in the United States is used for livestock feed. As feed it is nearly equal in nutritive value to kernel corn. It is especially valuable as hog feed, giving desirable portions of firm fat and lean meat. The entire kernel is used in feed, generally after grinding or steam rolling. Malt sprouts from malting as well as brewers grain--byproducts of brewing--are also valuable livestock feeds.

Around 25 percent of the barley crop is used for malting in the United States. Of the malted barley some 80 percent is used for beer, around 14 percent for distilled alcohol products, and 6 percent for malt syrup, malted milk and breakfast foods. For malting, the barley is steeped in aerated water in large tanks for 45 to 65 hours, then transferred to germinating tanks or compartments where it is held with intermittent stirring for 5 to 7 days at temperatures of 60-70°F. During this treatment root sprouts emerge, but not the stems. This "green" malt is then dried in hot air kilns. For making beer the dried malt is crushed between rollers, mixed in proper proportions with slightly warm water, and held under rigidly controlled temperatures. The starch is converted by enzymatic reaction into maltose and dextrins. Proteins are also broken down by enzyme action. Upon completion of this process the solids settle out, the extract is filtered, then boiled with hops to add flavor, then cooled. Yeast is added to ferment the sugars into alcohol and carbon dioxide. The hop residue and proteins are then removed and the product (beer) is aged, chilled, filtered, pasteurized and bottled. Keg beer is similar but is not pasteurized or bottled. The solids from this process (brewer's grain) are a valuable livestock feed.

Barley for human food is made into pearl barley by using abrasive disks to grind the hulls and bran off the kernels. Alter three successive "Pearlings" or grinding operations all the bull and most of the bran is removed. At this stage the remaining kernel part is known as pot barley. Two or three additional pearlings produce pearl barley, in which most of the embryo is removed. These later pearlings also produce barley flour. Pot and pearl barley are used in soups and dressings. The flour is used in baby foods and breakfast cereals, or mixed with wheat flour in baking.

Barley is also grown as a hay crop in some areas. For hay, only smooth-awned varieties or awnless are used. Winter barley also may be pastured moderately before the stems start to elongate. It furnishes nutritive pasturage, and grain yields are not seriously reduced.

Horse Nettle

Solanum carolinense L.

Figure 67.—Horse nettle (*Solanum carolinense*)

Other common names.—Sand brier, bull nettle, radical-weed, tread-softly, apple of Sodom.

Habitat and range.—The horse nettle is found in dry, sandy soil from Ontario to Illinois and Massachusetts, Florida, and Texas.

Description.—This plant is easily recognized in late summer and fall by its round, smooth, orange-yellow berries about one-half to three-fourths of an inch in diameter which are borne in small drooping clusters. It is an herb 1 to 4 feet high with an erect, branched stem and covered with fine hair. The branches, also the petioles and midveins of the leaves, are armed with straight yellow prickles. The leaves are 2 to 6 inches long with rather deep triangular lobes. From May to September the plant produces violet or white flowers about 1 to 1 1/4 inches broad.

Part used.—The ripe berries, carefully dried.

Smooth Hydrangea

Hydrangea arborescens L.

Other common names.—Wild hydrangea, sevenbark.

Figure 97.—Smooth hydrangea (*Hydrangea arborescens*)

Habitat and range.—Hydrangea frequents rocky river banks and ravines from the southern part of New York to Florida and westward to Iowa and Missouri being especially abundant in the valley of the Delaware and southward.

Description.—Hydrangea is a shrub 5 to 6 feet high with weak twigs, slender leaf stems, and thin leaves, the latter 3 to 6 inches long, oval or heart-shaped, and sharply toothed. The flowers, which are small and greenish white, are produced from June to July in loose, broad clusters. Sometimes the plant will flower a second time early in the fall. The stem has a peculiar tendency to peel off in several successive layers of thin, different-colored bark, hence the name "sevenbark." The root is roughly branched and when fresh is very juicy, but when dry it is very hard and tough.

Part used.—The root, collected in autumn. On account of its toughness when dry the root should be cut in short pieces while fresh and then dried.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Maté

(*Ilex paraguariensis*)

The author of this chapter is G.C. Giberti (Centre of Pharmacological and Botanical Studies, Buenos Aires, Argentina).

Botanical name: *Ilex paraguariensis* A. St-Hil. var. *paraguariensis*

Family: Aquifoliaceae

Common names. English: maté, Brazilian tea, Paraguay tea: Guarani: ka'a; Kaingangue: kongóñ: Spanish: yerba maté, té de los jesuitas: Portuguese: congonha, erva maté

Maté, with a very restricted distribution outside America, is a tree that produces a raw material for industrialization and consumption as a stimulating infusion. So far, this has been the main use of this somewhat overlooked crop.

Although no archaeological remains have been found that show that it was used in pre-Columbian times. it is assumed that it was the Guarani Indians who taught the Spanish how to use it. However, what seems to be an indirect consequence of the discovery is the fact that the first people to have cultivated this species were the Jesuit missionaries who, around 1670, already had artificial maté plantations. In time, the settlements of Guarani Indians converted to Christianity were to become economically dependent on maté production.

The expulsion of the Jesuits from the Spanish dominions (1767) was a step backwards in the history of maté. There was a return to the forest exploitation method which utilized the natural maté plantations exclusively and inadequately. It may be said that this type of laborious and uneconomical forest management extended up to the first decades of the twentieth century, in spite of maté planting having been renewed in Nueva Germania, Paraguay and in Santa Ana, Argentina, in 1897.

Although very much reduced, maté production did not disappear with the Jesuit plantations. During the remainder of the colonial period, the use of this herb, which had spread extensively, persisted even in the region of the Viceroyalty of Peru, where there was another methyl xanthine stimulant of the same genus: *Ilex guayusa* Loes. emend. Shemluck, also marketed by the Jesuits from that region in Quito.

It has been established that trade in maté was not interrupted and that it was commonly used in what is now Peru and Ecuador. However, following the independence of the Spanish colonies and the adoption of free trade, English tea began to be introduced into those countries and so maté gradually lost the markets of those Andean countries.

The decline and complete disappearance of the maté plantations in the settlements of Christianized Indians (which ended around 1820 after a series of wars waged in the region between the Spanish and Portuguese Crowns, followed by the struggles for independence) and the policy of isolation and control of international trade maintained by the first governor of independent Paraguay meant that, in the 1820s, Brazil began commercial exploitation of its natural maté plantations.

The most accessible plantations were situated in the vicinity of Curitiba, Paraná, and as they were slowly exhausted they were gradually replaced by the others located towards the west. The Brazilian product, which then began to spread on the markets as "Paranagua maté", was considered to be of inferior quality to that from Paraguay. However, in the course of time it replaced the Paraguayan product, a development which became more marked after the war of the Triple Alliance (1870).

At the end of the nineteenth century, the limitations of the exhaustive exploitation of this forestry resource stimulated efforts to produce large plantations of *I. paraguariensis* once again. Eventually. these efforts were successful, especially in Argentina.

At the same time as the increase in Argentinian maté production, the extraordinary expansion of the agricultural frontiers in traditional maté-growing states of southern Brazil (Paraná, Santa Catarina. Rio Grande do Sul, Mato Grosso do Sul) took place. Regrettably, the disappearance of enormous areas of natural forests in those states jeopardized the conservation of maté's genetic richness.

The complicated economic history of this crop (barely sketched out here) which is characterized by periods of scarcity alternating with periods of excessive demand, the sporadic but real existence of periods during which it was adulterated with other plants and the most common method of preparation—maté sucked through a small tube—considered by many to be unhygienic, had a bearing on the limited spread of maté outside southern South America.

Its main use is in infusions prepared as tea with leaves and dried stems which have been industrially shredded. Generally speaking, it is drunk by tilling small gourds (maté gourds or *cuias*) with maté. to which boiling water is gradually added, the liquid being sucked up through a metal tube (the *bombilla*). Infusions of *cimarrón,* or bitter maté, are usually modified with sugar (sweet maté), milk or aromatic herbs. Other methods of consumption are boiled maté, *tereré* (maté prepared with cold water, common in Paraguay and northeastern Argentina), liqueurs prepared with maté, ice-creams, desserts, etc. The industry also produces compound maté (which contains aromatic and/or medicinal herbs), soluble maté and maté teabags.

The aqueous infusion of maté owes its stimulant properties to the caffeine content (between 1 and 2 percent) so that, 60 minutes after consuming maté, an average of 80 to 120 mg of this pseudoalkaloid is consumed. Its nutritional qualities are due to its content of vitamins A, C and B complex and the existence of minerals (P, Ca and Fe).

Argentina, the main producer and consumer, grows around 130000 ha of maté in the northeast of the country (Misiones and Corrientes), which produce about 140000 tonnes per year. Brazil is the world's second producer, followed by Paraguay. For the Argentinan province of Misiones, maté cultivation represents an important part of the country's GDP.

Botanical description

The maté is a dioecious evergreen tree which grows up to 18 m in height. The leaves are alternate, coriaceous and obovate with a serrate margin and obtuse apex. The inflorescences are in corymboid fascicles, the male ones in a dichasium with three to 11 flowers, the female ones with one or three flowers. The flowers are small, and simple, number four or five and have a whitish corolla. The fruit is in a nucule; there are four or five single seed pyrenes (propagules).

Maté flowers in the spring (from October to November), has entomophilous pollination (diptera, hymenoptera) and fruits from March to June; dissemination is endozoic (birds). There is a rudimentary embryo in many externally ripe seeds which causes a long period of germination From the time of sowing.

Figure 29. A) Maté (*Ilex paraguariensis*); A1) inflorescence; A2) flower; A3) fruit; A4) gourd and tube for consuming the infusion

Ecology and phytogeography

Prominent among the ecological requirements of this subtropical species are climatic conditions, especially mean annual precipitation and an even distribution of rainfall throughout the year. This must not be less than 1200 mm annually and, during the driest quarter—which in the region is winter—the minimum must be 250 mm. *I. paraguariensis'* wild distribution area is always unaffected by water shortages. The mean annual temperature of the area is approximately 21 to 22°C. The absolute minimum temperature that this species is able to tolerate is -6°C, even though winter snows are frequent on the plateaus and mountain regions to the south of Brazil and east of Misiones.

It requires lateritic, acid (pH between 5.8 and 6.8) soils that are of medium to fine texture.

Figure 30 shows the natural distribution of *I. paraguariensis*. The area of economic cultivation of maté coincides approximately with the main dispersion area of the var. *paraguariensis*.

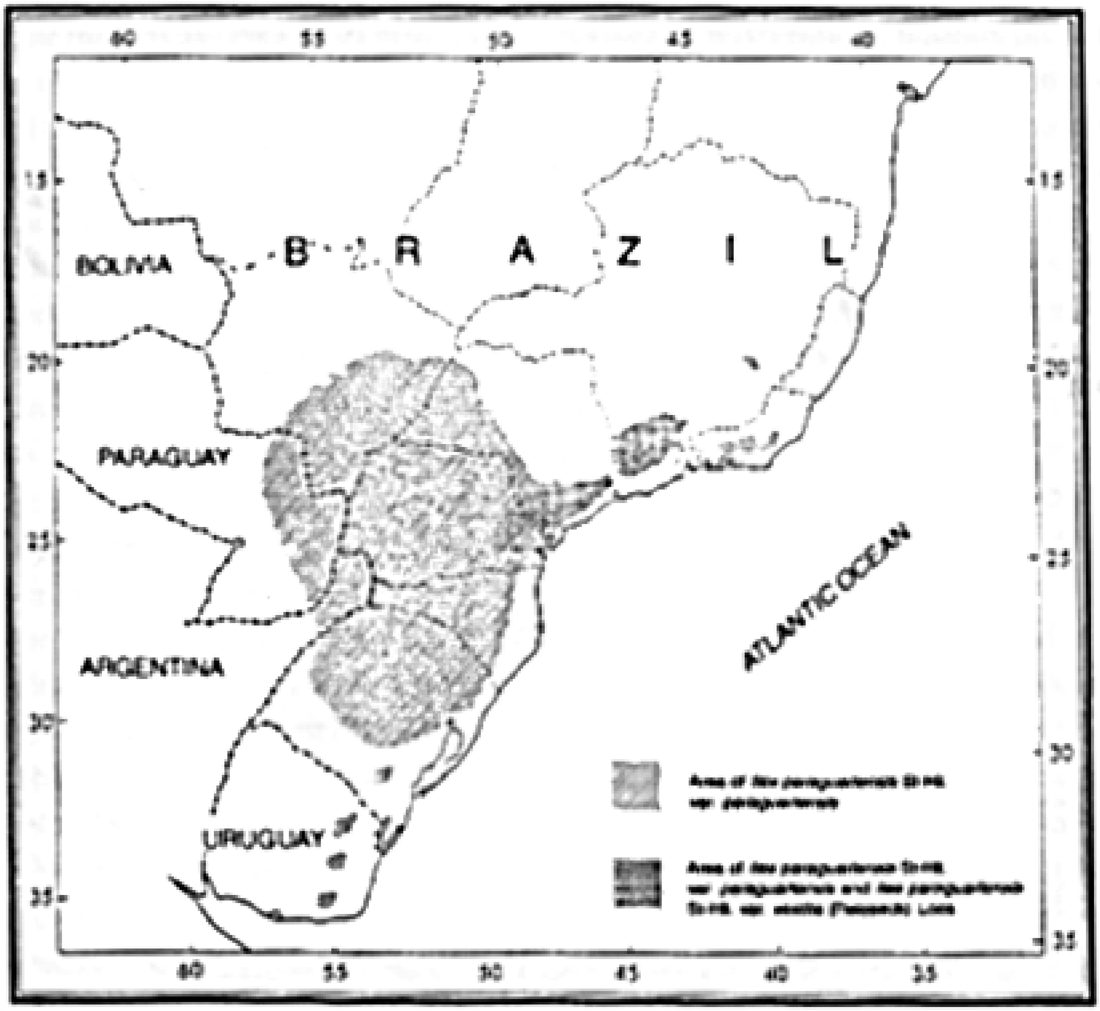

Figure 30. Distribution area of *Ilex paraguariensis* var. *paraguariensis* and var. *vestita*

Genetic diversity

There is still no exhaustive modern picture that explains in biological terms the infraspecific variability of this species, which is widely dispersed geographically in South America. Up to the present, taking as a basis the morphological characteristics alone, at least two varieties are recognized: *I. paraguariensis* A. St-Hill var. *paraguariensis* (cultivated maté, almost completely glabrous) and *I. paraguariensis* var. *vestita* (Reisseck) Loes. (not acceptable for industrialization, of dense pubescence). Both varieties coexist in limited areas of Brazil.

The wild species closest to *I. paraguariensis* belong to the subgenus *euilex* Loes., subsection *repandae* Loes. Only *I. cognata* Reisseck lives in the distribution area of maté. *I. cognata* is very little known; its vernacular name is chá do mato and it is used to adulterate maté.

A number of wild species of *Ilex* are sympatric with genuine maté and have been, or are, used to manufacture the product although, up to the present and according to the legislation in force, they are to be considered adulterations. Of those most frequently referred to, the following deserve mention: *Ilex affinis* Gardner (the ca' a chirí or congonha of Goyaz, a species abundant in central Brazil and northeastern Paraguay); *I. dumosa* Reisseck var. *guaranina* Loes. (*yerba señorita, aperea ka'a, cauna, caá chiri*), native to Paraguay, Argentina and Brazil, the producer of a bitter-tasting maté and supposedly cultivated in Misiones by the Jesuits to produce their famous "caá miní" maté; *I. theezans*, C. Martius ex Reisseck (cauna de folhas largas, ca'a na, congonha), a good substitute for *I. paraguariensis*, found in Paraguay, Argentina and Brazil. *I. brevicuspis* Reisseck, known as cauna or voadeira, like the previous species, is a faithful companion of *I. paraguariensis* in plant communities characteristic of the region—where *Araucaria* is also prominent—but the product obtained from its experimental industrialization is of low quality.

Outside the natural area of distribution and production of maté, in northwestern Argentina and southeastern Bolivia, *Ilex argentina* Lillo, a related species that is known not to accumulate caffeine but theobromine, has been used to prepare maté. It is a tree characteristic of the area of transition between the forests of Myrtaceae and alder (*Alnus* spp.) of the phytogeographical province of the yungas.

Known cultivars of *I. paraguariensis*. The infraspecific classification of *I. paraguariensis* is still under study. Consequently, the correspondence between the biological varieties and the horticultural varieties of genuine maté is not clear. Following is a list of some of the varieties recognized as such by growers in the three countries: Erva de talo roxo, Erva de talo branco, Erva piriquita (Brazil); Caá verá, Caá manduví, Caá panambi, Caá cuatí, Caá ñú, Caá eté, Caá mi, Caá chacra, Caá-je-he-ni (Paraguay); Yerba colorada, Yerba señorita, Caá miní (Argentina).

INTA in Argentina recently began to distribute seeds of clones and selected clonal progeny which, following comparative trials, demonstrated their superiority.

In wild South American *Ilex* species and in the maté-growing region, the risks of genetic erosion are high because the natural forest is gradually giving way to agroforestry and livestock production, a process accentuated by the relatively low germinating capacity of many species (especially that of maté). As no suitable method has yet been discovered for maintaining the germinating capacity of *I. paraguariensis* for prolonged periods, there are no seed banks of the species. Nevertheless, at the Cerro Azul de Misiones experimental agricultural station in Argentina, a maté clonal garden began to be developed in 1976, complemented by the nursery started in 1986 with *I. paraguariensis* of various origins and with other species of *Ilex*.

Cultivation practices

In the wide and varied economic production area of maté, the practices for the cultivation or exploitation of natural maté vary considerably in their technical aspects, resulting in different yields per hectare.

Three methods of production can be distinguished which are arranged here in increasing order of importance reflecting the use of techniques and their yields:

Extractive exploitation of the natural forest. Here the richness of natural maté plantations is utilized. Harvesting is not mechanized and the pruning system is generally incorrect. This form of production is diffused mainly in Brazil.

Mixed system or system for the enrichment of the natural forest. This consists of increasing the number of natural plantations and reconstituting those that have been lost. In Brazil, where this method is most commonly practiced, it is called densifying the maté plantation. Since, generally speaking, this technique is accompanied by others that increase the yield, such as cultivation care and improved pruning methods, the higher production cost is compensated for.

Cultivated maté plantations. This is undoubtedly the best system, and came into general use in Argentina around 1915. In spite of higher costs, the yield per hectare greatly increases. Complemented by measures such as improvement in the layout of plantations (which have evolved from trees planted in quincunxes, with spaced out plants used by Jesuits, to cultivation following contour lines, with a high density per hectare and use of the *corte mesa* pruning and plant management system), with well-timed pruning, cultivation work and harvesting, this system enabled Argentinian production to exceed that of Brazil, in spite of the former being carried out in a very reduced area and even outside the environments most suited for maté. For example, rising from a density of 1000 to 1500 plants per hectare (still fairly widespread) to a density of 2500 or 4000 plants per hectare, production can increase from around 1000 to 1800 kg to 2100 to 3300 kg per hectare.

The *corte mesa* system not only increases the yield but is also better suited to mechanical harvesting.

Yields are improved by: planting following contours; the use of natural or introduced cover (rape, legumes, etc.); fertilization (NPK); weed control (mechanical and/or using herbicides); suitable phytosanitary treatments; and rational harvesting. The relevant experiments have been going on for some years but, regrettably, their results have not become generalized. The introduction into cultivation of improved cultivars is much less widespread.

Conventional propagation techniques. *Sexual propagation* ("seeds" = pyrenes). This is the most common reproduction technique. In the case of maté, the advantage of sexual propagation lies in the fact that the variability in descendants may give rise to individuals better suited to different environments (which on other occasions may not be desired).

The seeds are harvested in the region (from February to April). They must be stratified or sown immediately, otherwise they quickly lose their viability.

Stored at 5°C, they maintain a very reduced germinating capacity (1.7 to 6.6 percent) for a further 11 months. The relatively short period of viability together with the low germination rate (immature embryos, phytosanitary problems) have undoubtedly been the cause of the difficulties in its cultivation spreading to other continents in the past.

Agamic reproduction. Grafting, propagation by cuttings and layering are not very widespread. It is relatively difficult to obtain rooted cuttings and this is generally achieved by using young branches from the stools, irrespective of whether plant hormone treatment is used. Additional experiments are necessary if the intention is to increase the rooting percentage.

In vitro cultivation of *I. paraguariensis* is being tried out in Brazil and Argentina by various research groups, with varying results which still do not clearly indicate which are the economically viable techniques for the clonal reproduction of selected individuals.

According to the Under-Secretariat for Agriculture and Livestock, in Argentina in 1988, the average yield of semi-processed maté was 1220 kg per hectare.

Prospects for improvement

The limitations of cultivation are due to the fact that there is no demand for the product on a macroeconomic scale. The recurrent cycles of surplus supply, low prices, disinvestment in plantations, scarcity of raw materials, high prices—very often linked with international trading terms between producer countries, which result in a greater distortion—have historically acted against a stable supply of the product in terms of quality and quantity. Even worse, they have discouraged the continuation of basic and/or applied research, which cultivation and processing require. The partial or total absence of knowledge concerning maté biology, plant chemistry, dietetics, agronomics and industrialization have made it difficult to adopt international standards which would lay down norms for the quality of the product and improve and guarantee it over time, depending on its distribution to the major international markets for the production of methyl xanthine infusions.

Potential areas for the introduction of this crop are subtropical regions with acid soils and a water supply similar to those of the species' natural area of dispersal.

It has recently been suggested that *Ilex verticillata,* a North American species, could be a source of biodegradable detergents because of its high saponin content. Since research regarding similar subjects is being continued on *I. paraguariensis* and, furthermore, since other related species are studied even less than maté from the chemical point of view, it would be advantageous to go into these aspects more deeply.

Ilex argentina is also a possible caffeine-free maté and is, moreover, remarkable for its richness in liver-protecting phenolics similar to those in artichokes (*Cynara scolymus*).

There are also reports of a range of non-traditional uses for *I. paraguariensis*, for instance as a source of edible oils, furfural and cosmetics.

Finally, the importance of the wild *Ilex* species in genetic improvement of the crop should be mentioned.

Lines of research

- **Botanical:** Infraspecific variability of *I. paraguariensis* and how it is related to other species of the genus; an updated chorology; crossing systems of *I. paraguariensis* and other species of *Ilex;* inheritance of sex.
- Physiology of the seed and micropropagation methods.
- **Plant chemistry:** Cycle of the xanthines in the species and its relatives; toxic and undesirable compounds of allied species; analytical determination of the infusion's flavour

components.

- Updating, from the food point of view and with relation to allied species.
- Architecture of the individual of *I. paraguariensis* and of allied species; phenology and adaptation of these trees to mechanical harvesting.
- **Industrialization:** Improvements in the drying and accelerated seasoning systems without organoleptic losses; alternative industries with cultivation by-products.
- New ways of consuming and presenting the product.

Common Winterberry

Ilex verticillata (L.) A. Gray.

Synonym.—*Prinos verticillata* L.

Other common names.—Prinos, winterberry, Virginia winterberry, black alder, false alder, white alder, feverbush.

Habitat and range.—This native shrub is found in swamps, moist woods, and along banks of streams in Canada and the eastern United States, and westward to Wisconsin and Missouri.

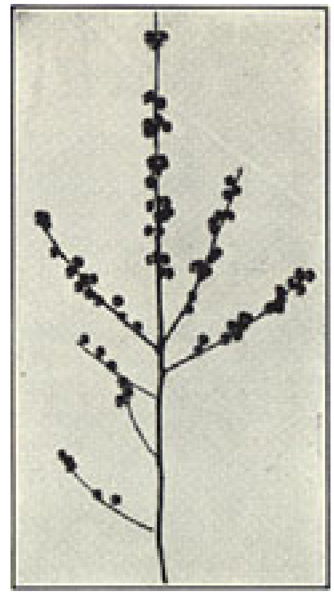

Figure 44.—Common winterberry (*Ilex verticillata*)

Description.—Common winterberry is a shrub usually from 6 to 8 feet high (sometimes much higher) with grayish bark and smooth twigs. The leaves are from 2 to 3 inches long and about an inch wide. They are usually rather thick and sharply toothed. In autumn the leaves turn black. The flowers which appear from May to July, are small and white, the male clusters consisting of 2 to 10 flowers and the female clusters of only 1 to 3. The bright-red, shining fruits about the size of a pea and each containing about six seeds, are clustered around the stem. Branches and twigs of this plant with their bright-red berries are a familiar sight during the Christmas season when they are much used for decorative purposes.

Part used.—The bark, and to a less extent the berries, collected in autumn.

Indian ricegrass

Gramineae *Oryzopsis hymenoides* (Roem. and Schult.) Ricker

Source: Magness et al. 1971

This is a native bunchgrass distributed from the Dakotas south to Texas and west to the Pacific Ocean. It is drought-resistant, adapted to dry, sandy soils. The plant grows in dense clumps, up to 2 feet tall. The leaves are slender and nearly as long as the stems. It is highly palatable to livestock, both while green in summer and dried in winter. Natural stands in many areas have been greatly depleted by over grazing. This is an important species for reseeding range lands. Seeds were formerly used by Indians for grinding into meal and making bread.

Indiangrass

Gramineae *Sorghastrum nutans* (L.) Nash ex Small

Source: Magness et al. 1971

This is a native bunchgrass with short rhizomes, widely distributed east of the Rocky Mountains from Canada south to the Gulf of Mexico and into Mexico. Under the best conditions stems may reach to 10 feet. Leaves are smooth and flat, near a half inch wide, elongated, narrow at the base. Indiangrass thrives best on fertile bottom soils but also occurs on sandy soils and dry slopes. It is palatable while succulent but only fairly so when dry. It is most useful in the Central and Southern Great Plains. Some selected varieties are in commerce.

INDIGO

Family: Fabaceae (Leguminosae), *Indigofera* species

Source: Simon, J.E., A.F. Chadwick and L.E. Craker. 1984. Herbs: An Indexed Bibliography. 1971-1980. The Scientific Literature on Selected Herbs, and Aromatic and Medicinal Plants of the Temperate Zone. Archon Books, 770 pp., Hamden, CT.

Indigo refers to several species of *Indigofera*, famous for the natural blue colors obtained from leaflets and branches of this herb. Of primary importance are French indigo, *Indigofera tinctoria* L., and Guatemalan indigo, *Indigofera suffruticosa* Mill., which was formerly classified as *Indigofera anil* L. These plants are perennial shrubs with an erect stem reaching a height of 1 to 2 meters. The French and Guatemalan indigo differ in size and shape of the leaflets and pods (14.1-3). Prior to the development of synthetic aniline and indigo dyes, the indigo species were grown commercially in the East Indies, India, and parts of North, South, and Central America for export and domestic use. Popularity and economic value of the plant reached a peak during the Middle Ages, when indigo was the most important dye plant for blue color in the western portion of the world (9.1-5).

The reported life zone of *Indigofera tinctoria* is 16 to 27 degrees centigrade with an annual precipitation of 0.7 to 4.2 meters and a soil pH of 5.0 to 7.3 (4.1-31). Indigo is generally grown as a perennial shrub, although in Morocco it grows as a biennial herbaceous plant (13.1-76).

The blue dyestuff is produced during fermentation of the leaves, commonly with caustic soda or sodium hydrosulfite. A paste that exudes from fermenting plant material is processed into cakes and finely ground. The blue color develops as the material is exposed to air (13.1-76). The indigo dye is a derivative of indican, a natural constituent of several of the *Indigofera* species (14.1-19). Indican is enzymatically converted to blue indigotin (14.1-35). The colorfast dye is mixed with different mordants and other plant materials to produce a wide range of colorants. The species name *tinctoria* refers to tinctorius, meaning "of dyes" or "belonging to dyes" (14.1-3). Today almost all indigo for dyeing cotton and wool is synthesized commercially.

As a medicinal plant, indigo has been used as an emetic. The Chinese use *Indigofera tinctoria* L. to clean the liver, detoxify the blood, reduce inflammation, alleviate pain, and reduce fever (11.1-10). The powdered root of *Indigofera* cf. *patens* is used in South Africa to alleviate toothache (11.1-96). *Indigofera spirata* is known as a plant teratogen because of the presence of indospicine (11.1-96). *Indigofera endecaphylla* plant, creeping indigo, is poisonous and has been responsible for livestock death (11.1-96). *Indigofera arrecta* Hochst. ex A. Rich and *Indigofera caroliniana* Mill. are used as dye plants (9.1-5).

False, wild, and bastard indigo are names for *Baptisia tinctoria* L., a native North-American member of the Leguminosae family, whose leaves, pods, and bark are used to make a blue color. Medicinally, it is employed as an astringent, emetic, stimulant, and antiseptic. Fake indigo and *Baptisia leucantha* are reported to have caused poisonings, diarrhea, vomiting, and loss of appetite (11.1-96, 11.1-136). *Strobilanthes flaccidifolis* and *Dalea emoryi* L., known as indigo bush, have been used as indigo dye plants.

Italian ryegrass

Gramineae *Lolium multiflorum* Lam.

Source: Magness et al. 1971

This is an annual grass from Europe, grown for hay in Oregon and Washington west of the Cascade Mountains. In the Southern States it is grown as a winter annual for pasture, hay, silage and as a cover crop. The plant develops rapidly from seed, making a quick cover suitable for early grazing. It is nutritious and palatable. Many seed sources contain both Italian and perennial seed. See perennial ryegrass.

Mungesa or Jangli Moong (*Phaseolus trilobatus* (L.) Schreb Syn. *P. trilobus* Ait)

Contributor: Pankaj Oudhia

Copyright (c) 2002. All Rights Reserved. Quotation from this document should cite and acknowledge the contributor.

Common Indian Names:
Hindi: Mugani, Mudagparni, Mungawana, Trianguli, Mungesa, Jangli Moong.
Gujrati: Adabanmagi, Adavada, Magavala
Canarese: Kohesaru
Marathi: Ranmath , Ranwum
Saskrit: Koshila, Kurangika, Shimbi parni, Vanmudga
English Name: Wild gram

Family: Leguminosae

Botany: It is a trailing, straggling and suberect annual herb. Leaves are trifoliate, petioles 3–12 cm long, stipules peltate, ovate-oblong ciliate, leaflet, palmately trilobed, middle lobe larged and broadly spathulate, lateral oblong or more or less spathulate. Flowers are in sub-capitate, few flowered racemes, peduncles 10–23 cm long and yellow. Pod up to 5 cm long slightly curved. Seeds 6–12. Flowering time in India is Oct–Nov.

Distribution: In India it is found as wasteland and crop fields. Found in all most every part.

Useful parts: Leaves and fruit

Medicinal properties and uses: According to Ayurveda fruit is cooling, dry, bitter, aphrodisiac, astringent, styptic, anthelmintic and good for the eyes. Cures constipation, inflammations, fever, burning sensation, thirst, piles, dysentry, cough, gout, biliousness etc. Mungesa is one of the popular folk remedies in India. In many parts of India, the leaves and its decoction are used in case of fever and cough. It is also used in eye-diseases.

Besides medicinal uses, Mungesa is also a popular fodder. The paddy workers use the ripe fruit as breakfast during their field work. Stimulatory allelopathic effects of this weed on many agricultural crops viz. rice, wheat, chickpea etc have been reported.

Japanese Knotweed

Jointweed, Mexican Bamboo, Ong Toy

Polygonaceae *Polygonum cuspidatum* Sieb. and Zucc.

Source: Magness et al. 1971

Erect unarmed glabrous perennial with round-ovate leaves. The immature stems are edible and used especially by the Chinese in salads or cooked as a potherb. The long succulent young stems can be produced in the field or grown under glass. A crop grown under glass is under high humidity in water saturated soil and harvested continuously. Plants root very rapidly. This is a close relative to Smartweed.

Production in the U.S.: Limited.

Use: Mainly in salads.

Part of plant consumed: Immature stems.

Last update February 18, 1999 by ch

Japanese millet

Japanese barnyardgrass

Gramineae *Echinochloa crusgalli* var. *frumentacea* (Roxb.) W.F. Wight

Source: Magness et al. 1971

This is a warm season annual grass from Asia grown to a limited extent in the Northeastern States for green feed, silage and hay. It is superior under cool summers to sudangrass or foxtail millet. Stems reach to 4 feet or more. Leaves are large, more than 0.5 inch broad. Seed heads are dense and drooping. once exploited as "a billion dollar grass" it is now grown much less than formerly. It produces good tonnage but is coarse and only fair in feed value.

JASMINE

Family: Oleaceae, *Jasminum* spp.

Source: Simon, J.E., A.F. Chadwick and L.E. Craker. 1984. Herbs: An Indexed Bibliography. 1971-1980. The Scientific Literature on Selected Herbs, and Aromatic and Medicinal Plants of the Temperate Zone. Archon Books, 770 pp., Hamden, CT.

The *Jasminum* species, primarily represented by poet's *Jasminum officinale* L., and royal jasmine, *Jasminum grandiflorum* L., are an important source of natural fragrances. Poet's jasmine, also known as white jasmine, is native to the Himalayas of western China. The vine-like plant reaches a height of 10 meters, and has ovate leaves and clusters of fragrant white flowers that bloom in summer and fall. Royal jasmine, also known as Catalonian and Spanish jasmine, grows similarly to poet's jasmine but has leaflets of a different size, shorter branches, and larger flowers (11.1-50). This jasmine is most valued for its fragrance and is the most extensively cultivated. Jasmine is grown in France, Spain, Italy, and several North African and Middle Eastern countries.

The reported life zone for *Jasminum officinale* is 11 to 27 degrees centigrade with an annual precipitation of 0.3 to 2.8 meters and a soil pH of 4.9 to 8.3 (4.1-31). The perennial jasmine plants that grow outside in warm regions are grown inside as greenhouse plants in northern climates. Poet's jasmine is much more cold tolerant than royal jasmine, and cultivated jasmine plants are usually grafted onto poet's jasmine rootstocks (11.1-50, 14.1-4). Jasmine can be produced on almost any soil type, with ample water supply and full sun. Full production begins after grafting in the second year. Flowers are picked in the early morning, since they are the most fragrant at daybreak (11.1-50, 14.1-10). Flowers from higher altitudes are of a finer quality than those of lower altitudes (14.1-10).

Jasmine flower oil is extracted immediately after the flowers are collected by enfleurage or the use of volatile solvents (14.1-10). The extraction process to obtain high-quality jasmine oil is delicate and laborious. The oil contains benzyl acetate, terpineol, jasmone, benzyl benzoate, linalool, several alcohols, and other compounds 14.1-10). The concrete and absolute of jasmine are available commercially.

The flower oil is important in high-grade perfumes and cosmetics, such as creams, oils, soaps, and shampoos. Flowers are used in jasmine tea and other herbal or black teas. Several types of jasmine are used as ornamental plants.

As a medicinal plant, jasmine has traditionally been considered an aphrodisiac and calmative. The roots and leaves of some jasmine species have been used in folk medicine as an anthelmintic, active against ringworm and tapeworm (11.1-50). The plant has been employed against cancer (14.1-18).

Jasminum sambac (L.) Ait., commonly called Arabian jasmine, is a white-flowered evergreen plant, from 2 to 3 meters in height, of uncertain origin. The plant has been used to flavor teas and is reported to have antimicrobial activity (2.1-54). The names yellow jasmine and Carolina jasmine actually refer to *Gelsenium sempervirens* (L.) Ait. f., a poisonous plant of the Loganaceae family. Cape Jasmine is actually *Gardenia jasminoides* Ellis, a common gardenia of the Rubiaceae family that has fragrant flowers.

Jasmine is generally recognized as safe for human consumption as a plant extractive or essential oil (21 CFR section 182.20 [1982]).

Twinleaf

Jeffersonia diphylla (L.) Pers.

Other common names.—Jeffersonia, rheumatism root, helmetpod, ground-squirrel pea, yellowroot.

Habitat and range.—Twinleaf inhabits rich shady woods from New York to Virginia and westward to Wisconsin.

Description.—Twinleaf is only about 6 or 8 inches in height when in flower but reaches a height of 18 inches at the fruiting stage. The long-stemmed, smooth leaves are almost completely divided into two leaflets and arise directly from the base of the plant. The white flowers measuring about 1 inch across. which appear early in spring, are borne singly on a slender stalk arising from the root and are followed by a leathery, somewhat pear-shaped capsule containing many seeds. Twinleaf has a thick, knotty, yellowish-brown, horizontal root. stock with man fibrous, much-matted roots.

Part used.—The rootstock, collected in autumn.

Walnut, California black: *J. hindsii* (Jepson) Jepson

Walnut, Texas (New Mexico): *J. cordiformis* var. *ailantifolia* (Carr.) Rehder

Source: Magness et al. 1971

Black walnuts in the U.S. are widely distributed and are of several species, not all of which are listed. The trees vary from small, up to 20 feet, to very large, near 100 feet in height. All have long, compound leaves, with up to 20 or more leaflets. Leaflets are generally oblong-lanceolate, and smooth. In all, the nuts are encased in a semi-pulpy husk, which does not separate from the nut readily. The nut shell is thick and very hard. The kernel does not separate from the shell readily. Only the American or Eastern black is in any cultivation, and commercial cultivation of that kind is limited. Substantial quantities of the latter are gathered from native trees and marketed, mainly after shelling.

Juniperus virginiana L.

Cupressaceae
Red cedar

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Berries of some cedars have been roasted as substitutes for coffee or tea. Hemmerly (1970) gives an interesting account of the economic uses: In 1970 the uses of this species included fence posts, furniture, cedar oil, ornamental Plantings, Christmas trees, souvenirs, novelties, kindling, shavings, etc. Plastic bags of cedar shavings were used as bedding for pets. The bark of the tree is useful as tender in starting fires Boy Scout style. According to Guenther cedarwood oil comes from *Juniperus*, but white cedarwood and cedarleaf oil from *Thuja*. Cedarwood oil is used in insect repellants, perfumes and soaps. Cedar chips have been used as moth repellants. The oil also shows up in furniture polish. Refined oil is used in microscopy. Chippewa Indians used strips of bark in matting. They used the red inner bark as a source of a red dye. Widely used for boundary markers, reforestation, shelterbelt, and wild life plantings.

Folk Medicine

According to Hartwell (1967–1971), the powdered leaves are used in folk remedies for venereal warts and other excrescences. Reported to be abortifacient, diaphoretic, diuretic, emmenagogue, stimulant, sudorific, and taenifuge, red cedar is a folk remedy for arthritis, bronchitis, catarrh, debility, dropsy, rashes, rheumatism, skin ailments, venereal diseases, and warts (Duke and Wain, 1981). Cedar "apples" (see illustration), the fungal excrescences of red cedar are used as an anthelmintic. Leaves used as a stimulant, emmenagogue, and taenifuge. In Appalachia, a mixture of nuts, leaves, and twigs is boiled and inhaled as a treatment for bronchitis. In New Mexico, some Spanish-speaking people use a boiled mixture of bark and water to treat skin rash. Rappahannock used an infusion of the berries with wild ginger for asthma. Cree used the leaves as diuretic. Powdered leaves used for venereal warts and excrescences. Dakota, Omaha, Pawnee, and Ponca burned the twigs and inhaled the smoke for head colds, while patient and fumigant were enclosed in a blanket. Comanche regarded juniper as depurative; Creek used the fumes for neck cramps. Cedar decoctions or steam were also used to promote delivery. Chickasaw heated the limbs with elder in hot water and applied topically for headache. Chippewa decocted the twigs for rheumatism, Dakota used for cholera, cold, and cough; Pawnee used juniper smoke for bad dreams and nervousness, Ojibwa took bruised leaves and berries for headache. Delaware steamed juniper for rheumatism; Fox decocted the leaves to strengthen convalescents. Western Indians believed that juniper berry tea taken on three consecutive and appropriate days was considered contraceptive. Scully relates that in 1849–1850 there was an Asiatic cholera among the Teton Dakotas, killing many of them. After failing with many other medicines, Chief Red Cloud succeeded with a decoction of red cedar leaves (which does contain germicides).

Chemistry

Oil from the leaves contains borneol, cadinene, d-limonene, and α-pinene (Guenther, 1948-1952). Hager's Handbuch adds sabinene, γ-terpinene, elemoacetate, 3-carene, myrcene, 4-terpineol, citronellol, elemol, eudesmols, estragole, safrole, methyleugenol, elemicine, traces of thujene, cymene, and linalool (List and Horhammer, 1969–1979). The cedarwood oil contains ca 80% cedrene, some cedrol and pseudocedrol, and cedrenol. *Juniperus virginiana* contains the poisonous antitumor compound called podophyllotoxin (Lewis and Elvin-Lewis, 1977).

Description

Medium sized tree to 30 m, broadly pyramidical to narrowly columnar. Bark brown, shredded, short scale leaves in close overlapping pairs, forming 4-sided twigs; (juvenile leaves are longer, flat, pointed, more distant and in whorls of 3) leaves vary from yellowish green to bluish green; fragrant. Male cones 3–4 mm long, on tips of small twigs, shedding pollen as early as January, as late as March; female cones small, inconspicuous, on tips of short branches, generally receptive for pollen several days after the cones on male trees have started shedding pollen; mature as bluish black, glaucous "berries" by October–November of first year (Radford et al., 1968).

Germplasm

Reported from the North American Center of Diversity, red cedar, or cvs thereof, is reported to tolerate acid soils, frost, limestone, poor soils, sands, and slope (Duke, 1978). ($2n = 22$)

Distribution

Southwest Maine, west to Northern New York, Southern Quebec, Ontario, Michigan, Wisconsin, to Southwest North Dakota, south to West Kansas, Okalahoma to Central Texas, and east to Georgia, the most widespread and common juniper in the eastern US.

Ecology

No specific data available. Estimated to range from Warm Temperate to Boreal Dry to Moist Forest Life Zones, and to tolerate annual precipitation of 4 to 16 dm and annual temperature of 5 to 13°C. Although said to "prefer" calcareous soils, it thrives on dry hillsides and in swampy land.

Cultivation

Germination is delayed in most junipers because of embryo dormancy. Cold stratification for 30–120 days at 5°C is commonly recommended. Freezing temperatures during stratification have either arrested germination in after-ripened seed (for 3 months) or damaged them beyond germanability. Seeds should be fall-sown or stratified and spring- or fall-sown. Seeds may be drilled 6–7 mm deep in rows 15–20 cm apart, or broadcast, and seedlings should be shaded during the first summer. Do not be alarmed if seedlings turn purple in fall, but be prepared for frost heave.

Harvesting

Fruits may start bearing at age 10, and can be stripped, for seed purposes thereafter in the fall. Hemmerly (1970) mentions a Shelbyville Lumber Company in Tennessee for making oil from cedar stumps, then paying only $2/ton for stumps which were dried, chipped, and pulverized, and then steam-distilled and condensed with the oil rising to the top. The company was turning out nearly 150 kg oil per day using only three workers.

Yields and Economics

In 1950, when oil was derived almost exclusively from shavings and refuse from cedar wood utilization, more than 200 MT oil were produced. Chips and dust yield 2–2.5% oil. Following the Civil War, poor farmers along Mississippi tributaries solidified their fiscal positions by floating cedar logs to New Orleans where they were cut into staves destined for French wineries. At one time, red cedar was used for split rail fences, but the value of the wood for pencils became so high that fences were cut down and sold by the pound (Hemmerly, 1970).

Energy

Not a fast grower, trees 20–30 years old being only 6–8 m tall and 5–7.5 cm in diameter, this is not a productive firewood species, though the wood burns well. The residues after oil extraction (or pencil production) should make excellent fuels, enough to feed the distillation or sawmill.

Biotic Factors

According to Ag Handbook 271, few insects damage the trees seriously. Occasionally boring insects feed on living trees and bagworms eat the foliage. As an alternate host of cedar-apple rust, *Gymnosporangium Juniperi-virginianae*, red cedar is the enemy of apple growers. The following are reported to affect red cedar: *Aleurodiscus nivosus, Botryosphaeria ribis, Caliciopsis nigra, Cenangella deformata, Cercospora sequoiae* var. *juniperi, Chloroscypha cedrina, Coccodothis sphaeroidea, Cytospora cenisia, Daedalea juniperina, D. westii, Dothidella juniperi, Fomes annosus, F. juniperina, F. pini, F. roseus, F. subroseus, F. texanus, Gymnosporangium bermudianum, G. clavipes, G. corniculans, G. davisii, G. effusum, G. exiguum, G. exterum. G. floriforme, G. globosum, G juniperi-virginianae, G. nidus-avis, G. trachysorum, G. tubulatum, Lenzites vialis, Lophodermium juniperinum, Macrophoma,juniperina, Pestalotia funerea, Phomopsis juniperovora, Phymatotrichum omnivorum, Physalospora abdita, P. cupressi, P. obtusa, Pithya cupressina, Poria pupurea, P. subacida, Stagonospora pini, Streptothrix* spp., *Trametes americana, T. carnea, T. septum,* and *Valsa cenisia* (Browne, 1968; Ag Handbook 165). *Pratylenchus penetrans* is one nematode pest. (Golden, p.c., 1984)

Pakchoi

Spoon cabbage, Japanese white celery mustard, Pak Choy Sum, Chinese chard, Mustard cabbage, Pak Choy, Pak Toy, Celery Mustard

Kai choy

Gai choy, Gai chow, Mustard cabbage

Cruciferae *Brassica campestris* L. (Chinese group)

Source: Magness et al. 1971

Pakchoi is quite closely related to Chinese Cabbage, which see. Pakchoi resembles miniature Swiss chard. As compared to Chinese Cabbage, the head is shorter and more loose. Kai Choy has broader petioles as compared to Pakchoi. and develops a loose bead as Pakchoi. Leaves are cupped or spoon-shaped. In culture and use Pakchoi and Kai Choy are similar to Chinese Cabbage, but exposure of edible parts to pesticides is somewhat greater. No data on production in the Continental U.S. are available, as it is included with Chinese Cabbage. Hawaii produced 655 tons on 80 acres in 1968.

Part of plant consumed: Leaves and petioles

Tyler, V.E. 1999. Herbs affecting the central nervous system. p. 442–449. In: J. Janick (ed.), Perspectives on new crops and new uses. ASHS Press, Alexandria, VA.

Herbs Affecting the Central Nervous System

Varro E. Tyler

LAWS AND REGULATIONS GOVERNING HERBAL MEDICINES IN THE US

As a result of the existing laws and regulations, most herbal remedies (botanicals, phytomedicines) are currently marketed in the United States as dietary supplements, a food category, not as the drugs they are. This situation stems directly from the passage, in 1962, of the Kefauver–Harris Amendments to the Federal Food, Drug, and Cosmetic Act of 1938. These amendments required drugs to be proven effective prior to marketing, in addition to the purity and safety requirements already in effect.

Although the law specifically exempted from this requirement all drugs marketed prior to 1938, which included almost all of the herbal remedies, the Food and Drug Administration (FDA), by a clever application of administrative law, i.e., regulations, circumvented the will of Congress. The agency declared that although sale could continue, any unproven claim of efficacy would cause the herb to be considered as misbranded which could result in confiscation.

To determine efficacy of over-the-counter products, in 1972 the FDA established 17 panels to evaluate, on the basis of submitted information only, the data supporting such claims. The panels were not permitted to utilize anecdotal information, product popularity, nor did they conduct detailed literature surveys. Because proof of efficacy studies are extremely expensive—current estimates for new chemical entities range up to one-half billion dollars—a limited amount of data was submitted to the panels for the old botanical remedies for which patent protection and market exclusivity with consequent profitability were doubtful.

In consequence, very few herbal remedies were approved as drugs. The few that were found acceptable included capsicum (*Capsicum* spp.) as a topical analgesic, slippery elm (*Ulmus rubra* Muhl.) as a demulcent, psyllium seed and husk (*Plantago* spp.) as a laxative, and distilled extract of witch hazel (*Hamamelis virginiana* L.) as an astringent (due to the 14% alcohol added to the final preparation). On the basis of inadequate data submission, the FDA declared peppermint (*Mentha* × *piperita* L.) to be an unsafe and ineffective digestive aid and placed other useful remedies such as the antitussive eucalyptus (*Eucalyptus globulus* Labill.) and the laxative prune (*Prunus domestica* L.) concentrate in the same category.

Sales of such herbal products declined for a time but began to increase once again in the 1980s as consumers became more health conscious and displayed a significant interest in natural products. Finally in 1993, Commissioner David Kessler of the FDA threatened additional controls on such products. The public rebelled, and submitting to the will of the people, Congress passed the Dietary Supplement Health and Education Act of 1994. That Act permits any herb sold in the United States prior to October 1994 to continue to be marketed as a dietary supplement (food) without FDA approval.

Labeling of such products is, however, restricted. Therapeutic claims are not permitted. This prompts the potential user to turn to the herbal literature, much of which is hyperbolic and advocacy in nature—especially on the internet—designed to promote sale of the product. Claims regarding the effect of the remedy on the structure or function of the human body are permitted on the label, but such a statement must be followed by another indicating the claim has not been approved by the FDA. A third statement must then follow indicating the product is not intended to diagnose, treat, cure, or prevent any disease. That, of course, is why the potential user wanted to purchase the product in the first place, so the entire situation becomes very confusing, even to the sophisticated consumer.

Another serious problem with the herbal product status quo is the total lack of quality standards for such preparations. Products and the companies selling them range from very bad to very good. Consumers have few resources to determine which is which, and published analyses of particular brands have been quite limited, probably due to the fear of litigation.

Other advanced nations have solved the herbal problem in one of two ways. The first is simply to allow botanicals to be sold as "traditional" drugs whose efficacy is based on long usage and anecdotal information, not on scientific or clinical studies. This is not a satisfactory solution because many of such claims of utility remain unverified.

The best solution, without question, is to modify existing regulations to allow herbal remedies to be sold as drugs, with appropriate quality standards, following absolute proof of safety and "reasonable" proof of efficacy. The reasonable qualification would allow the marketing of a product with a research investment of perhaps a few million dollars as opposed to the hundreds of millions now required. Such an expenditure is just a small fraction of the marketing budget of many herbal product manufacturers.

This type of drug approval is the one that exists today in Germany. It has functioned well there for decades, and no serious problems have been encountered. Safety and efficacy are determined by an independent panel of experts, designated Commission E, appointed by the German equivalent of our FDA. The Presidential Commission on Dietary Supplement Labels recommended the appointment of a similar panel in the United States to evaluate herbal safety and efficacy. So far, the FDA has not acted upon that recommendation nor has the agency given any indication that it will do so. Likewise, the FDA has not acted upon a long-standing petition that would allow the safety and utility of herbs to be evaluated as OTC remedies on the basis of the voluminous scientific and clinical studies already carried out in European countries, especially Germany.

Adherence to standards for drug approval designed for new synthetic chemical entities is obviously not realistic for long-used herbal remedies. In view of the fact that one-third of the adult population in this country now employs herbal remedies and the retail market approximates $4 billion annually, serious consideration needs to be given to modifying outdated regulations. A change is urgently required to assure that consumers will be supplied with quality products providing appropriate information regarding their therapeutic utility directly on the label.

Among the numerous botanicals marketed in the United States today are several that produce significant direct or indirect effects on the central nervous system. Some of the more prominent ones have been extensively studied with respect to their chemical composition and physiological and therapeutic activities. Others continue to be employed largely on the basis of their folkloric reputations as useful remedies.

CONSIDERATION OF SPECIFIC HERBS

Ephedra or Ma Huang (*Ephedra* spp.)

Ephedra, commonly referred to by its Chinese name *ma huang*, has received much publicity recently. The herb consists of the dried green stems of several species of *Ephedra* native to Central Asia. These include *E. distachya* L., *E. equisetina* Bunge., and *E. sinica* Stapf. Ma huang has been used in China for the treatment of bronchial asthma and related conditions for more than 5000 years.

The therapeutic use of ephedra is due to its content of several closely related alkaloids of which ephedrine is both the most active and the one present in largest amount. A typical ephedra plant contains about 1.5% total alkaloids of which some 80% is ephedrine. American species of *Ephedra*, one of which is *E. nevadensis* S. Wats., often referred to as Mormon tea, contain no active alkaloids. Ephedrine was carefully researched here in the United States during the 1920s and was a standard over-the-counter (OTC) medication for many years. Like all other effective medications, it may also produce undesirable side effects.

The alkaloid's vasoconstricting effect makes it a useful nasal decongestant, but it also raises blood pressure and increases heart rate. It is an effective bronchodilator, but it also stimulates the central nervous system (CNS) with side effects ranging from nervousness to insomnia. This stimulation is greatly increased by consumption of caffeine or caffeine beverages such as coffee, tea, or cola. Consequently, ephedrine has been replaced to a large extent in over-the-counter cold and cough products by related chemicals such as pseudoephedrine or phenylpropanolamine. These have a similar action but much reduced CNS effects.

In recent years, ephedra and caffeine combination products have been promoted as appetite depressants and metabolic stimulants for weight loss, as athletic performance enhancers and, in very large doses, legal euphoriants or intoxicants. There is a considerable literature about the effects of ephedra on weight loss with some modestly favorable results. As one of my pharmacologist friends quipped, "You're bound to lose weight if you take ephedra and caffeine because you'll be so hyper the soup will slop out of the spoon before it reaches your mouth." That is, of course, a slight exaggeration.

Detailed studies of the herb's effect on athletic performance or its euphoriant activities do not exist. But that is of little moment because ephedra should not be taken chronically for any purpose unless the consumer is under the direct care of a competent physician. Many of the herbal products do not list the concentration of ephedrine present. Some manufacturers almost certainly "spike" their dosage forms with additional quantities of synthetic ephedrine.

As a result, the Food and Drug Administration (FDA) convened a special advisory group on ephedra in October 1995. That committee of experts made a number of recommendations regarding the sale of ephedra products, including strict dosage limitations, appropriate warning labels preventing chronic use, prohibition of sale to persons under age 18, and warnings to individuals with specific health risks.

These recommendations were never implemented, although in April 1996 the FDA did issue a warning cautioning consumers not to buy any high-dose ephedra products marketed as "legal highs." By August 1996, the FDA had compiled a list of some 800 adverse reactions, including 22 deaths and a number of serious cardiovascular and nervous system effects, including heart attack, stroke, and seizures, which they attributed to the consumption of ephedra, often in combination with caffeine-containing herbs. (The numbers in both categories have increased significantly since that time.) Consequently, another special advisory group meeting was held, but after lengthy discussion, no consensus was reached, and no concrete recommendations were made.

Food and Drug Commissioner David A. Kessler, who attended the meeting, said the agency would consider the matter and act quickly on ephedra's marketability, almost certainly before the end of 1996. He subsequently resigned, and no action was taken prior to the self-imposed deadline.

Finally, in June 1997, the FDA requested comment on a series of proposed restrictions on the sale of ephedra as a dietary supplement. These included a limitation of 8 mg per dose of ephedra alkaloids, labels warning consumers not to take more than 24 mg of ephedra alkaloids per day, labels advising at-risk persons not to consume ephedra, and limitation of consumption to a maximum of 7 days. As of June 1999, these proposed regulations have never been implemented.

Several states have acted, or are considering action, to control ephedra products. Most authorities continue to believe that small doses of ephedra, equivalent to not more than 40 mg of ephedrine per day, consumed on an occasional, not a chronic, basis for the relief of bronchial asthma, are safe for otherwise normal persons.

Another concern often expressed about ephedra is the possibility that the contained ephedrine may be illegally converted to methamphetamine or "speed," a common drug of abuse, by basement chemists. Although this is possible, it is not likely because of the difficulty in separating the product from the accompanying plant material. A much more likely starting product is pseudoephedrine which is readily available in pure form. Indeed, large-scale sales of that alkaloid are now monitored by the Drug Enforcement Administration (DEA).

Ephedra remains a prime example of an age-old dilemma in medicine. Must a useful therapeutic agent be banned because of its abuse potential? In many cases, this has proven to be necessary. Whether ephedra herb falls in this category remains to be seen.

Ginkgo (*Ginkgo biloba* L.)

An important breakthrough in herbal medicine took place in October 1997 when the *Journal of the American Medical Association* published the results of the first clinical trial conducted in the United States of the effect of *Ginkgo biloba* extract (GBE) on patients suffering from mild to severe dementia caused by Alzheimer's disease or multiple clots in the blood vessels. The generally positive results showing modest improvement in the cognitive performance and social functioning of the demented patients basically confirmed results previously obtained in European studies. Some 36 clinical trials with GBE had been conducted there between 1975 and 1996.

The ginkgo tree is well-known, particularly to residents of our large cities where its resistance to pollution and its overall toughness has caused it to be much planted as an ornamental along the very busy streets. This resistance to stress has enabled the species to survive for at least 70 million years; it is often referred to as a living fossil.

The seeds of the tree, after removal of the smelly, outer fleshy layer, have been used in China, both as a medicine and a food, for thousands of years, but it is the dried green leaves, not the seeds, that yield the herbal medicine that has become so popular today. Research beginning in the 1930s identified a number of constituents in the leaves, and in 1965 a product containing 24% flavone glycosides and 6% terpenes (ginkgolides A,B,C, and bilobalide) was first marketed for the treatment of conditions resulting from cerebral and peripheral circulatory disturbances. The product subsequently became very popular as an approved drug in Germany where sales in 1996 exceeded $163 million.

GBE is used primarily to treat cognitive deficiency, a condition caused by inadequate blood flow and nerve degeneration in the brain and expressed by symptoms such as vertigo, tinnitus, headache, short-term memory loss, reduced vigilance and concentration, and confusion. It is also useful in peripheral vascular disorders, having been shown to increase pain-free walking distance in patients with intermittent claudication. Evidence is also accumulating to support the value of GBE in alleviating sexual problems in males, particularly in those whose erectile dysfunction has been induced by the consumption of various antidepressant drugs.

Just how does GBE function to produce all of these beneficial effects? As is often the case with herbs, no single compound and no one mechanism is responsible. The ginkgo flavonoids reduce harmful brain effects by preventing the activity of enzymes that produce damaging free radicals.

They also act as antioxidants scavenging any free oxygen radicals that are formed. In addition, they affect calcium transport which has a powerful influence on brain metabolism.

The sesquiterpene bilobalide reduces increased water and electrolyte levels in damaged brain tissue. The diterpene ginkgolides are potent platelet activating factor (PAF) inhibitors. PAF can contribute to brain damage not only by inducing thrombosis but also by increasing the permeability of blood vessels, allowing liquid to seep through them into brain tissue. This is likely to result in nerve damage.

In contrast to many synthetic drugs (halperidol, fluoxetine, and tacrine) for the treatment of dementia, GBE exerts its beneficial action with a much lower incidence of side effects. Only 1.67% of 10,632 patients treated with ginkgo experienced mild stomach upsets, headache, or allergic reactions in comparison to 5.42% of 2,325 patients treated with synthetic drugs who suffered these or more serious reactions.

The customary daily dose of GBE is 120–240 mg taken in 2 or 3 separate doses. A minimal 8-week course of treatment is recommended for cognitive deficiency. Contraindications to ginkgo therapy are not known, but because it does inhibit PAF, the herb should be administered cautiously in patients undergoing anticoagulant therapy utilizing either other herbs, e.g., garlic (*Allium sativum* L.), ginger (*Zingiber officinale* Roscoe), feverfew [*Tanacetum parthenium* (L.) Schultz Bip.], or synthetic drugs (warfarin).

Consumption of unprocessed ginkgo leaves in any form, including teas, should be avoided because they contain several potent allergens known as ginkgolic acids. These compounds, removed during processing of GBE, are chemically related to urushiol, the active principle in poison ivy [*Toxicodendron radicans* (L.) Ktze.]. Current regulations in Germany limit the concentration of ginkgolic acids in ginkgo preparations to a maximum of 5 parts per million. No standard has been established in the United States, but quality products do not exceed that level.

The GBE preparations long marketed worldwide are concentrated about 50-fold and contain 24% flavone glycosides and 6% terpenes, often designated 24/6. Recently, one company has made available a 27/7 product prepared by a method that increases the ginkgolide B concentration. Studies show that it produces a higher concentration of ginkgolides in the blood for a longer period of time, thus enhancing the effects of the herb.

In contrast to such improved products, it is believed that there are many substandard GBE preparations on the market today. Because of the extensive processing required, ginkgo is relatively expensive to produce, and the standard 50–60 mg tablets usually retail in the $10–$15 range for 60 capsules, depending on the brand. So-called bargain herbs, sometimes selling for a dollar or two for the same quantity, are very likely not bargains at all.

Sometimes one sees ginkgo advertisements touting it as a "smart pill" that improves the cognitive function of persons in the absence of any pathological condition. There is practically no evidence to show that the herb produces significant beneficial effects in the normal human brain.

St. John's Wort (*Hypericum perforatum* L.)

Depression, at least in its milder forms, is a condition that seems to afflict many Americans, occasionally if not chronically. In this country, the disease is the fourth most likely reason for one to consult a family physician and costs our economy more than chronic respiratory illness, diabetes, arthritis, or hypertension. The treatment and rehabilitation expenses in the United States exceed $12 billion annually; but the true cost, including loss of earnings, absenteeism, and loss of productivity, totals nearly $44 billion annually.

Depression is characterized by a number of subjective complaints ranging from despondency and loss of interest to irritability and sleep and digestive disorders. One authority has noted that the depressed patient suffers from melancholia about the present, guilt about the past, and anxiety about the future. Mild to moderate depressive symptoms occur in 13–20% of the population; major depression, often characterized by suicidal tendencies, plagues 1.5–5%.

More than a dozen prescription drugs are routinely used to treat America's depression. All of them are synthetic, and they all produce more or less unpleasant side effects ranging from skin rashes to overtly violent behavior. Meanwhile, in Germany the most popular prescription drug of any type, natural or synthetic, for the treatment of depression is a concentrated extract of the flowers and leaves of St. John's wort, often simply called hypericum. More than 200,000 prescriptions per month are filled for a single brand (Jarsin) there compared to about 30,000 per month for fluoxetine (Prozac). This figure does not include sales of other hypericum products, whether prescribed or self-selected. Actually, 80–90% of the sales in Germany are prescriptions, which allows their cost to be reimbursed by the health insurance system.

During the past two years, St. John's wort has become extremely popular in the United States. In 1996, it was not even listed among the best-selling herbs. Now it is one of the five most popular botanicals. Favorable publicity on television, and subsequently in the popular press, had much to do with this phenomenal increase in use.

Many clinical trials show St. John's wort to be especially useful in treating mild to moderate depressive states. Studies in 3,250 patients found improvement or total freedom from symptoms in about 80% of the cases treated, with only 15% not responding. These results are typical of all drug therapies for depression. However, the side effects were far fewer than those observed with conventional antidepressants. The incidence was less than 2.5% and consisted mainly of gastrointestinal disturbances and allergic reactions.

The herb's multiple constituents apparently function in several different ways. Initially, St. John's wort was thought to act as a monoamine oxidase (MAO) inhibitor. This effect has now been shown to be insignificant. Some evidence supports its effect as a selective serotonin reuptake inhibitor (SSRI).

It may also inhibit COMT (catechol-*O*-methyltransferase), an enzyme capable of destroying biological amines. Still another mechanism seems to suppress interleukin-6 release, affecting mood through neurohormonal pathways. The advantage of this combined action is fewer side effects for the patient because the total response is not due to a single type of activity.

Some authorities have warned against exposure to sunlight while consuming hypericum because it may induce photosensitivity with its dermatitis and associated inflammation. However, while light-skinned animals grazing on great quantities of the herb have had such reactions, photosensitivity is very uncommon in people taking it in normal amounts. It has occurred in patients injected intravenously with very large amounts of hypericin—50 to 70 times the normal oral dose.

Although St. John's wort is marketed as a drug in Germany and has been approved there by the German equivalent of our Food and Drug Administration for the treatment of depression, anxiety, and nervous unrest, it is sold in the United States only as a dietary supplement. The most effective preparations are capsules containing an extract of the herb standardized on the basis of 0.3% hypericin. Dosage is 300–900 mg daily. Improvement of mild to moderate depression should result after 2 to 6 weeks of treatment.

Kava (*Piper methysticum* G. Forst.)

The first Europeans to observe the kava plant and its ritualistic consumption by natives of Oceania were Dutch explorers Jacob Le Maire and William Schouten. In 1616, they encountered the plant in the Hoorn Islands, now a part of the French territory Wallis and Fatuna. Later travelers in the Pacific region provided a wealth of detail regarding this highly valued and widely used pepper plant.

Long cultivated and known by a number of common names, including *kava-kava*, *ava*, *yagona*, and *yangona*, the plant is now classified by botanists as *Piper methysticum*, meaning "intoxicating pepper." In religious and social rituals that naturally vary somewhat from island to island, the rhizome of the plant is grated (originally chewed by young people with sound teeth), mixed with water in a bowl, strained, and the resulting beverage drunk to produce a feeling of well-being.

Observers and even scientists long disagreed on the effects of kava. Captain James Cook, who observed its use during his world voyage of 1768–1771, thought the symptoms resembled those of opium. Lewis Lewin, a pioneer pharmacologist in the field of mind-altering drugs, referred to it in the 1880s as a narcotic and sedative, but noted these effects followed a period of quiet euphoria. Modern authorities call kava a psychoactive agent; it reduces anxiety much like the potent, synthetic benzodiazapines (e.g., Valium) and is a potent muscle relaxant. Kava does promote relaxation and sociability, but its effects are very different from those produced by either alcohol or synthetic tranquilizers. It does not produce a hangover, and, even more significant, it does not cause dependency or addiction.

Naturally, people were interested in finding out how kava produced these interesting effects. It was once thought that chewing the root converted its starch into sugar which then fermented to produce alcohol. Although this sounds far-fetched, *chicha*, a corn-based beer brewed by natives in Peru and Bolivia, is prepared in just this fashion. Lewin said a resinous material was the active component. Finally in the 1950s and 60s, two teams of German scientists headed by H.J. Meyer in Freiburg and R. Hänsel in Berlin found that the various activities of the kava plant were due to some 15 different chemical compounds known as pyrones. Collectively named kavapyrones or kavalactones, the compounds were found to increase the sedative action of barbiturates, to have both analgesic and local anesthetic effects, to cause muscles to relax, and to have antifungal properties.

Shortly after these findings, preparations of kava extract began to appear on the European market, usually standardized to provide a daily dosage in the range of 60–120 mg of kavapyrones. German Commission E, the group responsible for evaluating the safety and efficacy of botanical medicines, reviewed the data on kava and, in 1990, approved its use for conditions such as nervous anxiety, stress, and restlessness. It is frequently marketed as an anxiolytic. Use of kava is contraindicated during pregnancy, nursing, and in cases of depression caused by internal factors.

With an herb as potent as this one, there is naturally concern about side effects. Observations on 4,049 patients consuming 105 mg of kavapyrones daily for 7 weeks noted 61 cases (1.5%) of undesired effects. These were mostly mild and reversible gastrointestinal disturbances or allergic skin reactions. A 4-week study of 3,029 patients taking 240 mg of kavapyrones daily produced a slightly greater incidence (2.3%) of similar side effects. This would be expected because of the larger dosages used.

Long-term consumption of very large quantities of kava may result in a yellow coloration of the skin, nails, and hair, allergic skin reactions, visual and oculomotor equilibrium disturbances. For this reason, Commission E recommends that kava not be consumed for longer than 3 months without medical advice. Driving and operating machinery during consumption should be avoided.

The results of 5 controlled, double-blind clinical trials carried out with a total of 410 subjects over periods ranging from 28 to 84 days, using daily doses of kavapyrones between 30 and 210 mg, were all positive. For example, in 1995, 100 patients suffering anxiety and stress symptoms were given 210 mg of kavapyrones daily. After 8 weeks, the treated subjects were clearly improved in comparison to those receiving a placebo. As for side effects, 15 persons receiving the placebo reported them in comparison to only 5 taking kava extract.

Kava products have been steady but unspectacular sellers in Europe for several decades. Until recently, no one in the United States seemed much interested in them. Ironically, when the Food and Drug Administration began to express concern over the safety of ephedra, a stimulant herbal product, herb marketers became enthusiastic about kava, a depressant. Both herbs have psychoactive properties, but the effects are almost exactly opposite.

Kava and its contained pyrones are, without question, effective medications. They are also subject to abuse. The kava scenario in this country is just beginning. It is too early to predict whether it will continue to be marketed freely or will eventually be subjected to rigid controls.

Valerian (*Valeriana officinalis* L.)

The dried rhizome and roots of this tall perennial herb have enjoyed a considerable reputation as a minor tranquilizer and sleep aid for more than 1000 years. They contain from 0.3% to 0.7% of an unpleasant-smelling volatile oil containing bornyl acetate and the sesquiterpene derivatives valerenic acid and acetoxyvalerenic acid. Also present is 0.5% to 2% of a mixture of lipophilic iridoid principles known as valepotriates. These bicyclic monoterpenes are quite unstable and occur only in the fresh plant material or in that dried at temperatures under 40°C. In addition, various sugars, amino acids, free fatty acids, and aromatic acids have been isolated from the drug.

Identity of the active principles of valerian has been a subject of controversy for many years. Initially, the calmative effect was attributed to the volatile oil; indeed, this kind of activity was long associated with most herbs containing oils with disagreeable odors. Then, beginning in 1966 with the isolation of the valepotriates, the property was attributed to them for a 20-year period. This was done in spite of the fact that they were highly unstable and were contained in most valerian preparations only in small amounts. Finally, in 1988, it was shown that although valerian did produce CNS depression, neither the tested valepotriates, nor the sesquiterpenes valerenic acid or valeranone, nor the volatile oil itself displayed any such effect in rats. Although the active principles of valerian remain unidentified, it seems possible that a combination of volatile oil, valepotriates, and possibly certain water-soluble constituents may be involved.

Because the valepotriates possess an epoxide structure, they demonstrate alkylating activity in cell cultures. This caused concern that the herb might possess potential toxicity. However, those valepotriates decompose rapidly in the stored drug and also are not readily absorbed. For these reasons, no toxicity has ever been demonstrated in intact animals or human beings, so there is no cause for concern.

Eight clinical studies conducted between 1977 and 1996 have shown that valerian is not a suitable herb for the acute treatment of insomnia. Rather, its principal utility lies in its ability to promote natural sleep after several weeks of use, without risk of dependence or adverse health effects. Users should realize the prolonged length of time required for valerian to exert its effectiveness. When properly employed, it offers a gentle alternative to synthetic hypnotics and benzodiazapines in patients with chronic sleep disorders. Recommended dosage is 2–3 g one or more times daily.

Miscellaneous CNS-Depressant Herbs

There are several botanicals with a folkloric reputation for utility in the treatment of restlessness and sleep disturbances whose efficacy is largely unproven by scientific methods. Some of them are frequently used in combination with other CNS depressants in proprietary herbal products.

Hops, the dried strobiles of *Humulus lupulus* L., is one of these. Although very small amounts of methylbutanol, a compound with sedative effects, have been detected in hops, clinical studies have not verified any such activity of the herb in human subjects.

Balm or lemon balm, the leaves of *Melissa officinalis* L., has long been purported to have sedative effects. In the only experimental study to date, its volatile oil did show some activity, but the results were not dose dependent. This suggests the effects were nonspecific.

Passion flower, the dried above-ground parts of *Passiflora incarnata* L., has an ancient reputation as a sleep aid. However, no controlled clinical trials have ever been conducted on single-herb preparations, so preliminary positive results in the few animal studies have not been verified.

Lavender, the dried flowers of *Lavandula angustifolia* Mill., yield a volatile oil, the calming and relaxing effects of which are better documented by both empirical medicine and experimental studies than the three previous herbs. Apparently, its actions are mediated by olfactory receptors, but it may possibly act directly on the CNS following systemic administration. Suitable research in human subjects is required to verify preliminary observations.

The German Commission E approved hops as a calming and sleep promoting drug, lemon balm as a sedative, passion flower for nervous restlessness, and lavender flower as a sedative. There is little or nothing in the published scientific or clinical literature to substantiate these recommendations.

This concludes a brief survey of the herbs that have either been demonstrated to have significant effects on the central nervous system or are postulated to have such effects. Because this broad overview does not present original research findings, specific references to previously established facts are not listed. They are simply too numerous to include. Instead, a general list of recommended reading in which all appropriate references may be found is presented here.

Kochia

D.J. Undersander[1], B.R. Durgan[2], A.R. Kaminski[1], J.D. Doll[1], G.L. Worf[1], E.E. Schulte[1]

[1]Departments of Agronomy, Plant Pathology, and Soils, College of Agricultural and Life Sciences and Cooperative Extension Service, University of Wisconsin- Madison, WI 53706.
[2]Department of Agronomy and Plant Genetics, University of Minnesota, St. Paul, MN 55108. September, 1990.

I. History:

Kochia (*Kochia scoparia* (L.) Roth), also known as fireweed, burning bush or summer cypress, was introduced to the United States around 1900 as an ornamental from Eurasia. Gardeners like this annual plant for its bright red foliage in autumn.

Farmers in dry areas, including the Southwest, have grown kochia as a drought-resistant forage crop on lands where other crops are difficult to grow -- hence the nickname "poor man's alfalfa." Because of kochia's low water requirements and resistance to diseases and insects, interest in it as a forage crop has increased in the last decade. Researchers at South Dakota State College have selected seeds from wild plants and produced satisfactory yields of leafy foliage.

Kochia, with its high protein content, requires relatively large amounts of nitrogen (100 to 250 lb/acre). If too much nitrogen is applied at once, however, toxic levels of nitrate may accumulate in the plants. Oxalate toxicity, which causes rough hair, humpback, jaundice, photosensitization and a stiff gait in livestock, is another potential problem for cattle that graze only on kochia for periods of 90 to 120 days.

Kochia grows wild throughout most of the northern half of the United States, except for parts of the Pacific Northwest. **The plant has become a serious drought-resistant weed in the Plains states.** Because of the wide genetic variability in wild kochia, it is possible that the problems associated with the plant as a forage crop can be overcome with plant breeding.

II. Uses:

Kochia is grown as a forage crop for sheep and cattle and as an ornamental. As a forage crop its feed value is slightly lower than that of alfalfa. Protein content ranges from 11 to 22%, and decreases as the plant matures. When cut at the recommended stage, kochia hay contains up to 60% leaves and has good aroma. Palatability of kochia is better than that of grasses, such as bromegrass, but a little lower than that of alfalfa. No objectionable milk flavor results from feeding kochia hay.

Oxalate levels for kochia range from 6 to 9%. Feeding calcium phosphate and other kinds of feed (such as alfalfa) tends to reduce oxalate toxicity. Animals with symptoms of oxalate toxicity should be removed from kochia immediately.

Kochia can be used in revegetation programs for erosion control. It will germinate and grow at any time in the growing season, and it thrives in sandy, alkaline and other poor soils. Kochia can be sown by airplane on large areas that need revegetation, such as areas that have been devastated by fire. It provides a quick groundcover to protect topsoil and provide a food source for wildlife until native grasses take over.

III. Growth Habits:

Kochia is an annual forb that reproduces by seed. The bushy plants grow 1 to 7 ft tall and have taproots. The erect, striated stems are light green and much branched. The many alternate leaves are hairy, 1 to 2 in. long, narrow, pointed and attached directly to the stems. Small, green flowers and seeds are produced in narrow heads at the leaf axils. The plant is dark green when young and turns red as it matures. The seeds, when mature, are rough, flat, triangular and grayish-black in color. In the fall, the plants often break away from the roots and tumble over the ground, scattering the seeds.

IV. Environment Requirements:

A. Climate:

Kochia grows wild throughout much of the country, including the Upper Midwest. It can produce forage with as little as 6 in. of annual rainfall and is relatively cold hardy. It can be planted when soil temperatures are as low as 50°F.

B. Soil:

Kochia is grown on dry pastures, rangelands and cropland with alkaline soils. It will grow on land where other crops will not. Wild kochia has not spread to areas with very acid soils, and it is not known how well kochia would perform in such soils.

C. Seed Preparation and Germination:

The seed needs no treatment prior to planting. A properly managed kochia field will reseed itself. Grazed plants appear to produce more seed than the ungrazed ones, providing there is enough plant remaining at normal seeding time to provide seed shoots.

V. Cultural Practices:

A. Seedbed Preparation:

For best results, the soil should be plowed or disked to provide a firm, even and relatively weed-free seedbed. Nitrogen at 50 to 100 lb/acre should be applied prior to planting.

B. Seeding Date:

Kochia should be seeded as early as the soil temperature reaches 50°F (late April to early May) and anytime thereafter throughout the growing season.

C. Method and Rate of Seeding:

Seeding rates vary from 1 to 4 lb/acre, depending on the seeding method. Drilling as little as 1 lb/acre in 36 in. rows with a standard drill will result in a good stand; broadcast or airplane seeding requires more seed.

Though kochia seed does not need to be incorporated, research conducted in New Mexico indicates that a 1/4 in. seeding depth results in best emergence. Emergence is poor when seed is planted 3/4 in. deep or deeper.

Most kochia stands need thinning to prevent the crop from crowding itself out, particularly if a volunteer crop emerges the second year. The crop can be thinned to 2 to 10 plants/ft of row by chiseling at right angles or windrowing portions of the field and letting livestock clean up the dry feed as they graze the green material. Another method is to let cattle graze the kochia field for a short time when the plants are only 2 in. high.

D. Fertility and Lime Requirements:

Kochia is well adapted to alkaline soils, but it is not known how well it does on acid soils. Therefore, lime to a pH of 6.0; or try liming to different pH levels and observe the performance at each.

Because kochia is not a legume, nitrogen needs to be applied in proportion to the amount removed. This amounts to 40 to 60 lb N/ton of hay removed, or 100 to 250 lb N/acre. Do not apply more than 150 lb N/acre in one application, or nitrate toxicity can result. Apply 50 to 100 lb/acre prior to planting, and topdress the remainder later in the season based on anticipated yield.

Kochia responds very little to phosphorus and is low in this element. Cattle grazing on kochia should be fed supplemental phosphorus. Under conditions of adequate moisture, high phosphorus, zinc and boron levels suppress yield. The use of manure to supply nitrogen will likely result in excess phosphorus. Because the potash requirements of kochia are not known, adjust soil K to a medium level. Experiment with additional potash to find a rate suitable for your growing conditions. Suggested rates are 24 to 50 lb K_2O/ton of hay harvested.

E. Variety Selection:

Though there is wide genetic variability in wild kochia, no improved varieties have been developed.

F. Weed Control:

Kochia does not compete well with grasses. This will be a major limitation to use in the Upper Midwest. It is best to plant kochia on a relatively weed-free seedbed with no quackgrass or other grassy weed history. There are no herbicides registered for use in kochia.

Volunteer kochia will be a problem in crops following kochia, thus cultural or chemical control of kochia will be needed in these crops.

G. Diseases and Their Control:

Kochia appears to be free of diseases that cause commercial loss.

H. Insects and Other Predators and Their Control:

Kochia is relatively unharmed by grasshoppers. No information is available on other predators.

I. Harvesting:

1. For pasture: To prevent oxalate toxicity, livestock should not graze on only kochia for more than 90 to 120 days. Rotational grazing of other crops will prevent oxalate poisoning. In contrast to perennials, the entire kochia plant can be eaten.

2. For hay or silage: Kochia should be cut for hay or silage when it is 18 to 26 in. tall and before it has produced seed. In the Southwest, three or four cuttings are possible in a growing season if live branches are left on the stubble each time.

If the kochia crop is thin, it can be cut with a mower with a windrower attachment. Thick stands should be windrowed with a side-delivery rake. The hay can be cured in the windrow or in shocks.

3. For seed: Seed can be harvested using a combine.

J. Drying and Storage:

It may take up to one day longer to field cure kochia hay than it does for alfalfa hay. Because kochia plants are hairy, the cured forage has a gray color which may resemble mold or spoilage. Hay can be stored in stacks or bales.

VI. Yield Potential and Performance Results:

Kochia produces hay yields of 1 to 4 ton/acre (dry matter) and seed yields of 1,500 to 2,000 lb/acre.

VII. Economics of Production and Markets:

Kochia is relatively inexpensive to produce and well adapted for use on dry or low fertility land. Markets for seed are few in number and may be difficult to identify.

Kohlrabi

Stem turnip, Colinabo

Cruciciferae *Brassica oleracea* L. (Gongylodes group)

Source: Magness et al. 1971

Kohlrabi is a cabbage relative. grown for the turnip-like enlargement of the stem just above ground level. Plants are grown from seed, and must be grown rapidly for good quality "bulbs." Leaves rise from the enlarged stem. The enlargement is globose or flattened, and 2 to 3 inches across at harvest. The "bulbs" are tender and succulent if rapidly grown and harvested, but become tough and fibrous with age. For eating, the peel is removed, and the interior sliced or diced and boiled.

Season, seeding to harvest: 2 months.

Production in the U.S.: 147 acres reported in 1954 census. No later data. Mainly in home gardens.

Use: Fresh or cooked vegetable.

Part of plant consumed: Enlarged, bulb-like stem, after peeling.

Sunolgrass

Graminea *Phalaris coerulescens* Dessf.

Koleagrass

***P. tuberosa* var *hirtiglumis* Batt. and Trab.**

Source: Magness et al. 1971

Sunolgrass, introduced from Australia in 1935, and Koleagrass, introduced from Morocco in 1955, are not being grown commercially at present in the United States but are in testing proorams to determine their usefulness. Both are bunchgrasses that have round bulb-like enlargements at the base of the stems. Both are rapid growers. Sunolgrass is a poor seed producer so Koleagrass, which produces ample seed, is of more promise. Adaptation of both is limited to areas having mild winters.

Korean lespedeza

Leguminosae *Lespedeza stipulacea* Maxim.

Source: Magness et al. 1971

Korean is an annual lespedeza introduced into the United States in 1919. It is adapted to a more northern area than striate varieties. It is mainly grown from Eastern Oklahoma and Kansas eastward to the Atlantic Seaboard. Leaves are broader and somewhat larger than striate leaves, and seed is borne somewhat differently. Otherwise, the two annual lespedezas are quite similar. Korean lespedeza is excellent both for hay and pasture, especially on soils that are acid or of low fertility. It reseeds readily to give semipermanent pasture.

Kura Clover

Contributor: Norman L. Taylor

Copyright © 1995. All Rights Reserved. Quotation from this document should cite and acknowledge the contributor.

Common Names

USA: Pellet's clover, honey clover, kura clover
Australia & New Zealand: caucasian clover
Other languages: unknown

Scientific Names

Species: *Trifolium ambiguum* Bieb
Family: Leguminosae (Fabaceae)

Uses

Cultivated as a forage legume for grazing. Formerly some usage as a source of nectar for honey production.

Origin

Caucasian Russia, Crimea, and Asia Minor

Crop Status

A strong perennial spreading by rhizomes. It is receiving some interest in USA, New Zealand, and Australia for use in pasture mixtures. It is apparently quite nutritious and persists many years in mixtures with grasses. Persistency is due in part to its heavy root biomass; up to 20 metric tons/ha. Root:shoot ratios in a 13 -year old stand were reported to be up to 4.6:1. Little or no domestic use occurs in countries of origin. In USA, livestock producers have sown very few acres primarily because of seed limitations. The cultivar Rhizo is being increased by commercial seed companies.

Botany

Taxonomy

The species is classified by most authorities in section Lotoidea, subsection VII Platystylium of the genus *Trifolium*. Three ploidies occur; diploid, tetraploid, and hexaploid, which are reproductively isolated. Hexaploids are generally, but not always, the most vigorous but cultivars have been developed at each ploidy level. Kura clover is closely related to *T. repens* and *T. hybriduum* with which it has been hybridized. Kura, like most perennial clovers, is self-incompatible, requiring cross-pollination by bees (honey, bumble, leafcutter, alkali) to produce seeds. The yellow brown seeds are about 1.2 mm long and average about 670/g, roughly the same size as red clover (*T. pretense*) and larger than white clover (*T. repens*). Corolla is white to pale pink turning flesh colored after anthesis. Typical legume inflorescences are grouped into heads, usually upright but with the lower ones deflexed. Pods are 1 to 2 seeded.

Crop Culture

Kura clover is adapted to about the same latitude as its origin, about 40 to 50 degrees. Consequently, it is very cold hardy and tends to be more productive in cooler than in warmer climates. However, breeding efforts are being made to extend its area of usage southward in the U.S., and northward in New Zealand. The clover performs best on well drained, fertile soil but may survive occasional swamping, and lower pH (5.0-6.0) than other forage legumes. During droughts in southern U.S., it tends to go dormant in the summer producing very little growth until moisture becomes available in the fall. The primary difficulty of the crop is slow seedling establishment. It generally flowers only once per season, but cultivars differ.

Cultivars

Cultivars or breeding populations (some not yet released) may be classified as to ploidy and country of release. They include:

Australia

- Alpine (2*X*)
- Summit (2*X*)
- Forest (2*X*)
- Treeline (4*X*)
- Prairie (6*X*)

New Zealand

- Manaro (6*X*)
- KZ-2 (6*X*)

USA

- Rhizo (6*X*)
- Cossack (6*X*)

Production Practices

In central and northern US., kura clover is usually sown in a similar fashion as other small seeded perennial legumes, in the spring, on a well prepared seed bed. Because of low seedling vigor it is mandatory to sow it without companion grasses or small grains. Renovation sowings are not recommended. Optimally, pH and fertility should be adjusted prior to sowing based on soil tests. Special inoculation is required because only one *Rhizobium* strain specific to kura clover is effective, and pains should be taken to assure that inoculation is effective. Some investigators claim that special seed coating techniques are helpful. Seeding rate probably should be 12 to 15 kg/ha. The use of herbicides such as balan, treflan, preincorporated to control weeds is necessary, and if weeds develop later it is necessary to control them with appropriate herbicides (Poast, Basagran, or Fusilade). **Failure to control competition may result in stand failure.** Very little growth is expected in the first season and flowering in most cultivars does not occur until the second season after induction by low temperature in the winter. Flowering in the next season will occur in early May in central U.S. If seed is to be produced, this flowering crop must not be removed as abundant flowering occurs only once per season. If saved for seed, yields may be expected to be 100 to 200 kg/ha. The primary usage of the forage is for grazing, and it may be desirable to sow grasses after the kura is established. In the central bluegrass region of the U.S., bluegrass may invade the clover stand, ultimately resulting in a mixture. Kura stands are slow to establish but, once established, may be expected to last indefinitely, depending upon management, because of its large root biomass. Rotational grazing may be more productive than continuous grazing.

Prickly Lettuce

Lactuca scariola L.

Synonym.—*Lactuca virosa* Amer. auth., not L.

Other common names.—Wild opium, wild lettuce.

Habitat and range.—The prickly lettuce occurs in fields and waste places from Vermont to Georgia and westward to the Pacific coast.

Description.—This is a bright-green plant, from 2 to 7 feet high, covered with a whitish bloom. It has an erect, rigid stem sometimes smooth throughout but at times hairy at the base, with numerous clasping, oblong lance-shaped leaves with finely toothed margins and spiny bristles along the under side of the midrib. The lower leaves are at times 10 inches long and 3 inches wide, but the upper ones are much smaller. The pale yellow flowers, which appear in the early fall, occur in very numerous heads up to a third of an inch broad, having the feathery appearance of the ripe dandelion bloom, arranged in open clusters, each head consisting of 6 to 12 flowers.

Laguncularia racemosa (L.) Gaertn. f.

Combretaceae
White mangrove

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Branchlets are browsed by camels in Africa (Irvine, 1961). The hard heavy wood is used for carpentry, construction, posts and tool handles. The bark is used for tanning and for dying fishermen's nets. Considered a honey plant (Duke, 1972)

Folk Medicine

Reported to be astringent and tonic, white mangrove is a folk remedy for dysentery (Duke and Wain, 1981), Hager's Handbook mentions that the bark is used for aphthae, fever, and scurvy (List and Horhammer, l969–1979). "The antitumor activity of the bark extract is attributed to its tannin content" (Morton, 1981).

Chemistry

Bark contains 10.3% tannin, gall's 10.7%, leaves 16.8%. Irvine (1961) puts the bark tannin at 12–24%, dry leaf tannin at 10 20%. According to Hager's Handbook, (List and Horhammer, 1969–1979), the bark contains maclurin ($C_{13}H_{10}O_6$).

Description

Evergreen tree to 12 m tall and 30 cm diameter, with rounded or irregular spreading crown. Bark gray-brown, becoming rough and fissured; inner bark light brown. Pneumatophores often present. Leaves Opposite, elliptical, 4–10 cm long, 2.5–5 cm wide, rounded at both ends, entire, glabrous, leathery, slightly fleshy, without visible veins. Petiole 10–13 mm long, stout, reddish, with 2 raised gland-dots near blade. Panicles at ends and sides of twigs, mostly branched and spreading, 3–10 cm long. Flowers mostly bisexual ca 5 mm long, bell-shaped, whitish. Petals, 5, rounded, whitish, 1 mm long, and stamens, 10. Pistil with inferior 1-celled ovary with 2 ovules, slender style, and tiny 2-lobed stigma. Drupes several, stalkless, obovoid, 12–20 mm long, flattened, ridged, gray-green with velvety hairs when immature, turning brownish, Seed 1, large, sometimes viviparous (Little, 1983).

Germplasm

Reported from the African and American Centers of Diversity, white mangrove, or cvs thereof, is reported to tolerate diseases, insects, pests, salt, and waterlogging (Little, 1983; NAS, 1980a).

Distribution

Both coasts of tropical America, northern Mexico to Brazil and Ecuador, Galapagos Island's and northwestern Peru. West Indies, Bermuda, southern and central Florida. Western Africa from Senegal to Cameroon. Not widely introduced elsewhere (Little, 1983).

Ecology

Ranging from Tropical Dry to Rain through Subtropical Dry to Rain Forest Life Zones, white mangrove is reported to tolerate annual precipitation of 10.4 to 23.4 dm (mean of 6 cases = 18.0), annual temperature of 24.9 to 26.4°C (mean of 5 cases = 25.7), and estimated pH of 6 to 8.5. Surely it tolerates rainfall up to 80 dm and annual temperature down to 18°C, without frost. Usually in well-drained brackish or saline soils along shores of lagoons and tidal rivers (Little, 1983).

Cultivation

According to the NAS (1980a) planting is usually not needed because natural regeneration is so successful. In Avicennia and Rhizophora direct seeding results in ca 90% survival.

Harvesting

May flower and fruit precociously (less than 2 years old). Harvested for fuel as needed. After cutting, there may be a multistemmed coppice.

Yields and Economics

It is stated that Brazilian tanneries use a million and a half kilos of mangrove leaves (e.g. *Laguncularia racemosa*) annually (Morton, 1965).

Energy

The wood, moderately hard and heavy (sp. grav. 0.6), is used for fuel and charcoal (Morton, 1981).

Tamarack

Larix laricina (DuRoi) K. Koch.

Synonym.—*Larix americana* Michx.

Other common names.—American larch, black larch, red larch, hackmatack.

Habitat and range.—This tree frequents swamps and moist places from Canada south to New Jersey, Indiana, and Minnesota.

Description.—The tamarack, a slender tree with horizontally spreading branches, sometimes reaches a height of 100 feet. The pale-green leaves, which have a feathery appearance early in spring, are very slender and needle shaped, from 20 to 40 being together in a bundle, similar to the manner in which pine needles grow. Unlike the pine, however, the tamarack loses its leaves upon the approach of winter. Male and female flowers are produced, the latter developing into small, erect cones. The bark is thin and close, becoming scaly with age.

Neglected Crops: 1492 from a Different Perspective. 1994. J.E. Hernándo Bermejo and J. León (eds.). Plant Production and Protection Series No. 26. FAO, Rome, Italy. p. 273-288.

Grain legumes for animal feed

The author of this chapter is L. López Bellido (Department of Agricultural Sciences and Resources, University of Córdoba, Spain).

The author thanks H. López Córcoies for the information provided on *Vicia narbonensis* and F. Varela for the data on the collections of the Madrid Centre for Plant Genetic Resource Conservation.

Among the grain legumes from the Old World, we may single out two species of the genus *Lathyrus* (*L. sativus* L. and *L. cicera* L.), one species of the genus *Trigonella* (*T. foenum-graecum* L.) and three species of the genus *Vicia* (*V. ervilia* (L). Willd., *V. monanthos* (L). Desf. and *V. narbonensis* L.) on account of their current state of marginalization. In Spanish, *L. sativus* is called by the popular names almorta, gija, muela and tito and in Latin America by the names alverja and chícharo (in Portuguese it is known as chicharo, in English as chickling vetch and in India as khesari). *L. cicera* is known as titarro, almorta de monte, chícharo, galgana and cicércula. *T. foenum-graecum* is known as alhlova and also heno griego or fenogreco (in English, fenugreek). *V. ervilia* corresponds to the yeros, also known as alcarceña, alverja, alcarraceña, ervilla, lenteja bastarda, etc. (in Portuguese, ervilha de pombo and gero, and in English bitter vetch). *V. monanthos* is the name of algarroba, garroba and lenteja de Aragón (in English, one-flowered or one-leaved vetch, and in Portuguese ervilhaca parda). Finally, *V. narbonensis* is known as alverjon and haba loca (in Portuguese ervilhaca de Narbona, and in English Narbonne vetch).

Figure 32. Grain legumes: A) one-leaved vetch (*Vicia monanthos*); A1) calyx; A2) flower; A3) legume; B) bitter vetch (*V. ervilia*); B1) flower; B2) legume; C) Narbonne vetch (*V. narbonensis*); C1) flower; C2) legume

Figure 33. Grain legumes: A) chickling vetch (*Lathyrus sativus*); A1) flower; A2) legume; B) vetchling (*Lathyrus cicera*); B1) legume; C) fenugreek (*Trigonella foenum-graecum*); C1) flower; C2) legume

This species, along with the garden pea (*Pisum sativum* L.), broad bean (*Vicia faba* L.) and chickpea (*Cicer arietinum*) were the first cultivated legumes, according to archaeological findings of the neolithic period, Bronze Age and Iron Age in Europe, the Near East and the Nile Valley.

Their location has demonstrated the spread of these species from their centre of domestication. Because of their larger size, the seeds that have been found are considered to be cultivated rather than wild forms.

Columela, in *De re rustica* (first century), mentions *Trigonella foenum-graecum* (fenugreek), *Vicia ervilia* (bitter vetch) and *Lathyrus cicera* (vetchling or flat pod pea), referring to their use, soil requirements, tillage and sowing dates. He refers specifically to *L. cicera* as it is cultivated in what is today Andalusia for feeding oxen as a replacement for *V. ervilia*—in the form of milled grains, moistened with water and mixed with straw - also stating that it is not an unpleasant food for humans. Libro de agricultura by Abu Zacarla (twelfth century) also mentions *T. foenum-graecum* and *V. ervilia*, referring to their soil requirements, methods and dates of sowing, fertilization and types of use in animal feeding as well as describing their use as a human medicine and other uses. In *Agricultura general*, by Alonso de Herrera (1513), *V. ervilia* and *L. sativus* are also mentioned, with different cultivation techniques and methods of use for feeding livestock and treating ailments recommended. *L. sativus* is used in the human diet in a similar way to chickpeas and is mixed with other grains to make bread.

Table 10 sets out the origin and distribution of the wild or cultivated form of the various species. Because of their marginal character, there are no data on a worldwide basis relating to the cultivated area of this group of legumes. Chickling vetch (*L. sativus*) is widely grown in India, with an area of 1.6 million ha referred to by Duke (1981). Vetchling (*L. cicera*) is currently grown only in Spain, although it was formerly grown throughout southwestern Europe. Fenugreek (*T. foenum-graecum*) is cultivated in the Mediterranean region, the Near East, Ethiopia, India and southern California. In North Africa, it has been grown for fodder around the Saharan oases from very early times. Bitter vetch (*V. ervilia*) is grown in Asiatic Turkey, central and northern Spain and other countries of the Mediterranean region and western United States; the seed is exported to the United Kingdom and other countries for feed, especially for sheep. There are barely any references to one-leaved vetch (*V. monanthos*) or Narbonne vetch (*V. narbonensis*), in spite of the fact that both species, particularly the former, were widely cultivated in the Mediterranean in past times. Figure 34 shows the regressive pattern of cultivation of these legumes in Spain; some of them are practically on the verge of extinction.

Table 10. Origin, distribution of cultivation and ecology of grain legumes

Species	Origin	Distribution	Climate	Soils
Lathyrus sativus L. (2n=14)	Mediterranean, central Asia	Central, southern and eastern Europe, India, Iran, South America	Suited to dry climates although tolerates an excess of rain. Annual precipitation: 320-1 360 mm. Annual mean temperature: 13°C	Suited to poor soils, it tolerates heavy, clayey soils. Sensitive to acid soils
Lathyrus cicera L. (2n=14)	Mediterranean, western Asia	Southern and eastern Europe Near East North Africa	Tolerates cold and frosts in the Mediterranean region, with autumn sowing; resistant to drought in the spring	Suited to poor soils, not too damp or saturated. Prefers heavy, well-limed soils with alkaline pH
Trigonella foenum-graecum L. (2n=16)	Mediterranean, Near East	Southern Europe North Africa, Near East India, Ethiopia, United States	Suited to regions with moderate or light precipitation Development favourable during the cool, temperate growth season. In a Mediterranean climate, with mild winters, it is sown in winter and ripens in spring. Annual precipitation: 380-1 530 mm. Annual mean temperature: 16°C	Grows well on drained, deep. Ioamy soils and on gravel and sandy soils III-suited to clayey, acid soils It is damaged by excessive soil dampness

Vicia ervilia (L.) Willd. (2n=14)	Mediterranean, Near East	Mediterranean, Turkey, United States	Very resistant to cold during the growing period because of its sparse habit and branching and slow growth. Very resistant to drought, even in spring. A harvest is obtained even during excessively dry years. In favourable conditions, high yields are obtained. Annual precipitation: 3601 160 mm. Annual mean temperature: 14°C	Suited to neutral or lightly acid soils Tolerates limy types of soil. provided they are not too clayey
Vicia monanthos (L.) Desf. (2n=14)	Mediterranean	Mediterranean	Very resistant to low temperatures during vegetative development and to prolonged drought. Suitable crop for regions with late dry autumns. Sensitive to drought during the flowering period, which reduces the yield drastically. Annual precipitation: 350-1230 mm. Annual mean temperature: 11°C	Suited to a wide range of soils provided they are not too damp Prefers soils that are not very clayey. that are deep and contain lime lime This is one of the legumes which requires the least soil fertility
Vicia narbonensis L. (2n=14)	Mediterranean	Central Europe Mediterranean, Near East Ethiopia, central Asia India	Temperature requirement greater than the broad bean (Vicia faba) and lesser humidity requirements. Replaces this species advantageously in warm dry areas. It does not tolerate cold, and is damaged by frost	The most suitable soils are loose and sandy deep and with a good lime content. Tolerates clayey soils that are not too damp

Sources: Duke, 1981; Mateo Box, 1960; Pascual, 1978; Villax, 1963.

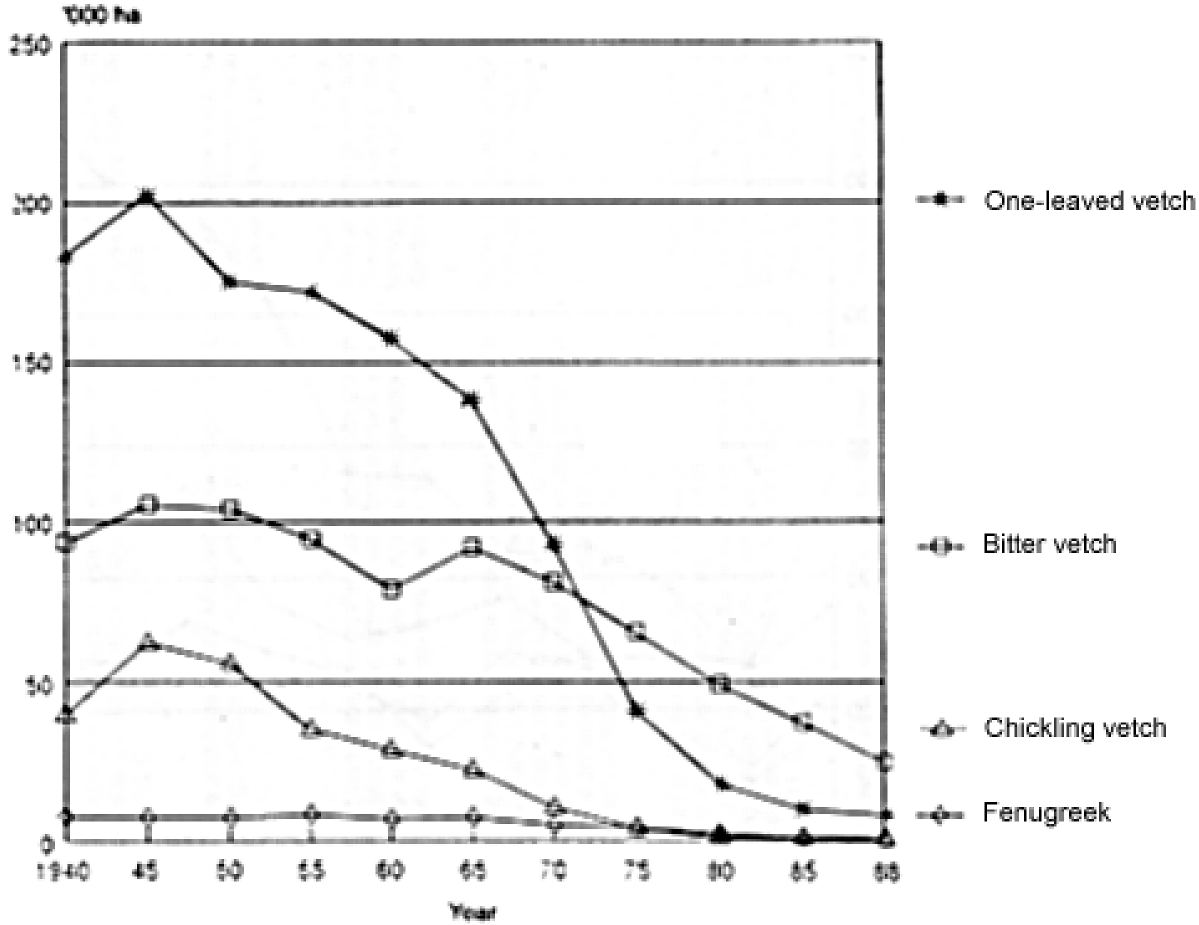

Figure 34. Changes in the cultivated area of legume species for animal feed in Spain

Composition and Use

Table 11 sets out the seed composition of the species studied. Protein content ranges between 20 and 30 percent and the fat content is generally very low except in the case of fenugreek (*T. foenum-graecum*). As in the other legumes, lysine is the most favourable amino acid and methionine is the most limiting. Several antinutritional properties are also present in the grain (Table 12). Chickling vetch and vetchling (*L. sativus* and *L. cicera*) contain a neurotoxic amino acid called ODAP (β-N-oxalyl-L-α–β-diaminopropionic acid) which causes neurolathyrism in humans and animals. This disease causes paralysis of the lower joints through neurological lesions brought about by degeneration of the spinal cord, particularly in equine stock, if the seed is eaten continually for months as the main component of the diet. In extreme cases it even causes death. Occasional consumption is not harmful and does not appear to affect sheep, so stockfarmers use these legumes for gestating females, fattening lambs and serving males. Macerating or soaking the seed in water, followed by cooking and treatment at high temperatures, seems to inactivate the lathyrogenic component, preventing its toxicity. Chickling vetch (*L. sativus*), which has a white flower and seeds, has a lower ODAP content. In some localities of northern Spain, selected white chickling vetch is traditionally eaten because of its lower content of lathyrogenic substances. There is a negative correlation between the total protein content of the Lathyrus and its ODAP content, which is of interest for improving varieties. The ODAP content of chickling vetch grown in Spain is lower than that of Asiatic chickling vetch. It has also been shown that the ODAP content of *L. cicera* is lower than that of *L. sativus* (0.146 and 0.205 percent, respectively).

Table 11. Composition of grain legume seeds

		Amino acids		Total		

Species	Proteins	Lysine	Methionine	Fat	carbohydrates	Fibre	Ash
	(Percentage of weight)						
Lathyrus sativus L.	25-28	1.84-2.47	0.1-0.15	0.6-1.9	55-61	4-15	3
Lathyrus cicera L.	25-27	--	--	1-1.3	56	6	3
Trigonella foenum-graecum L.	23-30	1.48-2.3	0.35	6-8	55	8-10	3.6-4.3
Vicia ervilia (L.) Willd.	17-21	1.53-2.02	0.37	1.3-2	61-64	4-6	2.4-3
Vicia monanthos (L.) Desf.	22	1.29	0.25	1.6	60	4.8	3.3
Vicia narbonensis L.	23-25	1.44-1.76	0.11-0.18	1-1.5	53	7.5-10	2.7-2.9

Table 12. Antinutritional factors of grain legumes

Species	Antinutritional factors	Remarks
Lathyrus sativus L.	β-N-oxalyl-L-α- β-diaminopropionic acid (ODAP), trypsin inhibitors, hydrocyanic acid, maltose, saponins, quercitin, flavins	Neurolathyrism
Lathyrus cicera L.	ODAP	Neurolathyrism (content less than *L. sativus*)
Trigonella foenum-graecum L.	Complex polysaccharides (gums and mucilages), trypsin inhibitors, sapogenins	Contains numerous chemical components of interest to the pharmaceutical, food, perfume and cosmetics industries (diosgenin mucilages, coumarin, lecithin, etc.)
Vicia ervilia (L.) Willd.	Cyanogenic glucoside, canavanine, trypsin inhibitors	
Vicia monanthos (L.) Desf	Cyanogenic glucoside, canavanine Cyanogenic glucoside	
Vicia narbonensis L.	Cyanogenic glucoside	

Sources: Arora, 1983; Harborne, Boulter and Turner, 1971; Gómez Cabrera, 1983; Mateo Box, 1960; Villax, 1963.

Fenugreek (*T. foenum-graecum*) has a high content of gums and mucilages (around 28 percent) which makes its direct use in the diet of monogastric species difficult. It contains other substances which give the plant an unpleasant smell, which permeates all its surroundings and is conveyed to the meat and milk of animals that eat it.

The antinutritional factors of the species of the genus *Vicia*, in addition to affecting the nutritional value of the grain, can cause pathological changes of varying extent in animals that consume them, especially birds.

The seed is the part mainly used in this group of legumes, although they are also grown as green fodder or hay and play an important role as a green manure, which is dug in at the end of the winter to improve soil fertility. The straw of these legumes is of high nutritional value for livestock.

Among the entire group, it is chickling vetch (*L. sativus*) which is most used for human consumption, in the form of green vegetables; the dry seed especially is soaked in water and boiled or else husked and made into flour for mixing with cereals and making bread or porridges. The latter method of preparation is usual in India (for *dhal*), and it was a popular recipe during times of scarcity and famine in the Spanish regions of Castilla-La Mancha and Extremadura, where many serious cases of neurolathyrism occurred as a result of it being consumed in the wrong way in the 1940s. The current Spanish Food Code prohibits human consumption of chickling vetch seed and the products obtained from its preparation. Mixtures with oilseed cake are used for sheep although, in Spain, its use in animal nutrition is not very widespread because of the fear of lathyrism.

Vetchling (*L. cicera*) is used as both a fodder plant and grain producer. The name *comuña* is given to the mixture of cereal grains, legume grains or both (as well as to their combined cultivation) which provides a complete food for livestock. Its etymological origin is from "*común*" in its meaning of mixture, referring to the mix of seeds obtained when cleaning the grain and which contaminate the main grain, generally wheat. The combination, which was of very variable content, was first formed from spontaneous plants which the farmer improved by introducing other species with a higher yield or quality. In the Spanish region of Tierra de Campos, vetchling began to dominate in *comuña* as a consequence of mechanical selection, since its grain was bigger than that of the vetches and tares, the two names used nowadays without distinction. There is therefore an ancestral knowledge of the use of *comuña* and its lathyrogenic side-effects. The use of *L. cicera* for sheep does not pose any lathyrism problems if doses do not exceed 50 percent of the ration in concentrates.

Fenugreek (*T. foenum-graecum*) is primarily grown for the production of its seed. Its strong smell somewhat discourages livestock from eating it. It must be used in low doses, since it imparts an unpleasant flavour to meat and milk and also causes animals to put on weight, which is not suitable for draught animals. Livestock dealers sometimes use it to tone animals up and give them a transient good appearance. It is also grown as a condiment, an essential oil being extracted for flavouring different foods and drinks, such as cheeses, sweetmeats, pickles and liqueurs. It is also used in the pharmaceutical and cosmetics industry because of the vast range of chemical products that it contains. The plant also has insecticidal properties and is used in stored grains as a repellent. Popular medicine attributes tonic and vermifugal properties to its seeds, the mucilaginous components being used to treat stomach ailments. In Hindu medicine, the seed extract is used because of its cardiotonic, diuretic, antiphlogistic, hypoglucemic and antihypertensive properties. It has active ingredients which act on the metabolism of fats and cause weight loss in women. In India, consumption of the seed is believed to stimulate lactation.

The species of the genus *Vicia* are traditionally used for feeding ruminants, particularly sheep, but they are practically unused for monogastric species in view of the seed's toxicity and its negative effect on growth. Bitter vetch (*V. ervilia*) must not exceed 25 percent of the ration in sheep and cattle feed. One-leaved vetch (*V. monanthos*) is more readily eaten by sheep, but refused by other types of livestock because of its slightly bitter taste. Birds, with the exception of pigeons, do not take to it. The seed of *V. narbonensis* can be used as feed for cattle which accept it more readily than pigs and sheep, provided it is fed to them in ground form. Like common vetch (*V. sativa*), it has a slightly bitter taste which animals grow accustomed to, but which can be passed on into milk.

Botany and Ecology

Table 13 describes the main botanical characteristics of the various leguminous species studied. Because of their origin, distribution and cultivation, they are suited to Mediterranean ecological conditions. Their cycle takes place in the autumn to spring period and they are resistant to cold and frosts as well as drought, especially in the final phase of cultivation. They are suited to poor soils and frequently to marginal ones

(Table 10).

Table 13. Botanical characteristics of grain legumes

Species	Structure of the plant	Flowers	Pods	Seeds
Lathyrus sativus L.	Branched. Stems suberect and climbing. Height: 40-90 cm. Main root: 50-70 cm. Secondary roots very numerous	Solitary, axillar with a long peduncle. Colour bluish-purple, pink or white	2.5-5 cm long, wide and flattened. Contain 1-5 seeds	Wedge-shaped. Cream or greyish brown, sometimes dark speckled and with a small hilum on the wider edge
Lathyrus cicera L.	Smaller than *L. sativus*. Height: 30-50 cm. Deep taproot (80-120 cm) and fewer secondary roots	Solitary, reddish colour	Typically grooved with 3-5 seeds	Similar to those of *L. sativus* but less angular and more rounded. Greyish colour with dark spots. 17000-18000 grains/kg
Trigonella foenum-graecum L.	Stems erect. Height: up to 40-80 cm. Branched only if there is a high planting density. The plant and seeds have a characteristic strong odour	Solitary or in pairs, axillar and sessile. Colour yellowish white, stained violet at the base of the corolla	7.5-15 cm long erect and sometimes curved. Longitudinal veins with a long point (2-4 cm). Contain 10-20 seeds	Oblong, quadrangular, sometimes compressed. Yellow or light-chestnut colour. Approximately 50000 grains/kg
Vicia ervilia (L.) Willd.	Low height (20-70 cm) and little branching. Very trailing habit. Highly developed root system	Inflorescence with 1-3 pendulous flowers joined at the axis by a small pedicel. Whitish colour sometimes with a violet tinge	2-3 cm. Seeds are prominent as the valves adhere to them closely. 2-4 seeds per pod	Tetrahedral, sometimes angular. Light colour, from cream to reddish brown. 25000-35000 grains/kg
Vicia monanthos (L.) Desf.	Trailing stems, polygonal in cross-section. Height: up to 80 cm. Deep, very branched roots	Uniflorous inflorescence with pedicellate, pendulous flowers. Whitish colour	Flattened, from 3-4 cm long. Light-brown colour. 2-5 seeds per pod	Similar to the lentil but smaller and less flattened. Colour variable, from light, pinkish yellow to dark chestnut, with black dots. 10000-20000 grains/kg

Vicia narbonensis L.	Stems erect and branched of quadrangular cross-section. Height: up to 70-80 cm. Deep well-developed roots	Inflorescence with large violet or reddish flowers and different contours in the various parts of the corolla	5-7 cm long, wide, ending in a short, curved point. Almost black in colour. 6-7 seeds	Spherical with dents, 4000-5000 grains/kg

Sources: Duke, 1981; Mateo Box, 1960; Villax, 1963.

Genetic Diversity

There is very little information on the genetic diversity, infraspecific variability and relations of these species with other related wild species. Few cultivars are known or well defined. Only limited areas of cultivation remain in some areas of the world and, in many of them, the individuals are threatened. The material available in gene banks is scarce. Consequently, there is the risk that important plant material obtained over thousands of years of cultivation might disappear, while only a few isolated works on classification and selection are to be found.

In the species *Lathyrus sativus*, there are a great number of varieties and types which differ in flower colour, form of growth and colour and shape of the seeds. Two varieties can be distinguished: lesser white chickling vetch and greater white chickling vetch. The first is possibly the original form of the species. Greater white chickling vetch is perhaps a selection of the former, featuring bigger seeds, a lighter colour and a more flattened shape. In India, 56 types have been identified. As in almost all this species group, the types sown are heterogeneous populations of botanical varieties. The centres of diversity are central Asia and the Mediterranean.

L. cicera is considered to be a semi-domesticated plant, with local varieties and spontaneous plants existing in Spanish cultivation regions, especially in the centre and north. There are local, primitive indigenous varieties in Castilla-León made up of very heterogeneous and widely varying material suited to adverse conditions. This material has traditionally been cultivated in combination with other plants (comuna) and its domestication has been rare, in spite of the fact that the plant has been grown for thousands of years. The main changes introduced in these varieties are: a more erect and compact habit of the plant, lesser dehiscence of pods and greater seed size. The wild populations of *L. cicera*, which are abundant in Spain, have characteristics very close to those of the cultivated plants. Domestication of *L. cicera* occurred in southern France and Spain when cultivation of chickling vetch (*L. sativus*) spread to those countries from its area of origin and domestication, which it subsequently replaced. Descriptors have been proposed for *L. cicera* and three botanical varieties are recognized: *pedunculatus, foliolatus* and *palentinus*.

Improvement programmes have been designed for fenugreek (*T. foenum-graecum*) to increase the yield of diosgenin, a steroid which is present in the seed and which is used in medicine, as well as to study the behaviour of a spontaneous mutant with earlier flowering and bigger sized seed. Twenty-nine different ecotypes have been recognized. The centre of diversity of fenugreek is situated in the western Mediterranean and the Near East.

The cultivated types and varieties of bitter vetch (*V. ervilia*) are very heterogeneous populations which frequently appear mixed with other cultivated or spontaneous species of Vicia. In Spain, the variety most used is common red bitter vetch but, in recent years, four selected varieties have been recorded. Comparative tests between these varieties and local controls, carried out in central Spain, have demonstrated the higher yield of the selected material. The centre of diversity of the bitter vetches is situated in the western Mediterranean and in the Near East.

Also in the case of one-leaved vetch (*V. monanthos*), the cultivated varieties are botanically very heterogeneous populations from which selections, lines and ecotypes adaptable to different environments could be obtained. In Spain, two types of one-leaved vetch can be distinguished: the white seed type and the black seed type, depending on the different shades of the background colours of the seed, the black type being grown in a greater proportion and the white type more rarely. The western Mediterranean, the Near East and the Euro-Siberian regions are quoted as centres of diversity.

Vicia narbonensis is considered to be a species very close to *Vicia faba*. It was once even thought that this was the original form of broad bean, although cytogenetic studies showed that this theory was without foundation. It is thought that the var. *serratifolia* is the origin of the current forms of *V. narbonensis*. Since ancient times, attempts have been made to cross *V. faba* and *V. narbonensis* to obtain an interspecific hybrid that combines the valuable characteristics of both species. In recent years, these crossings have been possible through genetic manipulation and through the embryo recovery technique, enabling valuable material to be obtained when using the appropriate genotypes as parents. Compared with *V. faba*, *V. narbonensis* has a high level of resistance to aphids (*Aphis fabae*), with intraspecific variations for resistance, hence it shows good agronomic potential. It also seems to have greater resistance to broomrape (*Orobanche* spp.), which is why farmers have grown it in the past.

Table 14 sets out the existing collections of germplasm of the legume species studied, according to the country and institution which keeps them. Probably the most complete collection is to be found in Spain. According to the most recent data, there are 49 lines of *L. sativus* from Spain and Portugal; 92 lines of *L. cicera* from Spain; 177 lines of *V. ervilia* from Spain and Portugal; 76 lines of *V. monanthos* from Spain; and ten lines of *V. narbonensis*.

Cultivation Practices

The cultivation techniques of these legumes are very rudimentary, given their marginal character, the small yields obtained and the little benefit which they bring the grower. Soil preparation is reduced and no type of fertilization is applied, as sowing is carried out in autumn or at the beginning of winter Nor is any type of herbicide applied. Harvesting is sometimes done manually and threshing is carried out on the threshing floor, although it is frequently done with a motorized reaper, followed by threshing and cleaning and, less often, with a combine harvester.

Table 15 sets out the traditional cultivation techniques for each species. Some tests on new cultivation techniques have been carried out in Spain recently. For L. cicera in addition to a better selection of seed, it has been proposed that 125 kg of seed per hectare be used and herbicides applied (propyzamide + diuron or trifluralin + linuron), while harvesting should be done by reaping and leaving the crop in rows to ripen, or else using a modified cereal harvester. For bitter vetch (V. ervilia) which, among these species, has the biggest cultivated area in Spain and of which selected varieties exist, the use of herbicides (alachlore + linuron, metholachlore + promethrin, cynazine or metazole) is recommended, as is harvesting with a cereal harvester during the first hours of the morning and harvesting only in one direction to avoid the problem of grain loss.

Table 15. Traditional cultivation techniques of grain legumes[1]

Species	Tillage	Fertilization	Sowing	Herbicides	Harvesting
Lathyrus sativus L. and *L. cicera* L.	First tillage (sometimes with cultivator or harrow)	None (sometimes 100-200 kg/ha of 18% superphosphate)	In autumn, after the first rains: 150-200 kg/ha of seed (sometimes barley is used as a support at 15-20 kg/ha). With cereal drill, 15-40 cm between rows	None (*Avena* sp., *Papaver* sp. and crucifers)	With cereal harvester (losses 20-30% because of dehiscence and plant's low habit). Also cut with motor scythe (in rows, dried) and harvester with pick-up

Trigonella foenum-graecum L.	Harrowing and rolling	None (sometimes 100-150 kg of 18% superphosphate)	In October: 110-130 kg/ ha of seed. With cereal drill, 15-18 cm between rows	None (*Avena* sp., *Papaver* sp. and *Veronica* sp.)	With cereal harvester (difficulties from flattening and grain drop)
Vicia ervilia (L.) Willd.	Harrowing and/or cultivator and rolling	None (exceptionally 100 kg/ ha of 18% superphosphate)	In October-December: 100-130 kg/ha of seed. With cereal drill, 15-20 cm between rows, sometimes broadcast	None (*Avena* sp., *Lolium* sp., *Papaver* sp., *Cirsium* sp., *Veronica* sp., *Poligonum* sp. and crucifers). Very sensitive to hormonal herbicides of cereals which cause serious damage	With cereal harvester and motor scythe, threshing and cleaning. Sometimes manual, with threshing on floor
Vicia monanthos (L.) Desf.	Tilling, harrowing and rolling	None	In October-December: 95-100 kg/ha of seed. With cereal drill, 15-20 cm between rows	None (*Avena* sp. *Lolium* sp., *Papaver* sp., *Matricaria* sp. and *Cirsium* sp.)	Motor scythe threshing and cleaning. Sometimes pulled up by hand, with threshing on floor

Note: There are no data on *Vicia narbonensis*, as its cultivation is practically non-existent in Spain.

Table 16 shows the grain yields of each species in different regions and countries, both in normal cultivation conditions and in trials.

Prospects For Improvement

Since the appearance of modern agriculture, biological, technical and economic limitations have caused the present marginalization of these cultivated legumes, the situation of which varies according to the geographical area. Of the countries of the Mediterranean basin, particular reference will be made here to Spain.

The biological limitations lie in the absence of genetic improvement in a plant material that is extremely diverse and has been cultivated for thousands of years, which is evident from the stability of yields during the last 50 years (Figure 35), depending on the ecological conditions (the differences in the trend of barley yield during the same period can be seen)

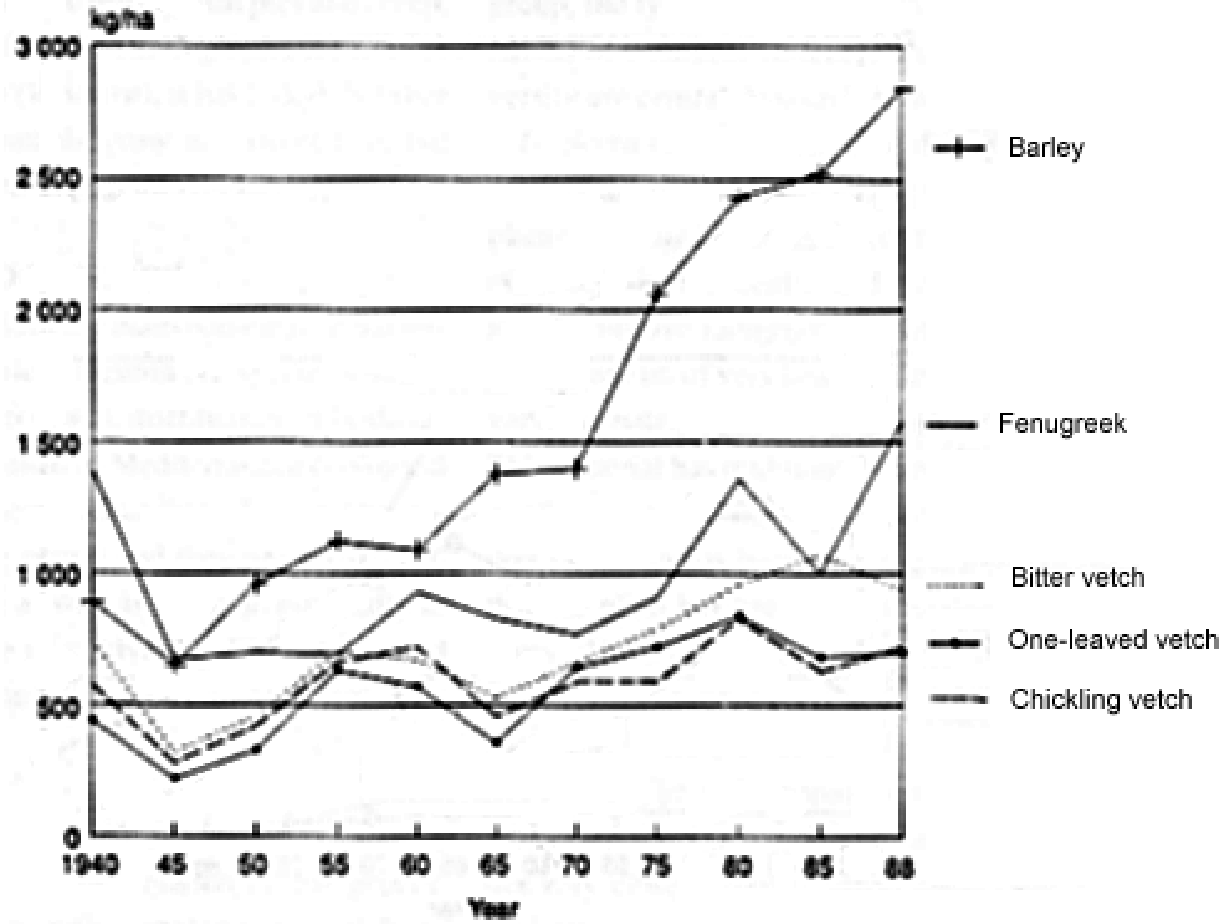

Figure 35. Changes in the grain yield of legume species for animal feed grown in Spain

The presence of toxic elements or antinutritional factors, the elimination or reduction of which would have to be tackled in breeding programmes, is a restriction on its use in human consumption and particularly in animal feed. Although the list of pests and diseases that attack this group of legumes is very extensive, there are important gaps owing to the low extent of its cultivation and the paucity of studies carried out. However, generally speaking, attack by pathogens is not found to be a serious limitation on cultivation.

Fenugreek (*T. foenum-graecum*) has been found to be tolerant to insects and diseases, chickling vetch (*L. sativus*) to rust and viruses, and *V. narbonensis* to *Aphis fabae*. Among the pests and diseases of economic importance are *Aphis craccivora* and *Myzus persicae* for fenugreek and *Ascochyta pisi* and *A. orobi* for the chickling vetches in India. In Spain, the major pests are aphids (not specified) in fenugreek and one-leaved vetch; *Bruchus* spp. in *V. ervilia, L. sativus* and *L. cicera*; and *Apion* spp. in *L. sativus* and *L. cicera*. The major diseases are rusts (*Uromyces pisi* or *U. fabae*) in one-leaved vetch, and nematodes (unspecified) in *V. ervilia*.

From the agronomic point of view, the precariousness of the techniques used has prevented yields from increasing. The use of such techniques is unavoidable because of the lack of response of cultivation to new practices and the low profitability of their application. The difficulty of mechanizing harvesting, given the aerial structure of the plant and its propensity to shedding its grain on ripening, is undoubtedly the factor of greatest importance. Also, competition from wheat has been a limiting factor on yields when suitable herbicides have not been used. For these reasons, there has been an increase in cereal monoculture and in the area of fallow, while new crops have been introduced on fallow land, for example sunflower, which has been extensively promoted by the extractive industry through the spread of techniques, machinery loans, the granting of advances to farmers and guaranteed purchases. Moreover, changes in irrigation have given rise to the introduction of much more profitable crops such as beetroot and maize.

Traditionally, there has not been a policy for the protection of these legumes (whereas there has been for cereals), nor any marketing channels; there have been shortages in regulation of the supply and the producer sector has been separated from the feedstuffs industry. The latter has been developed under the protection of measures that have favoured soya meal: low-price imports and all types of facilities and aid to producers. As an example, in its common organization of the market, the EEC has recently only provided for aid in the case of fenugreek production, completely disregarding the rest of this legume group.

Within the framework of a sustainable agriculture and the Common Agricultural Policy that seeks to encourage alternative crops, the several million hectares of fallow land in Spain could benefit from promotion of the cultivation of these legumes, which are sources of protein and which improve soil fertility. The role of the legumes in soil conservation and environmental improvement should not be forgotten, nor should their non-food uses, such as the production of pharmaceuticals and cosmetics in the case of fenugreek.

In addition, thorough research needs to be carried out in the short and medium term to provide a knowledge and evaluation of the plant material and its genetic improvement, as well as to develop more suitable cultivation techniques for increasing production. Such techniques would then be passed on to farmers, encouraging the cultivation of the different species according to the different cultivation systems and regions. The animal feedstuffs industry must take part in this process, gradually integrating the utilization of these raw materials into their processes.

Rough pea, Winter pea

Singletary pea, Wild winter pea

Leguminosae, Fabaceae *Lathyrus hirsutus* L.

Source: Magness et al. 1971

This plant, native to the Mediterranean region, is a winter annual adapted to the southern third of the United States. The stems are weak and trailing except in dense stands. The leaves have one pair of long, narrow leaflets and terminate in a coiled tendril. The seed pods are rough and hairy. Seeds are usually sown in the fall. Plantings are used for pasture, for hay, or for turning under for soil improvement. Livestock may be injured from grazing plants with mature seeds or feeding hay from such plants, but prior to seed ripening good pasturage and hay are produced. Growing of rough pea has declined greatly in recent years as Austrian winter peas and hairy vetch make more growth. Acreage harvested for seed was 34,631 in 1949 and only 8,109 in 1959, according to census figures.

Last update July 1, 1996 bha

Laurel, Cherry

Rosaceae *Prunus laurocerasus* L.

Source: Magness et al. 1971

The plant is an evergreen bush, up to 10 feet, with thick, glossy, oval to lanceolate leaves, widely grown as an ornamental; and with many horticultural varieties. The leaves have a taste and flavor resembling bitter almond, due to a glucoside, laurocerasin. The leaves are used in cookery, particularly to flavor puddings and custards. A distillate from the leaves is used medicinally.

Lemon, Garden

Orange melon, Mango melon, Melon apple, Vine peach, Vegetable orange, Naudin

Cucurbitaceae *Cucumis melo* L. (Chito group)

Source: Magness et al. 1971

This is a close relative of the muskmelon which it resembles, but has a less vigorous vine and smaller leaves. Leaves and vines are hairy. Fruit is of size, shape and color of an orange or lemon, with a smooth surface. Fruit flesh is white or yellow, resembling cucumber. It is not edible in its natural state, but is useful for preserves and pickles.

Season, seed to first harvest: 2 to 3 months.

Production in U.S.: No data. Very limited.

Use: Preserves, pickles.

Part of plant used: Whole fruit.

Cress, Garden

Cruciferae *Lepidium sativum* L.

Peppergrass

L. *virginicum* L.

Source: Magness et al. 1971

Cress plants are grown for the leaves, which are used as salads andgarnishes. The plant is an annual. attaining a height of 1 to 2 feet. Theleaves are aromatic and peppery in flavor. They rise from the root crown at thesoil surface, and are variable in shape, some forms being greatly divided likeparsley, others curled. If only lower leaves are removed, new leaves willcontinue to be formed on the central stalk. Growth habit and leaf exposure aresimilar to spinach.

Peppergrass is a closely related plant, native in the U.S., which is notcultivated, but often is gathered and used as with garden cress.

Season, seeding to harvest: 6 to 8 weeks.

Production in U. S.: No data. Minor importance.

Use: Fresh for salads, garnishes.

Part of plant consumed: Leaves.

Stott, K. and A. Broderick. 1996. Response of Australian strains of the mushroom *Lepista nuda* to temperature and substrate. p. 476-479. In: J. Janick (ed.), Progress in new crops. ASHS Press, Arlington, VA.

Response of Australian Strains of the Mushroom *Lepista nuda* to Temperature and Substrate

Karen Stott* and Andrew Broderick

Taxonomic classification of macrofungi is constantly changing as new species are discovered in North America, South Africa, and Australia. In Australia there are probably 3000 to 5000 species, most of which have not been properly described (Wood 1992). Improved techniques have enabled microscopic details to be better researched and this has resulted in changes in taxonomic classification.

The recent increase in consumption of wild mushrooms in many countries has provided the impetus to explore new sources of edible mushrooms. In addition, the wild harvesting of edible mushrooms must be curbed to ensure that the environment and ecosystems where these mushrooms grow are not destroyed. Mycologists need to explore new mushroom sources (Purkayastha and Chandra 1985) and develop cultivation techniques.

Worldwide there are 200 edible fungi of which only 25 species are widely accepted as human food and are cultivated (Hashioka and Arita 1978; Chang 1981; Pathak 1986). Fungi other than *Agaricus bisporus* represent about 30% of world production (Olivier 1991). The influx of migrants with a European heritage into Australia has created a demand for edible mushrooms produced locally. Amongst the gilled fungi, there are a number of edible species in the Agaricaceae, Bolbitiaceae, Lepiotaceae, and Tricholomataceae.

The fungus *Lepista nuda*, Tricholomataceae (syn: *Tricholoma nudum, Rhodopaxillus nudus, Clitocybe nuda*) is found in Europe, the Americas, and Australia. It has an international reputation as an excellent edible species and the combination of its lilac color, solid fleshy structure, good shelf life, flavor, and aroma makes the development of commercial cultivation techniques highly desirable. Developing techniques for commercial cultivation requires a detailed understanding of environmental and nutritional parameters which optimise vegetative growth and induce fruiting bodies.

The development of an appropriate substrate requires the chemical, physical, and biological conditioning of composted matter. This creates an environment selective for a particular species that is critical for fruit body production. Factors to be considered in the substrate are microbial activity, physical characteristics, pH, chemical components, aeration, water content, substrate composition, and extent of composting undergone by the substrate. Some species require the application of a casing layer of peat or soil to enhance yield and quality. Casing assists the induction of fruit bodies, but how this occurs is largely unknown. It is thought that casing provides a high water holding layer for hyphae, entraps volatiles released by compost, has a different mycoflora to the substrate, and physically supports the growing fruit body. The physical and chemical characteristics, optimal depth and number of applications for a given casing material can be different for each species. Temperature, light, O_2 , CO_2 , watering and care must be managed to encourage fruit body formation. Previous studies on substrate requirements of European *Lepista* (Vaandrager and Visscher 1981) indicate that fruit body production is enhanced by the addition of 10% uncomposted straw to commercial *Agaricus* compost. Guinberteau et al. (1989) and Brian et al. (1979) reported that a cold shock is essential for the formation of fruit bodies of *L. nuda* and temperatures of 8° to 15°C have been found to be effective. However Australian isolates (Young 1994) have been found under more variable environmental and substrate conditions than European isolates (Moser 1978, Breitenbach and Kranzlin 1991).

The objective of the present study was to provide the Australian mushroom industry with viable commercial cultivation techniques for Australian species of *Lepista*. This paper describes Australian forms of *L. nuda* isolated from the wild and examines the effect of temperature and substrate on hyphal growth and fructification.

METHODOLOGY

Isolates

Under Australian conditions *Lepista* appears in the wild from April to July. Isolates of *Lepista* were collected from various sites and voucher documentation, identification, and isolation of strains was carried out. Most isolates were confirmed as *L. nuda* and comparisons were undertaken with French isolates of *Lepista*, provided by Dr. Guinberteau of Station de Recherches sur les Champignons at Institut National de la Recherche Agronomique, France (Table 1).

Temperature

Optimum temperature for hyphal growth is a critical factor in obtaining rapid colonisation of substrate and casing. Isolates were selected from locations with different temperature and environmental characteristics to enable comparison with French isolates. Growth response of four Australian (A1, A2, A3, A4) and four French (F1, F2, F7, F8) isolates of *L. nuda* from warm (A1, A2, F1, F2) and cool (A2, A3, F7, F8) climates were compared at different temperatures to determine maximum and minimum temperatures for hyphal growth.

Isolates were grown on malt extract agar plus 2% yeast (MEAY) at 5°, 12°, 15°, 20°, 25° and 30°C. Radial growth of hyphae was measured on day 8 in two directions and the average taken. Data was analysed by analysis of variance.

Substrate and Cold Shock

Agaricus compost alone or suplemented with 10% uncomposted cereal straw (w/w) was inoculated with *Lepista* at 2%-3% w/w. Trays were sealed and placed at 25°C in a cabinet with temperature and light control. After 12 days substrate was cased with a 75% moisture content 50/50 mix of blond/dark peat. After hyphae had grown through casing, lids were loosened to allow air movement over substrate and cold shock of 12° or 15°C was applied to replicates of both substrates.

RESULTS

Isolates

The location and environment of selected isolates are shown in Table 1. Cool climate isolates (4° to 25°C during growing season) were found in leaf litter under *Rhododendron, Cedrus deodara, Quercus suber* or grass (*Poa pratensis*). Basidiocarp very robust and fleshy, lilac to lilaceous brown; pileus 75-132mm, lilaceous brown, shiny, convex to shallow convex with age; stipe 50-78 mm x 25-33 mm.

Warm climate isolates (8° to 35°C during growing season) were found in Kikuyu (*Pennisetum*) and Couch (*Cynodon dactylon*) grass in groups or rings. Basidiocarp strong lilac to lilaceous brown; pileus 30-75 mm, strong lilac, shallow convex with umbo at all stages; stipe 65 mm, bright lilac to deep lilac or lilaceous brown.

Temperature

The optimum temperature for Australian isolates was found to be higher than for French isolates as was the minimum growth temperature. The growth rate of Australian isolates is more than double the rate of French isolates at all temperatures except 5°C (Table 2).

Substrate and Cold Shock

The addition of 10% uncomposted cereal straw encouraged hyphal growth, but discouraged the initiation of fruiting bodies and was not beneficial to Australian isolates. A cold shock of 12°C encouraged more hyphal aggregations than 15°C. No fruit bodies were produced.

CONCLUSION

Australian isolates differ from overseas isolates morphologically in shape, form, and size. They are found at different temperatures and in different environments than European species. Whether they are new species or varieties resulting from the Australian environment and habitat has yet to be determined.

The response of Australian isolates to temperature indicates that these isolates have the capacity to colonise substrate more rapidly than French isolates. This would be advantageous to commercial growers as cropping time could be reduced.

The addition of 10% uncomposted straw to *Agaricus* compost had no beneficial effect on the initiation of fruit bodies. Whether it would effect quality or yield is unknown and further research into this area is recommended.

Information from this study can provide the basis for the development of viable commercial cultivation techniques for the exotic mushroom industry in Australia. The differences in cultivation requirements and growth rates of Australian and French strains indicates that a shorter production cycle than is currently achieved with French isolates will be possible.

Lespedeza

Leguminosae *Lespedeza* sp.

Source: Magness et al. 1971

Lespedezas are of major importance for pasture and, to a lesser extent, for hay production in the southeastern quarter of the U.S. Average seed production, 1966-67, was about 46 million pounds - sufficient to seed 2 million acres. Since pastures are generally self reseeding, acreage in lespedeza is probably near 40 million. The species grown in the U.S. are Sericea lespedeza, Korean lespedeza, and Striate lespedeza

Last update February 18, 1999 by ch

Sericea lespedeza

Leguminosae, Fabaceae Lespedeza cuneata (Dumont) G. Don

Source: Magness et al. 1971

Sericea is the only perennial lespedeza of importance agriculturally in the United States. Seed from Japan was first tested in North Carolina in 1896. From this and later introductions seed of vigorous, productive lines was widely distributed. The plants are long-lived, leafy, erect, with rather coarse stems reaching 2 to 4 feet high. Leaflets are long, narrow and blunt at the terminals. Annual growth dies in winter, new growth rising from crown buds. Range of adaptation is roughly from the Atlantic Coast west to Texas and Kansas and north to the Ohio River. Where adapted the crop is useful for pasturage, hay and soil improvement.

Striate lespedeza

Kobe

Leguminosae, Fabaceae *Lespedeza striata* (Thunb.) Hoak. & Am.

Source: Magness et al. 1971

Although some 140 species of lespedeza have been described, mostly native to Eastern Asia, only 3 are of importance in American agriculture. Striate lespedeza is an annual of which one variety, common, was established in Georgia by 1850. Its mode of introduction from Asia is unknown. The plant has slender, branched stems up to a foot or more in height and small, trifoliate leaves. An introduction from Kobe, Japan, called Kobe, was made in 1919. It is taller and larger growing than common and is useful both for pasture and hay. Although plants of both kinds are annuals they produce seed in late summer and reseed readily, so stands are long lived if properly handled. Striate lespedezas are palatable and nutritious both as pasture and hay. They are best adapted to the area suitable for cotton from East Texas to the Eastern Seaboard.

Current Comments

"In Davie, South Florida, I've managed to grow about 60 lychee trees. Lychees grow well in South Florida. The trees are very delicate when they are small, they may suffer from chlorosis, but this may be corrected with nutritional sprays and/or chelated iron supplements. Use fertilizer very sparingly or not at all until the trees are well established, I'm convinced that people kill more lychee trees by overfertilizing than by any other means.

There are significant differences in growing the different lychee cultivars. While some seem to tolerate the highly alkaline soils of Dade County quite well, such as the 'Brewster', others such as the 'Sweetcliff' simply will not grow unless the soil has an neutral or acid reaction.

Where I live the soil is mostly muck, which I suspect has an acid reaction. have ten different varieties of lychees and they all seem to grow well here. You should not have any problems growing lychees provided that you irrigate during dry spells."

Weeping lovegrass

Gramineae *Eragrostis curvula* (Schrad.) Nees

Source: Magness et al. 1971 This is a vigorous perennial bunchgrass, introduced from Tanganyika, Africa, in 1927. It has proved well adapted in the Southern States, particulariy the Southern Plains. Seed stalks are numerous and slender, reaching to 5 feet under the best conditions. Basal leaves are numerous, slender, 10 to 20 inches long, palatable while succulent, but of low palatability when ripe. Plants are semihardy, enduring temperatures to about -10°F. They are readily established by seeding and make a quick ground cover.

Nutmeg and Mace

Nuez moscada

Myristicaceae *Myristica fragrans* Houtt.

Source: Magness et al. 1971

While other species of *Myristica* produce nutmegs, the principal nutmeg of commerce is *M. fragrans*. The tree is a tropical evergreen, reaching up to 60 feet, with entire oval leaves up to 10 inches long. The fruit is oval or pyriform about 2 inches long, and consists of an outer fleshy husk and inner seed. The husk splits when ripe, exposing the seed. Immediately surrounding the seed coat is a crimson network of tissue, the mace. The mace is rather leathery in texture. Nutmeg is the inner seed or kernel. Both nutmeg and mace are used mainly as spices. The distinctive flavors are due to volatile oils, present in both tissues. The oil of nutmeg, used as a nutmeg butter, is obtained by crushing and pressing the seed.

Xeriscaping: Sources of New Native Ornamental Plants

Bart C. O'Brien

The use of the word xeriscape as a landscaping term has not received widespread public acceptance, even though its precepts are sound and widely followed. "Xeriscape" has often been interpreted by the general public to mean "zero-scape" and was equated with severe minimalist drought tolerant plantings. The terms "sustainable landscapes" and "appropriate horticulture" better convey the full intent of "xeriscape." Native plant materials are a vital and viable element of the future of xeriscape landscapes and gardens across America and are the primary focus of this paper. As more gardens and landscapes are designed and installed true to their local conditions, opportunities will continue to expand for the use and development of new native plants for ornamental horticulture.

THE XERISCAPE CONCEPT

The word xeriscape was coined in 1981, to capture the idea of water conserving landscapes but conceptually xeriscape involves much more. There are seven essential components of xeriscaping: appropriate planning and design; appropriate/minimal turf areas; appropriate soil preparation and analysis; appropriate plant selection; appropriate watering methods; appropriate use of mulches; and appropriate landscape maintenance. In essence, the underlying concept behind xeriscape is the doctrine of regionally appropriate horticulture.

In practice, however, xeriscape often has been reduced to the landscaping idea of maximizing the efficient use of water in gardens and landscapes by creating areas which group plants by their water requirements. Typically this has been interpreted as growing the plants with the greatest water need nearest the home and transitioning to very low to no irrigation at the zone furthest from the home. This zoning of the landscape according to water use may also have additional benefits pertaining to fire breaks, wildlife value, and in enhancing the diversity of plants that may be grown in the garden.

HISTORY

Due to the dominance of our primarily temperate European horticultural heritage, there has always been a predisposition toward water-loving exotic plants in our landscapes and gardens. The westward expansion and settling of the country brought these same traditions and plants into increasingly dry and warmer regions that are prone to long periods of drought. As long as water was cheap and abundant there wasn't a problem and a more or less standard set of coast-to-coast plants thrived in spacious green havens. Over much of the country, water is the limiting resource governing the use of ornamental plants in gardens. The huge increase in population in the U.S. Southwest has in many areas outstripped local water supplies. In some areas of the country, water for landscape or garden use is seasonally rationed or restricted. The cost of water, even during years of abundant rainfall, is always increasing. Water quality issues, including salinity and contamination by nitrates and bacteria, lead to increased costs due to necessary water treatment programs. As time passed, our use of gardens and landscapes changed from seasonal retreats and visual frames for our homes and buildings to heavily used outside multi-purpose spaces. These changes resulted in the establishment of the xeriscape concept.

CURRENT TRENDS

There are a number of trends in home landscapes and gardens which will influence the ornamental plant industry. Those which I consider to be among the most important are: (1) the decrease in the amount of time, money and expertise that most households have to invest in properly planting and maintaining gardens; (2) the shrinking in average size of new gardens; (3) the increasing use of gardens as living spaces and outdoor rooms; (4) the increasing cost of water, labor, fertilizers, and chemicals; and (5) the restriction or limiting of water use for garden and landscape purposes.

Although there is always a market for colorful annuals, biennials, and short-lived perennials, these are generally more difficult groups to depend upon in landscapes and gardens. Longer lived perennials, subshrubs, shrubs and trees are the backbone of landscapes and gardens and will constitute the primary nursery market.

Under current conditions, I am convinced that a greater diversity of plants which flourish under existing climatic conditions across the country are needed. These changes should be viewed as potential opportunities and require the search for, and development of, perennials, subshrubs, shrubs and trees in the following categories: dwarf or compact forms of existing plants; new plants of small stature; plants that are all season performers; low maintenance plants; long, or continuous, seasons of color, be it flowers, foliage, fruits, stems or bark; good-looking, water-thrifty plants; and plants that attract wildlife.

Native plants which fall into any or all of these categories will be particularly desirable as they have the additional benefit of fitting into the local and regional conditions both visually and ecologically. This opportunity creates a new, relatively unexploited regional niche market for the nursery industry, and should eventually lead to a more striking regionalism in the American landscape vernacular.

THE SEARCH FOR NEW NATIVE ORNAMENTAL PLANTS

There are a number of people and institutions throughout the country looking at our native plants as a direct or secondary source of new introductions for the nursery industry, but anyone can become involved in this process. The methods employed to create new native ornamentals can be as informal as selection from the wild or as sophisticated as plant breeding including even genetic engineering.

A good place to begin the investigation of new native plants for drier portions of our landscapes is to look at the large plant families and genera in the region you are serving, and to concentrate the search on those plants inhabiting drier habitats. In California and the southwest, these would likely include some of the following: Agavaceae (*Agave, Nolina*, *Yucca*), Alliaceae (*Allium*), Amaryllidaceae (*Brodiaea*, *Dichelostemma*, *Triteleia*), Asclepidaceae (*Asclepias*), Asteraceae (*Artemisia*, *Erigeron*, *Senecio*, *Haplopappus*--*Ericameria*, *Hazardia*, *Isocoma*), Cactaceae (*Opuntia*), Crassulaceae (*Dudleya*, *Sedum*), Cyperaceae (*Carex*), Ericaceae (*Arctostaphylos*), Fabaceae (*Astragalus*, *Lupinus*), Fagaceae (*Quercus*), Grossulariaceae (*Ribes*), Iridaceae (*Iris*, *Sisyrinchium*), Hydrophyllaceae (*Phacelia*), Lamiaceae (*Lepechinia*, *Monardella*, *Salvia*), Liliaceae (*Calochortus*, *Lilium*), Malvaceae (*Malacothamnus*, *Sidalcea*, *Sphaeralcea*), Poaceae (*Festuca*), Polygonaceae (*Eriogonum*), Ranunculaceae (*Aquilegia*, *Delphinium*, *Ranunculus*), Rhamnaceae (*Ceanothus*, *Rhamnus*), Rosaceae (*Adenostoma*, *Cercocarpus*, *Heteromeles*, *Holodiscus*, *Prunus*, *Purshia*, *Rosa*, *Spiraea*), Saxifragaceae (*Heuchera*), and Scrophulariaceae (*Penstemon*).

The majority of these large genera and families have yet to be tested or evaluated for horticultural purposes in a serious systematic fashion including most perennial members of *Phacelia*, *Monardella*, *Eriogonum*, and *Astragalus*. A number of these large genera have well known propagation problems (such as commercially viable method for asexual propagation of *Quercus* and *Calochortus*) or are known to be especially difficult to grow and/or maintain under nursery conditions (like *Calochortus* and many native *Delphinium* and *Lupinus* species).

The selection of an individual plant for possible introduction is generally accomplished by finding a desirable feature or set of features that are deemed desirable. These individuals can be found in the wild or in the garden and often represent extremes of the natural variation: compact growth habit, different foliage, albinos, and unusual color forms. Additional factors such as mutations including witch's brooms, variegated foliage, and natural hybrids also contribute to the possible pool of plants to choose from. Traditionally these matters of chance have been the most frequently reported sources of many excellent cultivars: *Heterotheca* (*Chrysopsis*) *villosa* 'San Bruno Mountain', a sterile, free-flowering dwarf selection; *Artemisia pycnocephala* 'David's Choice', a heat tolerant compact selection; *Erigeron* 'W.R.', a compact, free-flowering, heat and cold tolerant chance wild hybrid between *Erigeron glaucus* and an unknown species; and *Acer macrophylla* 'Seattle Sentinel', a fastigiate selection.

Another especially rich area for horticultural selection can be found in nearly all taxonomically confusing groups at either the generic [example: *Arctostaphylos* and *Zauschneria* (*Epilobium*)] or specific [example: *Mimulus aurantiacus* or *Mahonia* (*Berberis*) *aquifolium*] level. Taxonomic chaos is often indicative of the extreme plasticity found naturally in the group and by inference the potential horticultural availability of variation to select from. Similarly, there are a number of extremely variable species that are nearly as ripe for selection as the taxonomically complicated groups listed above. These species include *Rhamnus californica*, *Erigeron glaucus*, *Ceanothus maritimus*, *Quercus chrysolepis*, and *Juniperus communis*.

Peripheral populations of a desirable plant are another source of native plants for landscapes and gardens. Plants from these populations may be more tolerant of heat or cold, higher or lower elevations, drought or wetness, may exhibit resistance to diseases or pests, or may be adaptable to a different soil type or condition. An excellent example of this phenomena is *Arctostaphylos uva-ursi* 'Point Reyes', a selection from the fog-bound headlands of the Point Reyes peninsula in Marin County that is extremely tolerant of heat and drought in comparison to typical members of the species. The small relictual San Bernardino Mountains population of *Populus tremuloides* is remarkably well adapted to growing conditions at low elevations in southern California. When plants from these peripheral populations are not themselves horticulturally desirable, they may carry genes which may be useful in a breeding program.

Another particularly rich source of new plants to investigate are the genera that have been dependably used in landscapes and gardens before, and look for a different species with desirable characteristics. Cultivars of the "new" species can be selected directly or the "new" species may be used to create hybrids with the "established" species. The named *Heuchera maxima* x *Heuchera sanguinea* hybrids: 'Genevieve', 'Opal', 'Santa Ana Cardinal', 'Susanna', and 'Wendy', created by Dr. Lee W. Lenz are excellent examples of this approach.

Breeding programs involving controlled crosses and hybridization between species are relatively rarely encountered in the native flora. There are, however, a few exemplary programs which have yielded many fine plants: the pacific coast hybrid irises, the *Mimulus* hybrids (of the section *Diplacus*), the *Lewisia cotyledon* complex, and *Lilium* hybrids.

All new cultivars should be named, described, published and registered with the proper registration authority. A list of all currently accepted registration authorities for ornamental plants is available from the American Association of Botanical Gardens and Arboreta (AABGA).

TESTING, EVALUATION, AND MARKETING

All too frequently, a promising native plant species or cultivar does not live up to its potential. Almost without exception, these plants are victims of poor testing and evaluation.

Establishing a set of desirable traits and characteristics of plants which the public actively wants or desires is a critical first step in the development of a new plant introduction strategy. Consulting with focus groups from the nursery industry, the gardening public, native plant enthusiasts, realtors, horticultural groups and others should provide the researcher with plenty of input on a variety of desirable plant traits. As progress is made in the selection process, the new plants should be planted out in a number of test sites. Test plantings should then be evaluated by a number of outside reviewers. Plants surviving through the testing and evaluation process are then ready to be introduced and marketed to potential user groups. The most recent successful example of a western native plant to go through such a thorough program is *Arctostaphylos uva-ursi* 'Vancouver Jade', an introduction out of the University of British Columbia's well known plant introduction program.

CONSERVATION OF GENETIC RESOURCES

Everyone involved with the selection, use and promotion of new native plant species and cultivars and/or any of their close relatives must be fully aware of the potential negative consequences of their use in gardens and landscapes. Most of these concerns center around the issue of conservation of genetic resources and the genetic pollution of native plant populations in the wild. Three examples from the California flora will serve to illuminate this issue.

Nevin's Barberry [*Mahonia* (*Berberis*) *nevinii*], an extremely rare plant in nature, is found in widely distributed and ecologically varied small populations in southern California. It is, however, a relatively commonly seen landscape plant throughout the state. A molecular level study of these plants showed that there is little to no variation present in the gene pool. Therefore, the seed source of plants to be planted in the vicinity of the remaining individuals in the wild is not of concern--there will be no adverse consequences to the gene pool.

The California dandelion (*Taraxacum californicum*) from the wet meadows in the San Bernardino Mountains is a rare plant whose continued existence is threatened by ongoing hybridization with the common European dandelion (*Taraxacum officinale*), a weedy pest plant that is common throughout the range of the rare species.

The Monterey pine (*Pinus radiata*) is known from five geographically isolated populations (three are from central coastal California and two are on islands off Baja California). This tree is a significant forest tree in the southern hemisphere, particularly in New Zealand. Material from all five populations has been grown together on a massive scale in New Zealand, such that the primary seed source of Monterey pine (even in California) is from New Zealand. The issue of primary concern here is that the "mongrel" Monterey pines of New Zealand mixed origin will genetically pollute the "pure" native stands of these trees, such that the unique genetic character of the California populations will be lost due to homogenization of the gene pool over time (the Baja California populations are not threatened in this way at this time).

CONCLUSION

The development of new native plant crops for use in xeriscape landscapes and gardens is still wide open with innumerable opportunities waiting for the interested or inspired investigator. As more work is done to select and develop the native flora for use in gardens, the more likely it will be that these deserving plants will be used and appreciated by the general public. When the public is aware and appreciative of the beauty and utility of native plants they will be much more open to the conservation and preservation of this essential component of our natural heritage. The single most important caveat regarding the horticultural use of these native plants is that their use should not be allowed to adversely impact native plant genetic resources.

Pterocarpus indicus Willd.

Fabaceae
Malay padauk

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Sometimes recommended as an ornamental avenue tree. The reddish hard wood is an excellent timber in southern Asia. Listed among the most valuable timbers in the Philippines. Used for cabinetry, cart wheels, carving, construction, furniture, and musical instruments. Planted occasionally in Puerto Rico for shade and ornament (Little and Wadsworth, 1964). The young leaves and flowers are said to be eaten. The flowers are a honey source. The leaf infusion is used as a shampoo. The beautiful, termite resistant, rose-scented timber is marketed as Amboyna, Blanco's Narra, Burmese Rosewood, Malay Padauk, Narra, Philippine Mahogany, Prickly Narra, and Tenasserim Mahogany. The wood gives a reddish dye, more fugitive than that of *Pterocarpus santolinus.* It is also a source of kino.

Folk Medicine

According to Hartwell (1967–1971), the red latex is used in folk remedies for tumors, the plant for cancers, especially of the mouth. Endo and Miyazaki (1972) reported that the leaves "significantly inhibited the growth of Ehrlich ascites carcinoma cells in mice. A dried cold water extract of the leaves injected in mice bearing Ehrlich ascites carcinoma. All controls died within 21 days; of the treated group, 40/50 survived more than 84 days. The nuclei and cytoplasm of tumor cells became soft and larger, and then disintegrated. The active principle was isolated by gel filtration of aqueous extract. It was an acidic polypepticide, consisting of 17 amino acids. The LD_{50} in mice is 122 mg/kg i.p. Malayans apply the kino to sores of the mouth, and the root juice to syphilitic sores (Burkill, 1966). Javanese apply the young leaves to boils, prickly heat and ulcers. In the Carolyn Islands, finely powdered leaves are applied to a ruptured vagina. The kino, containing kinotannic acid, was once administered in diarrhea, often combined with opium (Lewis and Elvin-Lewis, 1977). Reported to be antibilious, emetic, and sternutatory, Malay padauk is a folk remedy for bladder ailments, diarrhea, dropsy, headache, sores, stones, thrush, and tumors of the abdomen (Duke and Wain, 1981). *Lignum nephriticum* (Latin for kidneywood) was the wood of this Philippine species and also of kidneywood (*Eysenhardtia polystachya*) from Mexico. It was known throughout Europe from the 16th to early 18th centuries for its reputed diuretic properties but is no longer employed in medicine. However, infusions of the wood are fluorescent, and this odd response to light may have been associated with remedies.

Chemistry

Wood contains the red coloring matters, narrin and santalin, and angolensin. Narrin is a dark red amorphous powder which yields phloroglucinol and resorcinol on fusion with alkali. Hager's Handbook (List and Horhammer, 1969–1979) reports pterocarpin and pterostilben homopterocarpin, prunetin (prunusetin), formonoetin, isoliquiritigenin, p-hydroxyhydratropic acid, pterofuran, pterocarpol, and β-eudesmol. Distilled wood gives a moderately heavy tar. Cups made from the wood and chips of wood impart to water a beautiful blue and yellow color, which changes in light and shadow (Little and Wadsworth, 1964).

Description

Large, deciduous tree, 30 m or more high, with large and high buttresses. Stipules caducous, linear, ca 7–15 mm long, hairy on both sides. Leaves ca 12–22 cm long in all, the petiole ca 2–4 cm, the rachis ca 6–18 cm, sparsely hairly, glabrescent; leaflets 5–13, chartaceous to subcoriaceous; surfaces concolorous, greyish-brown, sometimes greenish, above slightly shiny, glabrous, beneath slightly dull, sparsely hairy, glabrescent, petiolules ca 3–5 mm long, blade generally ovate, ca 1.6–2.5 times as long as wide, ca 4–5 by 6–10 cm; base generally rounded or sometimes obtuse to acute or very rarely attenuate, apex usually acuminate, sometimes acute, rarely obtuse, tip generally pointed. Inflorescences of laxly branched axillary panicles, sometimes together with a terminal one or with axillary racemes. Flowers few to numerous; calyx ca 5–6 mm long, hairy, all the lobes hairy inside towards the top, corolla with standard ca 16–18 mm long.

Fruit orbicular or semiorbicular, brown to blackish, densely hairy, ca 4–6.6 cm in diameter, stipe ca 5–9 mm long, the style (beak) lateral. Wing more or less membranaceous. The seed-bearing part ca 1 1/2–3 cm in diameter, thickened, ca 6–9 mm thick, more or less woody. Seeds 1–2, ca 2–5 by 8–10 mm, widest at or below the hilum; testa dark brown, smoothish.

Germplasm

Reported from the Hindustani and Indochina-Indonesian Centers of Diversity, Malay Padauk, or cvs thereof, is reported to tolerate waterlogging. The variety echinatus differs only in having prickles on the seed bearing part of the fruit. It does poorly in lalang wasts, shallow soils, and stiff clays. ($2n = 20$)

Distribution

According to Rojo (1977) its western limit is southern Burma, extending eastward to peninsular Thailand to Vietnam, farther eastward reaching the Solomons (eastern limit) in the Pacific via Sumatra, West Java, Borneo, Philippines, Sunda Islands, the Moluccas, New Guinea, and the Pacific (Ryukyu, Carolines). Rojo suggests that most species of *Pterocarpus* "prefer" seasonal climate, but *P. indicus* is a rainforest or evergreen forest species (able to withstand dry areas).

Ecology

Probably ranging from Tropical Very Dry to Wet through Subtropical Dry to Wet Forest Life Zones, Malay Padauk is reported to tolerate annual precipitation of 9.6 to 21.8 dm (mean of 10 cases = 16.4), annual temperature of 24.3 to 26.6°C (mean of 6 cases = 25.2), and estimated pH of 4.0 to 7.5. According to Rojo, it grows in forests, mostly evergreen, in the lowlands up to 600 m.Seems to prefer a seasonal climate, more everwet in New Guinea. Flowers (Philippines, N. Borneo, Malay Peninsula) mostly in February–May, occasionally in August–November and (Celebes, Moluccas, Carolines, Solomons, and New Guinea) mostly in July–December, occasionally in February–May; fruit seems to ripen within 4–6 months.

Cultivation

Grows rapidly from seeds and cuttings. Probably best started in seed nurseries and then outplanted with the rainy season.

Harvesting

The kino, the resin, and the timber are usually harvested as needed. Those people who eat the flowers and leaves probably concentrate such meals during the leaf flush and flowering periods.

Yields and Economics

Although this is regarded in the Philippines e.g. as one of the best furniture timbers, I find no yield data.

Energy

Although the wood is not necessarily recommended as firewood, it certainly could be used for firewood. Some *Pterocarpus* burn green. The wood is hard and heavy (625 kg/m^3), and can be air seasoned without difficulty. Studies in Hawaii, Malaysia, the Philippines, and Singapore, indicate that the species fixes nitrogen (Allen and Allen, 1981).

Biotic Factors

Browne (1968) lists *Ganoderma lucidum*, *Ganoderma pseudoferreum*, *Schizophyllum commune*, and *Sclerotium rolfsii* (fungi); *Hypomeces squamosus* (coleoptera); *Parasa lepida* (lepidoptera), and *Sus scrofa* (mammalia). According to Arroyo, *Pterocarpus* is visited by large numbers of bee species, representing many different genera.

Verkade, S.D. and G.E. Fitzpatrick. 1990. Development of the threatened halophyte *Mallotonia gnaphalodes* as a new ornamental crop. p. 470. In: J. Janick and J.E. Simon (eds.), Advances in new crops. Timber Press, Portland, OR.

Development of the Threatened Halophyte *Mallotonia gnaphalodes* as a New Ornamental Crop

Stephen D. Verkade and George E. Fitzpatrick

Climatic and ecological adaptability coupled with desirability for use in habitat restoration programs have increased consumer demand for rare and endangered plant species. Certain of these species have great potential for horticultural development once production barriers have been overcome. The sea-lavender, *Mallotonia gnaphalodes* is very rare in nature, but exhibits many desirable landscape characteristics. The recent delineation of successful propagation procedures for sea lavender has provided an opportunity for further economic development of this species.

Research has been conducted to determine optimum rooting conditions for sea-lavender and to evaluate transplant procedures. Successful rooting of cuttings was accomplished using fog propagation, 8,000 ppm indolebutryic acid, and a well-aerated rooting medium. Optimum transplant success on nonirrigated beach sites was achieved using organic topdressings composed of municipal solid waste compost.

Armitage, A.M., J.M. Laushman, and F. Vogel. 1990. Photoperiodic control of flowering of *Salvia leucantha* L. p. 470. In: J. Janick and J.E. Simon (eds.), Advances in new crops. Timber Press, Portland, OR.

Photoperiodic Control of Flowering of *Salvia leucantha* L.

Allan M. Armitage, J.M. Laushman, and F. Vogel

Salvia leucantha, velvet sage, has potential as a cut flower crop grown under protected environment or in the field. In the field, flowering naturally occurs in August in north Georgia (34°N), and continues until frost. Yields of *Salvia leucantha* in the field ranged from 250 to 330 stems per square meter. Investigations were conducted to determine the response of *Salvia leucantha* to photoperiod and to light drift. Macrobud development occurred when the photoperiod

was 12 hours or less but anthesis required photoperiods of 10 hours or less. A minimum of 14 SD cycles (8 hr) resulted in macrobud development but at least 42 cycles were necessary for anthesis. Low irradiance drift resulted in inhibition of macrobud development and anthesis. Inhibition occurred when plants received more than 0.13 umoles m-2 s-1 irradiance from 2200 to 0200 hours.

Kitto, S. and P. Geiselhart. 1990. Regeneration and proliferation of *Veltheimia bracteata*. p. 470. In: J. Janick and J.E. Simon (eds.), Advances in new crops. Timber Press, Portland, OR.

Regeneration and Proliferation of *Veltheimia bracteata*

Sherry Kitto and Pamela Geiselhart

The common red-flowered, as well as the rarer yellow-flowered, forms of *Veltheimia bracteata* would be valuable to the ornamental market if available in large quantities. Conventional propagation techniques are slow; however, rapid mass propagation may be possible via tissue culture. Red- and yellow-flowered *Veltheimia bracteata* scape sections (0.5 cm thick) and floral parts (ovary, immature seeds and bracts) have been cultured on medium containing Murashige and Skoog (1962) salts and the following addenda in mg/liter: sucrose, 60,000; nicotinic acid, 0.5; thiamine-HCl, 0.4; pyridoxine-HCl, 0.4; glycine, 2; washed Difco Bacto agar, 6,000 and growth regulators (NAA; 0, 1, 2, 4 and BA; 0, 1, 2). Cultures were maintained at 23±2°C with a 16 hour photoperiod (60 µmol m^{-2} s^{-1}) and were recultured every 4 weeks. Bulblets have been regenerated from scape sections and bracts. Histological analysis has demonstrated that bulblets regenerate from callus. Proliferating cultures have been established from regenerated bulblets. Immature seeds have germinated to produce plantlets when cultured on growth regulator-free medium.

Manioc

Cassava, Mandioca, Tapioca plant, Sweet potato tree, Yuca

Euphorbiaceae *Manihot esculenta* Crantz, *Manihot* sp.

Source: Magness et al. 1971

Manioc, or Cassava, is a highly important food crop of the tropics and is grown to some extent in the Southern States, mainly for stock feed. The plant is a large herbaceous shrub up to 10 feet, resembling castor bean in appearance, with large, compound leaves. It is cultivated for the large, tuberous roots which are rich in starch and are the source of tapioca, Brazilian arrow root, and other foods. The tuberous roots form in a cluster at the stem base. Plants are propagated by stem pieces laid horizontally in furrows, somewhat like sugar cane. The roots used as food sources are formed entirely underground. Only 15 acres were reported for continental U.S., 1954 census, but there is substantial production in Puerto Rico and Hawaii.

Marmaladebox

Genipap, Genip

Rubiaceae *Genipa americana* L.

Source: Magness et al. 1971

This fruit is borne on a medium-size tree, native to the Caribbean area. Leaves are up to a foot long and are clustered at branch tips. Fruits are ovoid in shape, up to 3 inches broad and 4 inches long. The skin is thin, enclosing a granular pulp and a seed cavity with numerous small seeds. The fruit is popular in Puerto Rico, especially for macerating the pulp in water to make a refreshing drink. The fruit is rarely eaten out of hand.

Martynia

Unicorn plant, Proboscis flower

Martyniaceae *Proboscidea louisianica* (Mill.) Thell.

Source: Magness et al. 1971 This is an annual plant, up to 2 to 3 feet in height, with entire leaves, round to cordate, 4 to 12 inches wide. The fruit is hairy, about 1 inch thick and 4 to 6 inches long at maturity, about half the length consisting of a slender curved beak. The small, immature pods are made into pickles, like cucumbers. The plant is grown as an ornamental, and sparingly as a pickling vegetable.

Season, seeding to first harvest: 3 to 4 months.

Production in U.S.: No data. Of minor importance.

Use: Pickles.

Part consumed: Entire young pods.

CHAMOMILE

Family: Asteraceae (Compositae)

ROMAN CHAMOMILE (*Chamaemelum nobile* [L] All.)

GERMAN CHAMOMILE (*Matricaria recutita* L.)

Source: Simon, J.E., A.F. Chadwick and L.E. Craker. 1984. Herbs: An Indexed Bibliography. 1971-1980. The Scientific Literature on Selected Herbs, and Aromatic and Medicinal Plants of the Temperate Zone. Archon Books, 770 pp., Hamden, CT.

Roman chamomile, *Chamaemelum nobile* (L.) All., and German chamomile, *Matricaria recutita*, are two different species of plant commonly known as the same herb.

Formerly classified as *Anthemis nobilis* L. and called English or Russian chamomile, Roman chamomile is a creeping, herbaceous perennial native to western Europe and North Africa. Reaching a height of about 0.3 meters, the aromatic plant is characterized by downy stems and yellow-disc, white-ray flowers that appear in late spring or early July. Roman chamomile is cultivated in Europe, especially in Belgium, France, and England.

German chamomile, *Matricaria recutita* L., is also known as matricaria, wild chamomile, Hungarian chamomile, and sweet false chamomile. This many-branched, erect-growing annual, formerly classified as *Matricaria chamomilla* L., reaches a height of about 0.3 meter and has yellow disc white ray flowers. Cultivated in Germany, Hungary, Russia, and several other European countries, German chamomile is native to Europe and western Asia and naturalized in North America.

The reported life zone for the chamomiles is 7 to 26 degrees centigrade with an annual precipitation of 0.4 to 1.4 meters and a soil pH of 6.5 to 8.0 (Roman) or 4.8 to 8.3 (German) (4.1-31). Seeded or transplanted into the field for cultivation, Roman chamomile requires full sun but will grow in most soils having good drainage. Cultivated from seed, German chamomile grows in poor, clay soils. With Roman chamomile, the flower heads are hand picked and dried at the height of bloom about five times each growing season. The short, two-month growing season of German chamonile allows it to be interplanted with other biennial herbs or planted as an early or late crop.

The essential oil of Roman chamomile consists chiefly of chamazulene, angelic acid, tiglic acid, and several sesquiterpene lactones (1.4-34, 14.1-10). Other constituents of Roman chamomile include anthemic acid, athesterol, anthemene, resin and tannin (14.1-35). The essential oil of German chamomile contains chamazulene, -bisabolol, -bisabololaxides A and B, spathulenol cis-En-yn-dicycloether and farnesene (1.7-121, 2.3-74). Other constituents of German chamomile include a volatile oil, anthemic acid, antheminidine, tannin, matricarin, and apigenin (11.1-136, 14.1-35).

Dried flowers from Roman and German chamomile are employed in herbal teas. Flower heads of Roman chamomile have been used in the manufacture of herb beers (11.1-49). The essential oils are used as agents in alcoholic beverages, confections, desserts, perfumes, and cosmetics. Roman chamomile is often grown as a ground cover or as an ornamental in flower gardens.

As medicinal plants, the chamomiles have been traditionally considered to be antispasmodics, carminatives, diaphoretics, emmenagogues, sedatives, and stomachics. The plants have been used as bitters, tonics, insect repellents, and as a folk remedies against asthma, colic, fevers, inflammations, and cancer (14.1-13). German chamomile has been used to induce sleep and as an anthelmintic. Roman chamomile is a pharmaceutical aromatic bitter, and chamazulene, obtained from German chamomile, is a pharmaceutical anti-inflammatory and antipyretic agent (14.1-35). Extracts of Roman chamomile have shown antitumor activity and extracts of German chamomile are reported to have antiseptic, antibacterial, and antifungal properties (1.4-34, 1.8-13, 7.2-19). Chamomile in tea may cause toxic reactions in individuals sensitive to ragweed or allergens (11.1-96). The chamomiles can also cause contact dermititis (11.1-96).

Roman and German chamomile are generally recognized as safe for human consumption as natural seasonings/flavorings and as plant extracts/essential oils from the flowers (21 CFR sections 182.10, 182.20 [1982]).

Yaniv, Z., D. Schafferman, M. Zur, and I. Shamir. 1996. *Matthiola incana*: Source of omega-3-linolenic acid. p. 368-372. In: J. Janick (ed.), Progress in new crops. ASHS Press, Arlington, VA.

Matthiola incana: Source of Omega-3-Linolenic Acid*

Zohara Yaniv, D. Schafferman, M. Zur, and I. Shamir

Current research in nutritional medicine indicates that the omega-3 fatty acids are receiving more and more attention as essential components of the human diet (Adam et al. 1986; Simopoulos 1986). The observed low incidence of arteriosclerosis and chronic inflammatory heart disease in Greenland Eskimos has been attributed to their traditional ethnic diet, consisting in great part of marine foods rich in two omega-3 fatty acids: C22:6 and C20:5.

Dietary fish oils containing omega-3 fatty acids are increasingly recommended for their antithrombic and hypolipidemic effects to persons consuming typical western diets (Phillipson et al. 1985). Additional benefits include improving immunologic function and fighting allergies (Leaf and Weber 1988). Omega-3 fatty acids from vegetable oils could provide health benefits without any concomitant intake of cholesterol (Hunter 1990).

Based on preliminary evaluations (Yaniv et al. 1991) we have chosen to investigate germplasm of *Matthiola incana* (Brassicaceae) with an average oil content of 20%-24% in the seeds and maximum levels of 65% omega-3-linolenic acid (omega3LA) of the total fatty acids in the oil (Ecker et al. 1992). This is one of the highest known content of omega3LA in a plant species (Table 1). A second important aspect of this vegetable oil is its quality as drying oil, due to the high content of omega3LA. Various *Matthiola* lines were tested and evaluated as a potential new-oil crop for dietary supplement and industrial uses.

METHODOLOGY

Cultivation

Five lines of *M. incana* selected from a collection of commercial lines for flower production, having a high content of omega3LA were tested. Plants were grown in the experiment stations at Bet Dagan, Ramat haGolan, and Jerusalem, Israel, representing three different climatic regions, during the 1991/92 growing season. Each line was replicated four times in a random block design. Seeds of each line were sown in small plots of 1.2 m^2 consisting of four rows with 30 cm between rows. Basic fertilization was done at the time of soil preparation, at rates of 2N-2P-1K. 'Trifluralin' (2.5 kg/ha) was applied as a herbicide. The plots were irrigated until seedling establishment. Mean monthly temperatures at the three sites during the growing period (Nov. 1991 to June 1992) are presented in Fig. 1.

Observations were made on plant height, percent of fertile plants, and seed yield (number of pods/plant, number of seeds/pod, and weight of 1000 seeds). Plants were harvested at each location according to the time of full maturity. Fully mature seeds from each line were oven-dried overnight at 50°C and analyzed for oil content and fatty acid composition (Yaniv et al. 1991).

Lipid Extraction

Seeds were dried overnight at 50°C and ground into powder in a Moulinex coffee grinder; 5 g of powder was mixed with 100 cc petroleum ether (40° to 60°C), and the lipid fraction was extracted in a Soxhlet apparatus for 16 h at 60°C. The solvent was evaporated, and the lipid fraction residues were weighed (Yaniv et al. 1991).

Direct Transesterification from Seeds

Seeds (200 mg) were dried overnight at 50°C and ground into powder with a mortar and pestle, after which 0.3 cm^3 of dichloromethane and 2.0 cm^3 of 0.5 N sodium methoxide (MeONa) were added. The tube was heated to 50°C and shaken for 30 min. The reaction was stopped by adding 5.0 cm^3 of water containing 0.1 cm^3 of glacial acetic acid. The esterified fatty acids were extracted with 2.0 cm^3 of petroleum ether (40° to 60°C). The clear fraction was kept at -20°C until further analysis. Samples of 2.0 mm^3 were injected into the gas chromatograph for fatty acid analysis.

Gas Chromatography of Methylated Fatty Acids

A Megabore column (DB-23, 0.5 mm film thickness, 30 m x 0.54 mm, J&W Scientific) was used in a gas chromatograph equipped with a flame ionization detector (Varian model 3700 GC) and an automatic area integrator (3390A HP). The flow rate of N_2 (carrier gas) was 30 cc/min and the oven temperature was 135° to 200°C, programmed at a rate of 4°C min. The following fatty acids were identified using known standards (Supelco): C16:0, palmitic; C18:0, stearic; C18:1, oleic; C18:2, linoleic; C18:3, linolenic; C20:1, eicosenoic; and C22:1, erucic acid.

RESULTS AND DISCUSSION

Agronomy

Table 2 summarizes the results of the evaluation of five lines of *M. incana* cultivated in the Bet Dagan (BD), Jerusalem (JM), and Ramat haGolan (RG) experiment stations during autumn 1991 to spring 1992. The best location was BD with all lines showing higher yield potential at that site. Yield per plant was by far the highest at BD (3.5 g vs. 0.9 g at JM and 0.7 g at RG). Number of pods/plant was 73.3 in BD as compared with 36.7 in JM and 26.7 in RG. Number of seeds/pod, plant height, pod length, and 1000 seed weight were also slightly higher at BD than at the two other sites. The best performing lines were ROZ 45 and ROZ 19. At BD, both lines showed the highest yield potential. Under the low temperature conditions prevailing in winter at JM and RG (Fig. 1), ROZ 45 and ROZ 19 maintained the highest yield. ROZ 45 and ROZ 19 had the highest fertility rate (close to 90%) at all sites tested.

Oil Content and Quality

Table 3 summarizes the oil content and fatty acid evaluation of the three test sites. Oil quantity ranged from 21% (V6) to 28%-29% (ROZ 19 and ROZ 46), with the best sites at Jerusalem and Ramat haGolan.

Seeds of ROZ 46 and ROZ 19 accumulated 29% oil in JM and RG, as compared to 25% at BD. Temperatures during seed maturation were lower at JM and RG than at BD (Fig. 1) and it is known that low temperatures during seed development have a positive effect on oil quantity (Canvin 1965; Yaniv et al. 1989). Difference in oil quantity of the three sites is probable due to temperature.

Our main goal is to obtain a high concentration of omega3LA (C18:3) in the seed oil. The levels obtained ranged from 50% to 60%, with ROZ 45, the highest at all three locations. The best locations were JM and BD. Temperature plays a major role in the relative concentration of unsaturated fatty acids of seed oils (Mazliak 1988), and cooler conditions usually favor the production of polyunsaturated fatty acids (Yaniv et al. 1995). When *Matthiola* were grown under controlled temperature in a Phytotron, the content of seed unsaturated omega3LA was 69% at 12°C night 17°C day as compared to 58% at 22°/27°C (Yaniv et al. 1992). However, in spite of the fact that the coolest temperatures prevailing during seed maturation were in RG (Fig. 1), the highest content of C18:3, was obtained at JM and BD, and did not go above 60% (Table 3). It is important to note that temperatures never dropped below 15deg.C during the maturation period (May-June). It could be that in order to induce a significant increase in the level of C18:3, maturation should occur under a much cooler temperature regime than tested by us in the three sites.

Potential Yield

A yield of 750 kg seeds/ha, calculated on the basis of 17 plants/m^2, was obtained at BD. With 20% to 25% oil in the seed, this yield is equivalent to 150 liters oil/ha. A 50% content of omega3LA in the oil will yield 75 liters/ha pure omega3LA. Due to the fact that the research is in an early stage, we can't predict the profit per ha of the producte. This will be evaluated in during the second stage of the research.

Melon, Winter

Casaba, Honeydew, Persian

Cucurbitaceae *Cucumis melo* L. (Inodorus group)

Source: Magness et al. 1971

These are melons grown on plants similar to cantaloupes, but fruits are without distinctive odor and late in ripening. The fruits are medium to large with generally smooth surface. In all cultural aspects they resemble cantaloupes except for longer growing season requirement. Included in the group are the Honey Ball, Honeydew, Casaba, Crenshaw, and Persian.

Season, seeding to maturity: About 4 months.

Production in U.S.: 6,700 tons.

Use: Fresh eating, salads.

Part of plant consumed: Internal pulp.

Moonseed

Menispermum canadense L.

Other common names.—Canada moonseed, menispermum, yellow parilla, Texas sarsaparilla, yellow sarsaparilla, vine maple.

Habitat and range.—Moonseed is usually found along streams in woods climbing over bushes, its range extending from Canada to Georgia and Arkansas.

Description.—This woody climber reaches a length of from 6 to 12 feet, the round, rather slender stem bearing very broad slender-stalked leaves which are from 4 to 8 inches wide, roundish in shape, an] resembling the leaves of some of the maples. In July the loose clusters of small, yellowish or greenish-white flowers are produced, followed in September by bunches of black 1-seeded fruit, covered with a bloom and very much resembling grapes.

Part used.—The rootstock, collected in autumn.

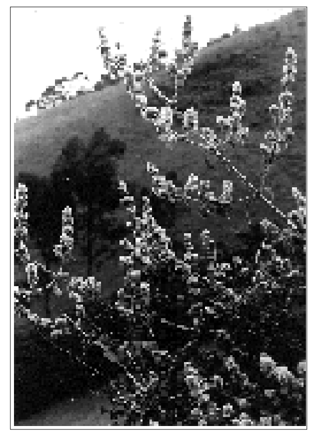
Tipo, Poleo, Muña, Peperina

Labiatae or Lamiaceae *Minthostachys sp.*
Tipo, Poleo, Muña *M. mollis* (Kunth.), ***M.tomentosa*** (Benth.), ***M.setosa*** (Briq.) and other species.
Piperina of Argentina is *M. verticillata*.(Griseb.)
Source: Alkire B.H.,and A.O. Tucker and M.J. Marciarello. *Economic Botany* 48(1) pp.60-64. 1994

The "mint-like" aromatic herbs of the genus Minthostachys are limited to the Andean zones of South America, with perhaps 12 species distributed at various altitudes from Venzuela to Argentina. The plethora of integrating phenotypes typical of *Minthostachys spp.* adds uncertainty to species determination. The use of vegetative characters to separate species is confounding. Species are separated by counting and measurement of calyx ribs. "Taxonomically the genus is in need of revision." - Ray Harley, Kew Botanical Gardens. Pollen morphology has indicated that the genus is most closely linked to *Pycnanthemum* and *Bystropogon* of the Canary Islands.



Use: *M. mollis, tomentosa, setosa* and other species:. As a as refreshing beverage, as a condiment in food, and as medicine for colds and coughs. Leaves are combined with storage potatoes; which have a definite inhibitory effect on tuber sprouting and also serves as a potato insect anti-feedant.

In Argentina *M. verticillata* tea is a well-known and widely commercialized product, packaged in tea bags as "Peperina". This species was once comercially distilled for a l-carvone rich essential oil. A scanned image from a boxtop from an Argentine peperina-containing commercial tea is displayed below (*courtesy of Dolly Bell-LeLong*).

Part of plant consumed: Leaves and flowering stems.

Scientific Name: *Scoparia dulcis* Linn.
Family: Scrophulariaceae
Hindi Name: Mithi Patti

General Description: It is introduced in India from Tropical America. It grows as wasteland herb. The traditional healers have developed its many promising traditional medicinal uses.

Botanical Description: it is a small, much branched, glabrous, leafy annual herb or under shrub with erect or ascending branches; Leaves opposite and 3-notely whorled, rhomboid, elliptic or elliptic lanceolate, obtuse at apex, base tapering, margins serrate; Flowers many, in terminal panicles, pedicelate, pedicels slender, rigid; Calyx lobes 4, oblong; Corolla white, tube very short, Capsule globose; seeds minute, many.

Useful parts: All parts.

Medicinal Uses
Leaves are used in treatment of fever, cough, bronchitis and dental trouble.
Leaves and stems are used for diabetes.

Chemical Constituents: A triterpene and mannital have been isolated from roots and dulcitol from aerial parts.

Neglected Crops: 1492 from a Different Perspective. 1994. J.E. Hernándo Bermejo and J. León (eds.). Plant Production and Protection Series No. 26. FAO, Rome, Italy. p. 111-115.

Spanish plum, red mombin

(*Spondias purpurea*)

The author of this chapter is J. Axayacatl Cuevas (Department of Plant Science, Ethnobotanical Unit, UACH, Mexico).

Botanical name: *Spondias purpurea* L.

Family: Anacardiaceae

Common names. English: Spanish plum, red mombin; Nahuatl: ateyaxocotl; Spanish. jocose (Mexico [Oaxaca], Central America), ciruelo (Mexico [Jalisco, Yucatán])

Spondias purpurea was grown widely from Mexico to the northern region of South America when the Europeans arrived, as can be deduced from the descriptions of the first chroniclers (Oviedo, Sahagún). It spread through the Antilles and the rest of South America and was possibly taken from Mexico to the Philippines. The fresh fruit has a very pleasant taste and its consumption is increasing. It is a valuable but economical raw material for the preparation of soft drinks, preserves and syrups and is also eaten as a dried fruit. The current marginalization and scarcity of commercial plantations are largely due to a lack of attention on the part of producers, technical experts and agricultural extension workers, who are concentrating their efforts on other fruit-trees in greater demand on the foreign market.

The most widespread use of *S. purpurea* is as a fresh fruit for local consumption and for supplying city markets. In Mexico and Guatemala. it is used in other forms which are possibly of post-Hispanic origin. In one form, the fruit is boiled in brine for five to ten minutes and then dried in the sun, either on tables with a wire mesh or reeds for three days or on driers on mobile units for ten to 12 hours. By this process, the dried fruit is reduced to one-quarter of its fresh volume. Another way to prepare the fruit is to heat it in unsalted water and dry it in the sun, while a third process, used in Mexico to obtain *ciruelo negro*, consists of pricking the skin of the fruit, placing it in syrup (1 kg of sugar in a bottle of water) and letting it simmer until the sugar burns or becomes concentrated. *Ciruela cristillina* is a fourth method of preparing the fruit, similar to the previous one, only the fruit is gathered while it is ripening and is boiled for a shorter time.

Other uses of *Spondias* pulp include as an atole, mixed with maize flour and sugar, and in the preparation of wine, *chicha* (maize liquor) and soft drinks.

Analyses of the fresh fruit show that the percentage of moisture in the flesh ranges from 76 to 86 percent; it is very low in protein and fat and contains appreciable quantities of calcium, phosphorus, iron and ascorbic acid.

Its consumption is currently increasing throughout Mesoamerica. The bulk of production comes from isolated trees or hedges, while very little comes from well-ordered and maintained plantations, such as the ones seen around the city of Oaxaca. However, it is a very promising fruit-tree because it is accepted on the market; it is a hardy species with a high resistance to drought; it is easy to produce on poor soil; and its propagation is exclusively vegetative, which ensures an early harvest.

Botanical description

S. purpurea is a small tree, growing 4 to 8 m, with a broad crown, irregular trunk and fragile branches; its leaves are composed of five to 12 pairs of elliptical-acute leaflets, 2 to 4 cm in length and which fall before the flowering period. It has red flowers in 3 to 5 cm panicles, situated along the small branches; the fruit is an irregular oval drupe, somewhat gibbous, smooth and shiny, 4 to 5.5 cm long and a violet to yellow colour, with a woody kernel which contains the seeds. The flesh is sparse, creamy, yellowish and bitter-sweet in the cultivated plants and very acid in the wild plants. It contains malic acid, sugar, calcium malate and starch. The growth cycle has only been studied in Mexico, in Sinaloa and Puebla. In Sinaloa, the trees have foliage from June to October, leaves fall from October to December and the trees are without foliage from January to May. Flowering occurs in February and March and fruiting in June. In Puebla, the trees have leaves from March to October, leaf fall occurs from October to December and the trees remain leafless from January to April. Flowering takes place from December to January and the fruit ripens in April and May. Of great interest is the absence of seed formation in this species, an aspect that was first studied in the Philippines. In the "nut", which occupies the central part of the fruit, only remnants of aborted seeds are found. This is due to both poor pollen formation and the oosphere. Natural distribution is thus completely limited, but the ease with which stems and branches sprout, together with their fragility, allows a very limited natural propagation. Recognition and conservation of the numerous variants which this species displays is possibly due to the action of humans.

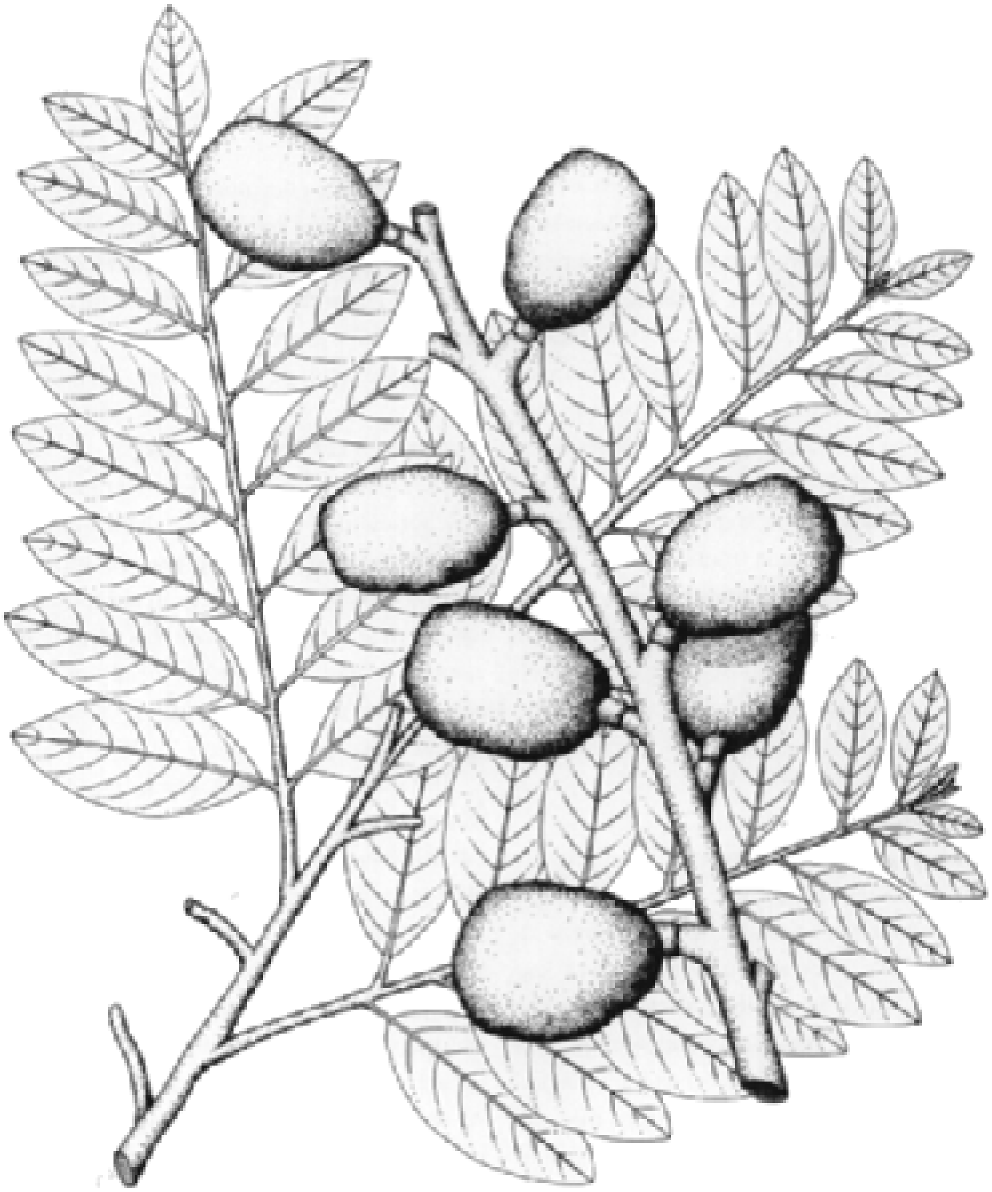

Figure 10. Spanish plum, red mombin (*Spondias purpurea*)

Ecology and phytogeography

The natural populations of *S. purpurea* grow from sea level to an altitude of 1 200 m in areas

with alternating seasons from Sinaloa and Jalisco in Mexico to Colombia. It is known that *S. purpurea* was taken from Nicaragua to Panama and South America in the form of cuttings with a viability of several weeks. It grows in regions of low humidity and remains leafless during the dry season. It has been introduced into similar tropical regions in Southeast Asia and also in subtropical areas (Florida).

Genetic diversity

Numerous clonal varieties of *S. purpurea* are known, but there has been no formal characterization of them. In Yucatán there are 20 varieties and, although some may be *S. Iutea*, this is perhaps the most notable varietal concentration in Mesoamerica. Ak-abal, with small, poor-quality fruit and smooth succulent roots, like those of the Brazilian species *S. tuberosa*, is used for pickles. The cultivated varieties may be divided into two groups:

Summer mombin. This fruits (in Central America) during the dry season from February to May, has ellipsoidal fruit that is 2.5 to 3 cm long with smooth, purple-red skin and yellow, smooth, sweet and slightly acid flesh. When green, these varieties look like olives. The varieties Tronador, Criollo, Nica and Morado grow between 0 and 800 m.

Winter mombin. This is of superior quality, with fruit that is 3.5 to 4.5 cm long, red or yellow, smooth or with protuberances, and has firm, sweet, slightly acid flesh. It ripens at the end of the rainy season (September to December). Most of these varieties grow between 800 and 1200 m and those known include Petapa, Corona and Cabeza de loro.

It has been suggested that these two groups should be considered as different species, but their distinctive characteristics are within the normal varietal range in the cultivated species. Wild populations, such as the iguana mombin in Costa Rica. have very attractive, red or purple fruit. with yellow flesh similar to certain grapes, although it is acidic and astringent. There are other wild varieties in Central America, some with common names. Being a species in which crossings must be very difficult, neither varietal richness nor related species, such as the jobo (*S. lutea*), are of great use in genetic improvement.

On the other hand, the study and evaluation of clonal variation may offer new material. In this connection. regions of particular interest are: the Pacific area of Nicaragua which has been famous for its mombin or Spanish plum since the days of colonial settlement; Yucatán, where numerous varieties exist; and southwestern Mexico and the neighbouring region of Guatemala. There are no collections of germplasm, but they should not be difficult to establish and maintain. In addition to *S. lutea*, there are two cultivated species: ambarella, Jew's plum or golden or Otatheite apple (*S. dulcis*) from Polynesia, which is grown sporadically in tropical America; and imbu mombin (S. *tuberosa*) from the dry region of northwestern Brazil, whose fruits are of excellent quality. These three species are propagated by seed.

Cultivation practices

Being a vegetatively propagated species, the sowing material consists of straight cuttings, more than 6 cm thick and at least 1.5 m long, with horizontal cuts. They are cut at the start of leaf production which generally coincides with the beginning of the rains. The cuttings are kept in the shade for a couple of weeks and are planted 8 x 8 m apart at a depth of 30 cm. As a rule, the only cultivation practice is pruning of the branches to cause numerous shoots to form along the main branches. Pruning can be done every year, since the flowers bud on the current year's branches. The experience of producers in Mexico is that pruning increases the size and weight of the fruit.

In Oaxaca, there are commercial plantations on which the trees are pruned at a height of 2 m; the cuttings are planted in double, inclined rows, with 3 m between the pairs of rows; when pruned, they look like European apple orchards.

There are no serious pests apart from the Mediterranean fruit fly (*Ceratitis capitata*) and Mexican fruit fly (*Anastrepha ludens*) which cause serious damage.

Harvesting on the pruned trees is an easy operation, performed by shaking the branches with poles or sticks; the fruit is gathered from the ground. Throughout the region where mombin is produced, the green fruit is eaten a great deal, as is the green fruit of the ambarela (*S. dulcis*).

Prospects for improvement

S. purpurea can be grown on marginal land of low agricultural value, on which the tree could be used for reforestation and produce extra profit for growers. Its production season is short, and late or early varieties that extend this period must be sought. Marketing, whether locally or in major towns, does not pose any major problems, as it is a widely accepted product.

The main limitation is attack from fruit flies, since control is expensive and beyond the range of small producers. An evaluation of cultivars that have some degree of resistance would be very advantageous, as would agronomic measures that tend to reduce infection by flies. Another theme to be investigated is the effect of defoliants on the acceleration of fruit formation.

So far, there has not been any industrialization of the fruit. Improving the primitive processes described earlier and research into others, as has been done in Florida with the artificial drying of slices of the flesh, may open up new possibilities for consumption.

Varieties of *S. purpurea* urgently need to be collected in one or more gene banks, which allow a quick evaluation of their genetic characteristics (resistance to insects, production period, response to pruning), and sowing material must be distributed among growers. In areas with sufficient space, it is recommended that *S. purpurea* be planted as a hedge, since its fruit production represents extra profit for the grower. Finally, transport and packaging problems must be studied to see how they can be Improved, since they are at a very primitive stage.

New Fruits for Arid Climates

Yosef Mizrahi, Avinoam Nerd, and Yaron Sitrit

INTRODUCTION

In many countries around the world "developers" take the best agricultural lands for housing, and urbanization spreads rapidly. As a result, the agricultural industries are pushed into less productive lands in which the climate is not the most suitable for crops. A very good example is found in Israel. The best agricultural area is along the Mediterranean coast where the citrus industry flourished for almost a century and is the area where the famous 'Shamouti' (syn. Jaffa) orange was found and developed. Later, "Jaffa" became the trade name for the whole successful Israeli citrus industry. Today, most of this area is heavily populated and the agricultural industry is pushed into the Negev Desert where extreme temperatures exist, the soil is less fertile, and water, if available, is saline and/or very expensive. Labor is also less available and very expensive. The government by doing "more of the same" is encouraging the reestablishment of the citrus industry in the Negev and planting olives for oil (Negev of Growth Campaign).

Traditional crops in Israel appear to be at the end of their viable economic-life-cycle, but there is hope that new crops could establish a future profitable agricultural industry (Mizrahi and Nerd 1996). New crops could also ameliorate the increase in atmospheric CO_2 concentration (greenhouse effect) which increases temperature and drought, changing fertile lands into deserts (Mizrahi and Nerd 1996). The old traditional crops cannot cope with these expected changes. Over a decade ago Noel Vietmeyer (1986, 1990) raised the point that humans are "stupid" to neglect the huge treasure-house of biodiversity available in the thousands of wild plants and neglected crops that might solve many of our present and future agricultural problems. The aim of our program that started 16 years ago was to develop totally new fruit crops not known in the world markets, as new crops for desert areas (Nerd et al. 1990, 1993; Mizrahi and Nerd 1996, 1999). After many years of extensive R&D we had both failures and successes and we wish to share our experiences with others interested in new crops.

FRUIT TREES INTRODUCTION UNDER DIFFERENT DESERT ECOZONES

Since 1984 we have introduced and tested over 45 fruit tree species. Many of them are totally wild while others are neglected crops known only in their country of origin. All these species were tested in different ecozones around our Negev Desert, each differ from the other by average and extreme high and low temperatures and salinity of the irrigation water. In Israel, climatic and socio-economical considerations dictate that almost all crops are irrigated and in the Negev desert, most areas are irrigated with saline water. Salinity differs in the various ecozones not only by degree of salinity but also by ion composition. Whenever Na^+ is more abounded than Ca^{++} (Rengel 1992) and Cl^- is more abounded than SO_4^{--}, the damage of salinity is more pronounced and more species will die even under $4dS/m^2$ (Nerd et al. 1990; Mizrahi and Nerd 1996).

FAILURES WITH SOME AFRICAN SPECIES

As would be expected we have had many failures. Among our unsuccessful attempts is the yehib (*Cordeauxia edulis* Hemsl., Caesalpiniaceae), a wild shrub from the horn of Africa. This shrub produces a tasty edible nut even under extreme drought conditions when most plants will die. Unfortunately, we found yehib to be extremely sensitive to chilling temperatures, and plants have died at 4°C (Mizrahi and Nerd 1996). This unique bush deserves much more R&D efforts to save it from extinction (Miege and Miege 1979; National Research Council 1979).

Mongongo (*Ricinodendron rautanenii* Schniz, Euphobiaceae) is a nut-producing wild tree from the Kalahari Desert in southern Africa. It is highly nutritious and tasty nut but the yields are very low with no hope for the Israeli horticultural industry (Biesele et al. 1979; Fox and Norwood-Young 1982; Mizrahi and Nerd 1996). In all of the tested ecozones we only established fruiting mongongo trees in the Besor region with moderate temperatures and good quality irrigation water (Nerd et al. 1990).

A species which performed very well in most tested ecozones is the African plum (*Harpephyllum caffrum* Bernh. ex C. Krauss, Anacardiaceae). This wild tree of Southern Africa produces many small, tasty, aromatic, red fruits in bunches with different hues. However, there are problems that inhibit cultivation. First, the fruit is very small (few grams) and hence labor intensive and second the flesh is only 10% of the total weight. However it can be used for home gardens and city and park gardening with fruits that children and others will enjoy picking.

CACTI

Of the many plant families we have explored, the Cactaceae is the most important one for Israel, since water is the major limiting factor and becomes scarcer every day. In the future, the water authorities think that only recycled water will be used for agricultural production. The high water use efficiency of the cacti stems from their Crassulacean acid metabolism (CAM) pathway (Gibson and Nobel 1986; Nobel 1994; Mizrahi et al. 1997). Cacti have many uses as crops (Mizrahi et al. 1997). Our efforts have concentrated on fruit production of the unknown pitayas and not on the well-known prickly pear now called cactus pear [*Opuntia ficus-indica* (L.) Miller] that is already grown world-wide (Mizrahi et al. 1997, Mondragon Jacobo 1999, 2001).

Pitaya is a common name to many genera and species of cacti, all with elongated coloumnar stems (Ortiz 1999, 2001). Most of our work was recently reviewed (Mizrahi and Nerd 1999; Nerd et al. 2002) and here we would like to concentrate on updating the data and on the take-home-lesson and consequences from dealing with “real new crops.” These crops are not well known and there is great confusion about their botanical identity. We shall describe briefly each one of the species that have made their way into the European markets.

Vine Cacti

Yellow pitaya [*Selenicereus megalanthus* (Schum.) Britton & Rose], is a vine cactus that needs a trellis system for support. In Israel net-houses are required to avoid photo-inhibition and bleaching of its stems (Mizrahi and Nerd 1999; Nerd et al. 2002). Colombia was the first country to sell *S. megalanthus* in the world market under the name “yellow pitaya.” Until now, the incorrect names of *Hylocereus triangularis* and *Hylocereus undatus* have been used to describe this plant (Weiss et al. 1995). This plant can tolerate high temperatures more than the other vine cacti, yields spiny fruits where the spines abscise easily upon ripening and are unseen by consumers (Fig. 1). The fruits are smaller than the other vine cacti fruits but the taste is superior, hence, the higher prices obtained in the markets in comparison with other vine cacti. Most of the plantations in Colombia have been uprooted due to heavy infestation with fungi (Bibliowicz and Hernandez 1998). We found that desert environment is better than tropical, both from the phytosanitary point of view and the possibility to control and regulate plant production via irrigation, fertilization, and manipulation of shade regimes (Raveh et al. 1996; Mizrahi and Nerd 1999; Nerd et al. 2002).

Fig. 1. Fruit of the real yellow pitaya—*Selenicereus megalanthus*. Notice the tubercles on the fruits' peel, before ripening they contain large spines (1–2 cm), which abscise easily upon ripening.

The red pitaya [*Hylocereus undatus* (Haworth) Britton & Rose] is known in Latin America but the Asian name is dragon-fruit (Fig. 2). There are red flesh clones but we do not know where they are produced. Some red flesh pitayas are produced in Nicaragua and are considered *Hylocereus costaricensis* (Weber) Britton & Rose. In Israel we cultivate *Hylocereus polyrhizus* Weber. Guatemalan researchers refer to it as *Hylocereus undatus* (Mizrahi and Nerd 1999). Pigments differ among the clones and species, and have not been fully explored. For example the *Hylocereus* sp. clone 10487 has red color while the *H. polyrhizus* clones show glowing purple, a unique color, which has been chemically identified as hylocerenin and iso-hylocerenin (Wybraniec et al. 2001). The major problem which exists in these plants in desert areas is their sensitivity both to low and high temperatures (Mizrahi and Nerd 1999). Since variability in these characteristics exist among genotypes, and since there is no genetic barrier among species and even genera, breeding may solve these problems (Lichtenzveig et al. 2000; Tel-Zur et al. 2001). Other important problems with these fruits which might be solved with breeding, is the bland taste and lack of distinct flavor. Sellers of these fruits in Europe claim that the dragon fruit and other red pitayas, which exist today in the market, are bought for their beauty and used mainly for decoration (A. Ronen unpubl. information). Our first hybrids released lately to our growers, exhibit much better taste than the original clones. However there is a lack of effort for breeding tolerance to extreme desert conditions, because of what we consider to be "establishment antagonism." We are convinced that in addition to marketing issues genetic and physiological R&D efforts are required to convert these exotics to mainstream commodities in the world markets.

Fig. 2. Fruit of red pitaya (Dragon fruit in Asia) *Hylocereus undatus*. Note that the fruit contains scales that shrivel post harvest, and they are the main reason for loss of fruit value.

Columnar Cacti

Among the various columnar cacti we believe that the most promising one is *Cereus peruvianus* Britton and Rose, which might be the same species as the *Cereus jamacaru* (Nerd et al. 1993; Mizrahi and Nerd 1999; Gutman et al. 2001). The plant is columnar with many branches (Fig. 3). Columns may bear spines to various degrees and length, but the fruits are smooth and totally spineless. The fruits are medium in size, and vary in skin color from yellow to red with various hues. Flesh is white and aromatic with a delicate sour/sweet taste. Black seeds are embedded in the flesh, but are soft and edible reminiscent of kiwifruit seeds (Fig. 4). Israel was the first country to sell this fruit both in the domestic market and in Europe (Fig. 5). Efforts have been carried out in the US and Australia to introduce this unique fruit to their markets. This plant might have other industrial uses because of polysaccharides which may be extracted from its stems (Alvarez et al. 1992). Stem pruning is necessary to ensure efficient fruit harvest. Our results in domestication of this fruit was recently reviewed (Mizrahi and Nerd 1999; Nerd et al. 2002) and here we would like to discuss difficulties in marketing which might hamper introduction. In Israel there are only a few producers. One producer is marketing the fruit at the proper stage of ripeness, with each package containing a leaflet describing the fruit, how to use it fresh, its other uses, storage and nutritional information. However, others sell it in simple boxes with other fruits, at various stages of ripening, from unripe, to ripe and over-ripe, without explanatory leaflets, acts which damage the future of this newly developed fruit. In Europe columnar cactus fruit was accepted quite well but supermarket chains required 300 tonnes/year, while the quantities produced in Israel in 2001 were only 70 tonnes. Special efforts are required from the exporters to sell it in small quantities and if they are not determined to market this fruit it will not be sold. The Israeli establishment (as other establishments) is not interested in new crops. Despite these difficulties, we foresee a great future for this crop due to early and precocious yields (Fig. 6), beautiful appearance, excellent delicate taste, long shelf-life to enable export, and, above all, minimum demand for irrigation and water-stress tolerance.

Fig. 3. Five years old *Cereus peruvianus* plant, multi branched + fruits. The picture was taken at Sde Nitzan in the Western Israeli Negev Desert.

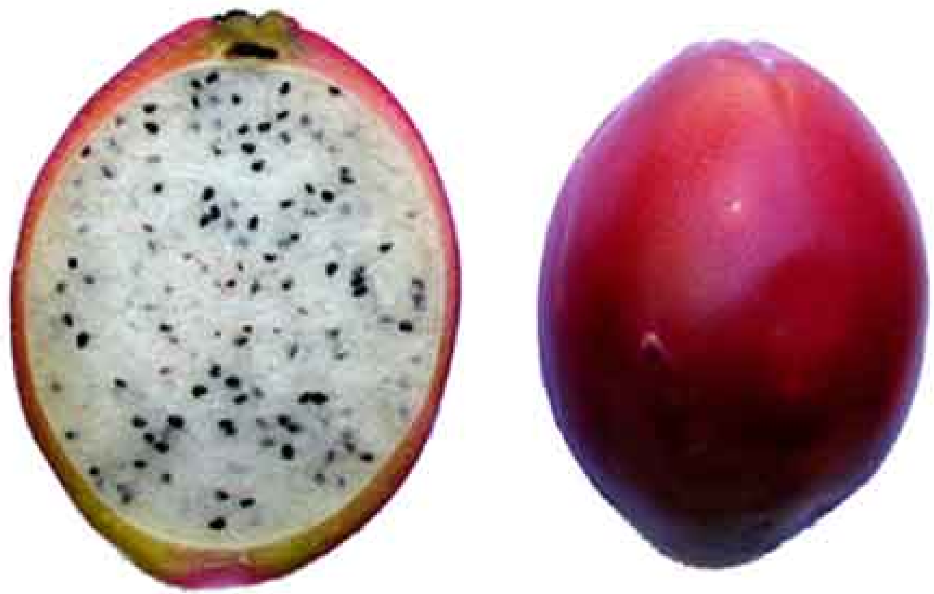

Fig. 4. *Cereus peruvianus* cut fruit. Note the smooth peel and the many black, soft edible seeds embedded in the pulp.

Fig. 5. Export box of *Cereus peruvianus* ripe fruits, ready to be shipped to Europe. The trade name Koubo is used by AGREXCO the main Israeli export company.

Fig. 6. Heavy load of fruits on 4 years old *Cereus peruvianus* plant. The picture was taken at Sde Nitzan in the Western Israeli Negev Desert.

OTHER FRUIT TREES SUITABLE FOR DESERT AREAS

Of the many fruit trees we have tested the following species are ready for the first trials to test their feasibility as new orchard crops under desert conditions. We have selected clones where we had information on tolerance to desert conditions, fruit yields, quality, and shelf life (Mizrahi and Nerd 1996). These fruits include white sapote (*Casimiroa edulis* Llave & Lex, Rutaceae) (Nerd et al 1992); black sapote (*Diospyros digyna* Jacq., Ebenaceae); desert apple ber or bor in India (*Ziziphus mauritiana* Lam., Rhamnaceae); marula from Southern Africa [*Sclerocarya birrea* (A. Rich) Hochst. sbsp. *caffra* (Sond.) Kokwaro, Anacardiaceae] (Weinert et al. 1990; Nerd and Mizrahi 2000); argan [*Argania spinosa* L. (Skeels), Sapotaceae], wild tree of Morocco, the best culinary oil is extracted from its seeds (Prendergast and Walker 1992; Nerd et al. 1994); and sapodilla [*Manilkara zapota* (L.) van Royen, Sapotaceae], from South East Asia, which is already a crop in many warm countries (Morton 1987). Some of these species (pitaya, white and black sapotes, and sapodilla) are also recommended for tropical zones such as Northern Queensland in Australia (Finocchiaro 2001). Unfortunately there is a lack of support to develop these and other new crops and farmers are afraid to take the risks. The daring farmers of Israel are already involved in production of various pitayas.

Another interesting fruit, which has not reached the R&D stage, is the monkey orange. It consists of three main species as follows: *Strychnos cocculoides* Backer; *S. spinosa* Lam.; and *S. pungens* Solereder, Loganiaceae, all native to Southern Africa (Wehmeyer 1966; Fox and Norwood-Young 1982; Taylor 1986). *Strychnos pungens* did not survive in any of our introduction orchards. *Strychnos cocculoides* which is considered the best of the three (in terms of eating quality), survived only in the Besor region (good quality water and moderate temperatures) and some trees started to bear fruits not of very high quality. It is too early to judge its performance. So far the best of the three under our conditions is *S. spinosa*. It survived in three of our introduction orchards and performed very well in the Besor area (Fig. 7). We have around 15 fruiting trees with high variability for growth, yields, fruit size, ripening season, and taste. Some of the seedlings bear astringent, bitter fruits, other bear very sour ones but two of the trees bear excellent tasty fruits. In organoleptic taste tests, people were requested to compare the monkey orange fruit with familiar fruits; the most common answers were, orange, banana, and apricot, and all possible combinations among them. The fruits emit a delicate aroma reminiscent of the spice clove. GC/MS analysis performed by Ephraim Lewinson of Newe Ya'ar, (ARO Israel) found eugenol, the essential oil found in clove (unpubl. results). Over 90% of the panel claimed that it was very tasty. Various products such as juices and dry fruit rolls are potential uses for this fruit. The fruit is large (400–1200 g), (Fig. 8), round, has a thick shell 4–7 mm, and contains 30%–45% juicy flesh with over 20% total soluble solids, and high acidity (over 200 μeq H^+/gFW).

Fig. 7. Six years old tree of monkey orange Strychnos spinosa bearing fruits. The picture was taken in the Besor Research Farm, in the Western Israeli Negev Desert.

Fig. 8. Open fruit of monkey orange Strychnos spinosa. Note the very thick peel.

We are aware of the difficulties in introducing a new product into a market which is full of other temperate and tropical fruits. The first questions we are asked is—who needs these strange fruits? Who is going to buy them? For how much? What is the volume that the market can receive? All these are legitimate questions, which are discouraging for the establishment to deal with. On the other hand it is quite clear that apples and citrus fruits will struggle to withstand the changing economic and climatic conditions (Vietmeyer 1990). Also it is known that among the affluent class in the Western societies there is an increasing demand for exotic fruits and vegetables and some such as kiwifruit have become mainstream products (Anon. 2000).

The health profile of these new fruits is unknown and needs to be explored. For example the non-proteinecious amino acid, taurine was found in Opuntia ficus-indica, in spite of the common belief that the main source of taurine in our diet, comes from animals especially sea-food (Stitzing et al. 1999). Taurine is an important ingredient in the so called "energy drinks" with proven positive activity on human well-being (Seidl et al. 2000). In spite of all these arguments, exotic new fruit trees have received strong antagonism from all possible established organizations, such as the officials in the Ministry of Agriculture, Associations of Fruit Growers, and the main Export Company AGREXCO. We conclude with a plea from a report which speaks for itself.

> *"Every production system and every mature organization is equipped with antibodies against deviations from routine. These antibodies work overtime to kill all interest in the new product and are very likely to succeed. It is an innate property of every established industrial organization, which is why most new products are created and brought to market by young organizations that have no standard products to occupy them. Established organizations (Israeli agriculture among them) that want to get into this business of introducing new products have to build themselves managerial mechanisms designed to act as a countervailing weight against the forces of routine."*

Yshai Sfarim (1989)

Winter purslane

Cuban spinach

Portulacaceae *Montia perfoliate* Howell

Source: Magness et al. 1971

Winter purslane is a short-lived annual with opposite, somewhat fleshy leaves mostly rising from the root, generally ovate in shape and up to 3 inches long. The plant is mainly grown in winter in warm countries, and the leaves are used as salad and pot herbs. Exposure of edible parts is comparable to that of spinach.

Velvet bean

Leguminosae *Mucuna deeringiana* (Bort.) Merr.

Source: Magness et al. 1971

This is a strong-growing annual plant native to the tropics. Most of the several varieties grown in the United States are *M. deeringiana* although some kinds are of other *Mucuna* species or interspecies hybrids. The slender stems may grow to 30 feet in some kinds. They are mainly grown with a support crop, usually corn, on which they climb and are partially supported. The leaves are trifoliate, with large ovate leaflets. Pods are pubescent, up to 6 inches long, with 3 to 6 seeds per pod. Velvet beans are well adapted to sandy soils and require a long growing season to produce much pasturage. They are grown mainly in the Southeastern Coastal Plain for late summer pasturage and soil improvement. All parts of the plant are nutritious and palatable to livestock.

Sweetgrass: History, Basketry, and Constraints to Industry Growth

Robert J. Dufault, Mary Jackson, and Stephen K. Salvo

Sweetgrass is a native, perennial, warm-season grass found growing sparsely in the coastal dunes extending from North Carolina to Texas. The "treads" or long, narrow leaf blades of this grass have been harvested by direct descendents of enslaved Africans of antebellum South Carolina and used as the principle foundation material for constructing African coiled basketry in the Southeast, especially near Charleston (McKissick Museum 1988). Originally, these graceful products provided useful, practical objects or "work baskets" for agricultural and household use on the plantations; today, they have evolved as souvenirs treasured by tourists, and elegant objets d'art (Fig. 1).

Basketmakers are faced with changes and challenges that threaten the existence of their craft. The supply of sweetgrass is becoming more difficult to acquire because the natural habitats of sweetgrass have significantly diminished. Two primary factors have led to this situation. First, the urbanization of the area around Mt. Pleasant has led to the destruction of much of the natural sweetgrass plant communities. Second, the traditional gathering areas on the Barrier Islands off the coast of Charleston, have been developed as beach resorts or private communities with restricted access. Basketmakers now have to travel to Georgia and Florida to find adequate supplies.

Natural habitats of sweetgrass need to be preserved, protected, or relocated if this industry is to continue. The basketmaking community will need help from local governments to continue to sell baskets along the old Ocean Highway (Hwy 17) or relocate the stands to equally visible, safe locations. Alternatively, the ability to cultivate sweetgrass on inland soils in the Mt. Pleasant area would enable the production of readily available raw material. These practices would help to insure that the heritage of basketmaking will continue to flourish into the 21st century.

SWEETGRASS INDUSTRY

Mt. Pleasant, South Carolina, is located four miles north of Charleston on U.S. Hwy 17. Baskets are sold in a variety of places in the Charleston area. About 75 basket stands dot the old Ocean Highway in Mt. Pleasant. Baskets are also sold by the "basket ladies" in Charleston's Market area and even on major intersections within the historic areas of the city.

About 300 families are involved in sweetgrass basketry of which approximately 75% are full-time basketmakers and 25% are part-time (Mary Jackson pers. commun.). Twenty-five years ago, approximately 1,200 families were involved in basketmaking and this represents a 75% decline in the basketmaking community.

HISTORY

The variability of African baskets is as diverse as the 800 different ethnic groups that comprise the African people (Vlach 1978). Only certain African people however, especially those from Senegal, were brought to South Carolina as early as 1505 with the advent of the slave trade in the New World. By the end of slavery around 1808, Africans were abducted from areas down to Central Africa and Mozambique.

Rice was the main cash crop of South Carolina during the colonial period and the base of the State's economy until the 19th century. Slavers were paid premium prices for Africans from the West African Rice Kingdoms of the Windward Coast (Senegal to the Ivory Coast) and the mouth of the Congo River (Gabon, Zaire, and Angola) (Littlefield 1981). A man or women who made baskets was worth more than one who did not, age, strength, and other skills being equal (Chas. Gaz. Adv. 1791). Since colonial South Carolinians knew little of rice culture, the success of the American Rice Kingdom is credited to enslaved Africans (Joyner 1984).

The technique of basketmaking crossed the Atlantic in slave ships and took root in the new land. The art of making sweetgrass baskets is a three-century old African-American tradition that has been "passed-down" over the centuries from parent to offspring. Sweetgrass basketmaking is one of the earliest traditional rafts with a rich documented history from "carryover" from African enslavement and plantation days to the present (McKissick Museum 1988). Although the materials used are different in the United States, the form and function of the African counterparts of sweetgrass baskets are unchanged to this day (Mary Jackson pers. commun.).

Folk history recounts that enslaved men and women weaved African coiled baskets to fan rice in order to separate the grains from the chaff. After the Emancipation Proclamation in 1863, former slaves were dedicated to preserve the African traditions of their ancestors. A reaffirmation of this goal has been made by each generation of the descendants of enslaved Africans and sweetgrass basketry is a symbol of this devotion.

SWEETGRASS IDENTITY AND HABITAT

Sweetgrass (*Muhlenbergia filipes* Curtis, Poaceae) was first identified and described botanically by Moses Ashley Curtis in 1843 and later by Pinson (1971). There is still a dispute as to whether sweetgrass should be identified as a variety of *Muhlenbergia capillaris* or remain a distinct genus and species (Rosengarten 1987). There is a lack of concise, comprehensive descriptive information on this species (Pinson and Batson 1971.)

Sweetgrass grows in bands about 50 to 75 m from the mean high tide line in undulating sand dunes usually behind the first dune along the ocean from North Carolina to Texas. Occasionally, plants are found growing on well-drained, sandy uplands bordering brackish marshes and in open maritime forests (Pinson and Batson 1971). Sweetgrass grows on many of the barrier islands along South Carolina's coast, such as, Kiawah, Seabrook, Dewees, Bulls, Fripp, and Hilton Head.

BASKET CONSTRUCTION

Rosengarten (1987) has provided an excellent review of basketry technique. Coiled basketry involves sewing or stitching unlike other types of baskets that are woven. Each basket begins with a small knot of long-leaf pine needles (*Pinus palustris* Mill.) or the fine-threaded sweetgrass. Pine needles may be used throughout the basket to provide a russet color that contrasts well with the more yellow sweetgrass. Coarse, thicker gauge black rush (*Juncus roemerianus* L.), also known locally as "bulrush, rushel, or needlegrass", may be added to the inside of the baskets for strength. Black rush turns a rich tawny color when dried. Strips of palm leaf (*Sabal palmetto* Lodd.) are used to sew the rows of coils to each other. A hole for the palm strips is made with a bone (a spoon with the bowl removed and the end smoothed and polished), nail, or bagging needle. Shape of the baskets is created by building upon the foundation, one row at a time and then row upon row. The coils of material must constantly be fed with new grasses to maintain a constant foundation of uniform thickness. The strength of the basket depends on how firmly the stitches are pulled. Today, baskets of great variability are constructed by modifying the amounts of these materials to create subtle changes of tone and radical change of texture.

CONSTRAINTS TO INDUSTRY GROWTH

The development of South Carolina's barrier islands and beach fronts has increased the areas economic prosperity and tourism which has been helpful to the basketmakers. However, changes in land ownership, land use and lifestyles have destroyed many plant communities or restricted access to remaining local sweetgrass habitats. Expensive and long journeys to Georgia or Florida are now necessary to gather raw materials. Political help is needed to preserve and protect natural sweetgrass habitats from destruction. Research is needed to learn how to domesticate this wild plant and cultivate sweetgrass as a row crop.

JUSTIFICATION FOR PRESERVING SWEETGRASS BASKETRY

The traditional basket stands along the Ocean Highway are being unintentionally forced out of the community by construction of shopping malls and business parks with road frontage along the highway. These stands have been located on this highway for over 60 years. The display of African baskets has been a major source of income for many basketmakers as well as providing tourists an appreciation of the beauty, significance, and value of this ancient art form. The danger in displacement from traditional marketing areas is that basketmakers would have very few alternatives to sell their baskets in highly visible locations. This frustration may require them to seek other sources of income and cause a loss of basketmakers from the community.

The Mt. Pleasant basketmaking community has become known throughout the United States and abroad for their art. Today, the baskets have become a symbol of coastal South Carolina. The downtown area of Charleston has over 2,000 buildings registered with the Historic Society, yet basketmaking is truly the only "live" viable symbol or relic of the extinct plantation days of colonial times. After 300 years, this tradition, as well as historic buildings, are the trademarks of Charleston. Postcards and photographic illustrations commonly depict basketmakers and their art. African coiled basketry are objects of scholarly research and commonly are featured in newspaper and magazine articles in the United States and abroad. Sweetgrass baskets are displayed in art galleries, traveling exhibits, and have been displayed in the Smithsonian, Vatican, and Gibes Art Museum in Charleston and other museums.

In 1988, the Mt. Pleasant Basketmakers' Association was formed. The function of the Association is to organize the basketmakers into a cohesive group and to form a common voice to influence the management of their resources. The Association's purpose is to promote, preserve, and protect the tradition of sweetgrass basketmaking.

The first Sweetgrass Basket Conference was held on March 26, 1988 to discuss the basketmaking tradition, biological assessment and ecology of sweetgrass resources, impact of coastal development and public and private concerns in relation to the basket industry (McKissick Museum 1988). Through the activities of the Conference, many immediate pledges of public and private aid were offered.

In October, 1988, the Town Council of Mt. Pleasant resolved to make preservation of the basket stands a goal of the zoning process. In December, 1991, the Sweetgrass Preservation Society was formed by the Mayor of Charleston to help the basketmakers work on strategies to help protect and preserve their craft and tradition.

The art of sweetgrass basketmaking has evolved from a practical craft, to a curio, to a genuinely valuable artform. The sweetgrass basketmaking tradition is a crucial element of the African cultural tradition. The descendents of enslaved Africans possess an intimate, loyal, and loving bond of their ancestry and heritage in colonial South Carolina and Africa. Sweetgrass basketmaking is the "living" symbol of this passion.

Mullein

Verbascum thapsus L.

Figure 79.—Mullein (*Verbascum thapsus*)

Other common names.—Common mullein, great mullein, mullein dock, velvet dock, Aaron's-rod. Adam's-flannel, old-man's-flannel, blanket leaf, bullock's lungwort, cow's lungwort, clown's lungwort, candlewick, feltwort, flannel-leaf, hare's-beard, velvet plant.

Habitat and range.—Mullein is a weed found in fields, pastures, along roadsides, and in waste places, its range extending from Maine to Minnesota and southward. It is also spreading in the Western States.

Description.—This plant is easily recognized by its tall, straight stem, its large felty or flannellike leaves, and its long, dense spike of yellow flowers. During the first year it produces only a rosette of downy leaves followed from June to August of the second year by the long flowering stalk. The densely hairy, erect stem sometimes reaches a height of 7 feet. The thick, felty leaves are from 4 to 6 inches in length and, with the exception of the basal ones, are stemless.

Part used.—The flowers and leaves, the former collected when fully opened.

New Crop Development in New Zealand

James A. Douglas

New Zealand lies between the 33° to 53° south latitudes in the South Pacific about 1,600 km east of Australia. It consists of two main islands similar in size to Japan or the British Isles. The climate is temperate and dominated by a westerly wind flow within an oceanic environment that gives a weather pattern which is changeable over short periods. In the southern main island a mountain chain exceeding 3,000 m in height modifies the weather pattern. The country as a whole is subject to extremes of wind and rain with annual rainfall varying from below 400 mm to over 12,000 mm in the Southern alps. Summer droughts are common in many areas and all regions of the country experience frost except the northern part of the North Island.

New Zealand has been settled by Europeans for 170 years with the total population now 3.3 million. About 18 million hectares are occupied with pastoral farming being the major form of land use. In 1988, New Zealand had 65 million sheep, 8 million beef and dairy cattle, 1.3 million goats, and 0.6 million farmed deer. Primary products from these stock, forestry products, fruit and vegetables, and fish make up 64% of the New Zealand export trade of $NZ15 billion ($NZ = 0.59 US$, 1991). The important point about this trade is that, with the exception of fish, it is based on animals and plants which have been introduced into New Zealand over the past 150 years. The pastoral industry is based on the European pasture species perennial ryegrass (*Lolium perenne* L.) and white clover (*Trifolium repens* L.), the forestry industry on the Monterey pine (*Pinus radiata* D. Don) from coastal California, and the fruit industry on the Eurasian apple (*Malus* x *domestica* Borkh.) and the kiwifruit [*Actinidia deliciosa* (A. Chev.) C.F. Liang & A.R. Ferg.] from China.

NEW CROP PROGRAM

The wide range of climatic variation in New Zealand from low to high rainfall, cool temperate to marginally subtropical gives a capacity to grow a very wide range of crops. The difficulty has been to narrow down the number of potential crops from those which are environmentally feasible to those which are profitable. To do this, the focus has been moved from examining what crops will grow in New Zealand to using market intelligence to identify crops with defined international or niche market opportunities and then working back to the feasibility of production in New Zealand. Published information about target markets has been used to identify growth areas within markets but often this information is too generalized to identify specific crops. Consequently, these desk studies have been followed up by commissioned within market investigations to gather the detailed information required to identify crops which have established markets but which are not currently grown in New Zealand. Available literature has been collected on each crop to characterize their environmental requirements and assess the likely adaptation to New Zealand conditions. Target crops are sourced, plant material imported, and grown in preliminary trials to assess their local environmental adaptation and their ability to produce the product required by the market place. Crop samples are sent to the target markets to assess the quality standard and market acceptability. Crops which exhibit potential proceed to more sophisticated trials with a greater selection of cultivars to determine their specific environmental, agronomic, and postharvest requirements to optimize yield and quality parameters.

The new crops program is carried out at a number of research stations which span the major island environments (Fig. 1). Climatic recordings from these research stations or close by, listed in Table 1, indicate the temperate nature of the New Zealand environment. In summer, temperatures above 30°C are uncommon and in winter, snow is normally only a one or two day phenomena in the southern regions. There are six programs: new export vegetable crops; European and Asian medicinal herbs; culinary herbs and essential oils; edible fungi; fruit; nuts; and ornamentals.

NEW EXPORT VEGETABLES

Research on new export vegetables has concentrated on investigating the requirements of the Japanese market. Already, New Zealand exports significant volumes of squash, asparagus, and onions to Japan. Traditional Japanese vegetables, which are not widely known outside Japan, have strong internal demand. The possibility of growing such vegetables in New Zealand and exporting them to Japan provide the basis of this program. New Zealand has many climatic features similar to Japan and is environmentally suitable to produce Japanese vegetables. The major constraint is the need to choose vegetables which have sufficient shelf life so that they can be freighted to Japan in good condition.

Subsequent to an examination of Japanese market information, two crops, wasabi [*Wasabia japonica* (Miq.) Matsumara] and myoga ginger (*Zingiber mioga* Roscoe), were identified as having strong market potential. Research began on wasabi in 1982 and myoga in 1983.

Wasabi

Wasabi or Japanese horseradish is a native perennial crucifer of Japan which is used as a traditional condiment of Japanese food. It requires specific conditions of light and water to thrive. In Japan, the highest quality fresh product is grown on tree shaded, terraced gravel beds covered by a thin layer of cool running water from mountain streams or on artificially shaded mounded gravel ridges formed in larger river beds (Hodge 1974; Follett 1986). Lower quality wasabi for processing is grown in soil.

Wasabi plants grow poorly in New Zealand in full sunlight and artificial shading is required to keep the light levels below 700 µmol m^{-2} s^{-1} otherwise the plant is liable to wilt. Japanese recommendations of using 50% shade cloth were inadequate under New Zealand conditions and a further 30% shade cloth was required during the summer. Further research on the shade requirement of wasabi is needed.

The initial New Zealand trials on wasabi were established in large concrete troughs filled with rock and gravel similar to the tatami ishi wasabi beds of Shizuoka, Japan. Spring water of 13° to 14°C was flowed over the beds at about 160 liters/min. Unrooted cuttings were planted at 25 cm centers and the crop grown for two years. Sequential harvests from 15 months indicated that there was a need to leave the crop at least 18 months before harvest to achieve a reasonable production of stems over 50 g (Table 2).

Wasabi has a number of major pests and diseases and is known to suffer from various mosaic viruses which can cause rapid crop decline if successive crops are grown from infected sideshoot cuttings. Regular spraying is required to control aphids and white cabbage butterfly caterpillars. Leaf diseases such as white rust (*Albugo* sp.) are also controlled by foliar sprays but the more difficult diseases to control include the stem and root fungal diseases, *Phoma* and *Botrytis* and bacterial softrot, *Erwinia*. Control of these diseases is largely unresolved in the natural running water systems.

Considerable progress has been made in New Zealand in the past 5 years on how to grow wasabi to produce a marketable crop, but it is only the beginning. A greater understanding of the physiology of the crop in relation to its environmental requirements, improved cultivars, and better disease control should all allow higher yields and more efficient production methods to be developed. Research in these areas is underway.

Myoga Ginger

Myoga ginger (*Zingiber mioga* Roscoe), a cold tolerant member of the ginger family (Zingiberaceae), is a native perennial of Japan grown as a traditional Japanese vegetable for its spring shoots or its summer/autumn flower buds. The production of flower buds is highly seasonal and consequently there is an opportunity for a southern hemisphere producer such as New Zealand to supply myoga to Japan when their supplies are low.

Preliminary research on myoga was conducted in New Zealand by Palmer (1984) and following an investigation of Japanese production systems (Follett 1986) further plants were introduced. The plant is established vegetatively from rhizome sections with faster and more even plant emergence from coolstored rhizomes (Follett 1991). The plant is frost sensitive and dies down in winter but the dormant rhizomes have proved to be quite winter hardy (Palmer 1984). Myoga is vigorous and largely disease and pest free when grown on free draining soils, although rhizome rotting from *Fusarium* and *Pythium* species has been noted on poorer drained soils. Under New Zealand conditions, myoga topgrowth sunburns and becomes chlorotic without shading and consequently trials have been established under 50% shade cloth. A comparison is presently being made between artificial shade and natural shade given by spaced Paulownia (*Paulownia elongata* S.Y. Hu) trees.

Myoga production beds established with 30 cm between rhizomes and 1 m between rows have yielded 6.75 t/ha of flower buds in the second year. This is comparable to Japanese production levels. The flower buds develop from underground stems on the edge of the plant mass and to achieve top quality produce, the buds should be picked before they emerge and turn green. To facilitate this, a 10 cm layer of sawdust was applied so that the buds could be located by fossicking and picked. Picking was carried out every 2 to 3 days over a 2 month period.

Myoga is a very new crop in New Zealand with little grown commercially. There remains considerable research to be undertaken in defining its agronomic management but research results to date and the successful test marketing of New Zealand grown myoga indicate that it is likely to be a successful new crop for New Zealand.

Medicinal Herbs There is a large and expanding international market for medicinal herbs and plants for the manufacture of pharmaceuticals (Principe 1989). New Zealand has no significant production of these products although in the late 1970s commercial extraction of solasodine from the native *Solanum* species (*S. aviculare* Forst., *S. laciniatum* Ait.) was begun but later abandoned (Mann 1978; Mann et al. 1985). Nevertheless, the New Zealand environment provides good conditions for the growth of a wide range of medicinal herbs and in many instances they are familiar as weeds. Examples include dandelion (*Taraxacum officinale* G. Weber), St John's wort (*Hypericum perforatum* L.), horehound (*Marrubium vulgare* L.), burdock (*Arctium lappa* L.), Variegated thistle [*Silybum marianum* (L.) Gaertner], briar rose (*Rosa rugosa* Thunb.), and hawthorn (*Crataegus monogyna* Jacq.).

The current research program is focussed on understanding the agronomic requirements of seven medicinal herbs: coneflower [*Echinacea purpurea* (L.) Moench], valerian (*Valeriana officinalis* L.), *Arnica montana* L., dandelion, feverfew (*Chrysanthemum parthenium* Pers.), goldenseal (*Hydrastis canadensis* L.), and ginseng (*Panax ginseng* C.A. Mey., *P. quinquefolius* L.). Test marketing of samples from preliminary research on valerian, dandelion, rosehips, and chamomile [*Chamomilla recutita* (L.) Rauschert] has already shown that these crops can be produced to international market standards. Collections of a wide range of European and Asian medicinal herbs are being assembled for preliminary evaluation of both their growth potential and quality assessment before proceeding to more sophisticated agronomic programs. A Plant Extracts Research Unit provides the quality assessment of the medicinal herbs and also produces plant extracts for examination of their biological activity. This research program is in its infancy and although few results are available, the initial indication is that a wide range of medicinal herbs should be able to be grown successfully in New Zealand.

Culinary Herbs

A wide range of culinary herbs are grown by home gardeners and herb enthusiasts in New Zealand and the more common ones are supplied fresh to local markets with a small export industry based on fresh herbs. There is however no significant industry growing herbs to supply the international dried herb market. Preliminary research has already shown that lemon balm (*Melissa officinalis* L.), lemon verbena [*Aloysia triphylla* (L'Her.) Britton], sage (*Salvia officinalis* L.), and thyme (*Thymus vulgaris* L.) have all produced good quality herbage which meets international market standards. Research has been planned on these crops as well as oregano (*Origanum vulgare* L.), peppermint (*Mentha* x*piperita* L.), and spearmint (*M. spicata* L.), to examine the environmental and agronomic requirements to produce high quality produce. It is expected that as a greater understanding of each crop is developed more emphasis will be placed on growing these crops organically.

Essential Oils

New Zealand has the potential to grow a wide range of essential oil crops but no major industry has yet developed. Considerable research has been conducted describing the essential oil content of New Zealand native species and a small industry extracts manool from the native pink pine [*Halocarpus biformis* (Hook.) Quin] (Brooker et al. 1988). Research on peppermint begun in 1968, led to some commercial planting but this industry did not persist due to the difficulties with mint rust (*Puccinea menthae* pers. commun.) (Lammerink and Manning 1971, 1973).

The current research program seeks to systematically define the oil yield, composition analysis, and international quality assessments of a number of species (Table 3). The results have been very encouraging from this research and commercial extraction of essential oil and sclareol from clary sage is currently under investigation. Agronomic trials have been established to examine the influence of cultivars, environment, weed control, time of harvest, and distillation on oil yield and quality.

Edible Fungi

New Zealand has an industry based on the cultivation of the button mushroom [*Agaricus bisporus* (Lange) Sing.] and a growing interest in the cultivation of shiitake [*Lentinula edodes* (Berk.) Sing.]. In the past, a small industry has been based on the collection of the jelly fungus *Auricularia polytricha* (Mont.) Sacc. to supply the Chinese market (Brooker et al. 1988).

The current research program is directed at developing techniques to establish and produce the sought after mycorrhizal fungi, black truffle (*Tuber melanosporum* Vitt.), white truffle (*T. magnatum* Pico.), matsutake [*Tricholoma matsutake* (S. Ito & Imai) Sing.], and cep (*Boletus edulis* Bull.). Research has successfully devised techniques to inoculate black truffle onto oaks and hazels and although the fungus is evident in the field no truffle production has yet occurred (Hall and Brown 1989).

Fruit, Nuts, and Ornamentals

Research on new fruits is directed at identifying appropriate cherimoya (*Annona cherimola* Mill.) cultivars for the northern regions of New Zealand. There are now over 60 named cherimoya cultivars in New Zealand and evaluation continues to seek a fruit which has the attributes of high yield, smooth skin, low seed number, good flavor, and a reasonable shelf life (Anderson and Richardson 1990). At the present time, there is no cherimoya industry in New Zealand.

There is a small and developing industry on macadamia (*Macadamia integrifolia* Maiden & Betche, *M. tetraphylla* L.A.S. Johnson) nuts in New Zealand but low yields limit the commercial success (Richardson and Dawson 1991). Research is continuing on evaluation of cultivars from mainly Australian and Hawaiian sources and investigating the effect of pollination and nutrition on crop yields to highlight possible ways to increase yields.

Preliminary research has begun to better define pollination of chestnuts (*Castanea sativa* Mill., *C. crenata* Siebold & Zucc.) and identification and control of fungal pathogens which spoil stored nuts. Small commercial plantings of chestnut have taken place based mainly on superior selected trees from local seedlings and there is a need for further cultivar evaluation.

Biogeographic principles are being used to pinpoint sources of appropriate plant material for new plant introductions into New Zealand where there are perceived market potentials not currently being addressed. Particular emphasis is being directed towards sourcing plants from the enormous germplasm resource of South America. Species collected are fed into the herb, essential oil, fruit, and ornamental programs. New ornamentals obtained in South America such as some *Begonia*, *Ennealophus*, *Fuchsia*, and *Tibouchina* species which are new to New Zealand are evaluated for growth habit, flowering behavior, and postharvest shelf life to estimate their potential as cut flowers or potted plants.

CONCLUSION

The emphasis in this research program is to identify and develop new export trade opportunities for New Zealand. The focus is on what the marketplace demands both in terms of type and quality of product. To reach this endpoint the new crops program is built around an approach of identifying the market opportunity, evaluating the adaptability and productivity of the new crop, and test marketing samples of the crop to be assured the product reaches market specifications. In this way, the New Zealand new crops program has a clear focus and clearly defined goals. The program is new and open-ended in relation to identifying new opportunities and although many of the crops under investigation have not been previously grown in New Zealand, we believe the approach will see many of them become established industries in the future.

Myrrh

Sweet cicely, Sweet chervil

Umbelliferae *Myrrhis odorata* (L.) Scop.

Source: Magness et al. 1971

The myrrh plant is a pubescent perennial, up to 3 feet in height, with thin, soft, pinnate leaves. Leaflets are lanceolate. Leaves, tender stems, and roots are sweet scented. The plants persist for years. Formerly myrrh was used for flavoring salads. Now apparently little grown, except as an ornamental.

Narrow Dock

Rumex crispus L.

Figure 80.—Narrow dock (*Rumex crispus*)

Other common names.—Yellow dock rumex, curled dock, sour dock.

Habitat and range.—This troublesome weed is now found throughout the United States, in cultivated as well as in waste ground, among rubbish heaps, and along roadsides.

Description.—Narrow dock has a deep spindle-shaped root from which arises an erect, angular, and furrowed stem, attaining a height of from 2 to 4 feet. The stem is branched near the top and is leafy, bearing numerous, long, dense clusters formed by drooping groups of inconspicuous, green flowers arranged in circles around the stem. These are followed by the fruits, which are in the form of small triangular nuts like buckwheat grains, surrounded by three very small veiny leaves. As the clusters ripen they become rusty brown. The lower leaves of the yellow dock are blunt, from 6 to 8 inches in length, with long stalks, while the upper leaves are narrower, only 3 to 6 inches in length, short stemmed or stemless. The root is large and fleshy, usually from 8 to 12 inches long, tapering or spindle shaped, with few or no rootless.

Part used.—The root, collected late in the summer or autumn after the fruiting tops have turned brown. They are washed, either left entire or split lengthwise into halves or quarters, and carefully dried.

Nasturtium, Garden

Indian cress

Tropaeolaceae *Tropaeolum majus* L.

Source: Magness et al. 1971

The plant is a somewhat succulent, climbing annual, with nearly round smooth leaves, 3 to 5 inches in diameter. The pods are near globular, ridged, about 0.33 inch in diameter. Nasturtiums are widely grown as ornamentals, but the peppery flavored leaves are sometimes used in salads, like cress. The young pods are made into pickles. Plants will develop pods about 4 months after seeding. While one of the most common garden flowers, nasturtium leaves and pods are used as condiments rather rarely, and appear not to be commercially grown for this purpose.

Tobacco

Solanaceae *Nicotiana tabacum* L.

Source: Magness et al. 1971

The tobacco plant is a thick-stemmed annual bearing large leaves with short petioles or leaf stems. Leaf blades are often more than 20 inches long and half as wide. They rise in a spiral along the stem. Stems grow 4 to 6 feet tall and terminate in a cluster of flowers if not topped. Except for seed production, however, plant terminals are usually removed when flowering begins in order to increase size and thickness of leaves - the marketable portion.

Plants are usually started in beds under cloth cover in early spring and moved to the field after all hazard of frost is past. Growth in the field from setting to harvest covers 3 to 5 months. Harvesting may consist of removing most mature leaves by hand at about weekly intervals or cutting the whole stem. The former method is more generally used as it gives higher leaf yield and better quality. Leaves are then dried by one of several processes. In flue-cured tobacco, heat is applied in such a way that no smoke reaches the leaf hung in racks. In fire-curing, open fires are used and the smoke results in a darker colored, distinctlv flavored leaf. In air-cured tobacco no heat is added except as necessary to prevent mold during humid periods. Kinds of curing depends on type of tobacco grown and ultimate use.

Cigar wrapper tobacco, grown mainly in Connecticut, is produced under partial shade - resulting in thinner leaves and less damage to the leaves.

In the final products from tobacco (cigarettes, pipe tobacco, cigars, chewing tobacco, and snuff) the leaf midribs and larger veins are largely removed. They may be processed to obtain nicotine insecticides or used as mulching material. They are not used as feed.

Tobacco was grown on 967,000 acres in the United States - average acreage for 1966-67. Almost 66% of this was flue-cured and nearly 33% aircured. Less than 3 percent was fire cured. Around 50,000 acres was devoted to cigar tobacco.

Peach and Nectarine

Rosaceae *Prunus persica* (L.) Batsch

Source: Magness et al. 1971

Peaches and nectarines are relatively large fruits with large, deeply ridged stones. Fruit 2 to 3.5 inches diameter. Peach fruits are pubescent throughout the growing season, and are usually brushed by machine prior to marketing to remove most of the pubescence. Nectarines have a smooth, plum-like peel. Nectarines have apparently originated from peaches by mutation. Trees of the two kinds are indistinguishable and are relatively small, usually held to under 15 feet by pruning. Both peaches and nectarines may be freestone - pit relatively free of the flesh - or clingstone - pit adheres to flesh. Many varieties, especially of peaches, are grown in the U.S., varying in season of ripening and climatic adaptation.

Peaches:

Season, bloom to harvest: 75-150 days, mostly 100-120 days.

Production in U.S.: About 1.800.000 tons.

Use: Fresh market, canned, dried, marmalade, baby food.

Part of fruit consumed: Mainly flesh only. Peel included in dried fruit

Nectarines:

Season, bloom to harvest: Same as peach.

Production in U.S.: About 70,000 tons.

Use: Mainly fresh eating.

Part of fruit consumed: All except stone.

Needle-and-thread grass

Gramineae *Stipa comata* Trin. and Rupr.

Source: Magness et al. 1971

This is a native bunchgrass widely distributed over the Western States and common on dry, sandy, gravelly soils of the Northern Plains. Seed stalks may reach to 4 feet. Leaves are up to 12 inches long and 0.125 inch wide. Growth starts early in spring and continues through the summer when moisture is available. The seeds are sharp-pointed and have long, twisted thread-like awns. The shape of the seed and awn account for the name. The grass is palatable and readily grazed except when in seed. This period begins in June, and the seed is shed in July. During this period the sharp seeds penetrate mouth parts and hides of stock. Although the grass is widely adapted and has many useful characteristics, it is little used for reseeding because of injury to stock while in seed.

Last update February 18, 1999 by ch

Needlegrasses

Stipas

Gramineae, Poaceae *Stipa* sp.

Source: Magness et al. 1971

Some 30 species of *Stipa* are indigenous to the Western States. They are long-lived bunchgrasses. Each spikelet has a single flower which terminates in a prominent awn, accounting for the name needlegresses. These grasses are abundant, widely distributed, cure well on the ground, and rank high for forage. The needle-like awns, however, cause injury to animals, especially sheep, and greatly detract from their otherwise value. The two most valuable species are Needle-and-thread grass and Green needlegrass.

Olive oil

Oleaceae *Olea europaea* L.

Source: Magness et al. 1971

See Olive, for tree and fruit characteristics.

Olive oil is obtained from the fleshy portion of the fruit, which contains from 14 to as high as 40 percent of non-drying oil, depending on variety and growing conditions. World production of oil totals around 1,000,000 tons annually, mainly in Mediterranean countries. For best oil, fruit is harvested just before full maturity. The fruit is crushed then pressed in various ways, depending on available facilities. Solvents are generally used for final extraction of the press cake, to obtain maximum oil yield. The oil is used as salad and cooking oil. Low-grade oils are used mainly for making soap. In the U.S., only about 5,000 tons are crushed for oil annually. Annual imports of olive oil average near 50 million pounds.

Orange, Trifoliate

Rutaceae *Poncirus trifoliata* (L.) Raf.

Source: Magness et al. 1971

The genus *Poncirus* is closely related to citrus, but the small, thorny trees are deciduous. Trees are hardier than citrus, in mid-winter enduring temperatures to near 0F. Fruits are globose, up to 1.5 inches in diameter, and very acid and bitter. *Poncirus* will hybridize with citrus, and such hybrids bave been made in efforts to increase hardiness in edible citrus fruits. *Poneirus* seedlings are used as root stocks for citrus, particularly for Mandarin oranges. Hybrids of *Poncirus* with sweet orange, called citranges, are now widely used as stocks.

Poncirus is grown as an ornamental dooryard tree in areas too cold for citrus, and occasional trees may be maintained by nurserymen as seed sources. Fruit appears valueless in the U.S., but may be used for flavoring or marmalade in other countries.

Season, bloom to maturity: 8 to 10 months.

Production in U.S.: No data. None commercial.

Use: Fruit not utilized in U.S.

Part of fruit consumed: None

Palm oil

Palmaceae *Elaeis guineensis* Jacq.

Source: Magness et al. 1971

The source of palm oil is the fleshy fruit of a tropical, spineless palm tree, native to western Africa but extensively cultivated in other tropical countries. The fruits are borne in large bunches, each of which may carry up to 20 pounds of fruit. The red fruits are oval, 1 to 2 inches long and an inch or more in diameter. The flesh contains 30 to 70 percent of nondrying oil. The seed also contains oil, the palm kernel oil of commerce.

Various methods are used to extract the oil from the pulp, including pressing or centrifuging or macerating the pulp and boiling in water, the oil floating and skimmed off. The oil is used in margarine and vegetable shortening as well as in soap manufacture in industry.

The kernel oil is extracted by crushing and pressing, or with solvents. The oil is similar to coconut oil, and is used mainly in margarine and soap.

Several other species of palm, some indigenous to South America, also yield pulp and kernel oils that are generally similar to African palm oil, but production of these oils is much less extensive. About 200 million pounds of palm oil were imported into the United States in 1966, more than half of which was kernel oil.

Vine-mesquite

Gramineae, Poaceae *Panicum obtusum* HBK

Source: Magness et al. 1971

This is a sod-forming grass, native from Missouri west to Colorado and south into Mexico, useful both for grazing and erosion control. Stems are up to 2 feet tall, and leaves are 4 to 6 inches long and 0.5 inch wide. Vine-mesquite grows in areas of low rainfall, producing a moderate amount of forage relished by livestock while green. Plants form stolons, which may grow to 15 feet in a season. Stands can be established by seeding or sod pieces.

Last update June 27, 1996 bha

Torpedograss

Gramineae, Poaceae *Panicum repens* L.

Source: Magness et al. 1971

Torpedograss is native along the Gulf Coast from Florida to Texas. It is a sod-forming grass with creeping rhizomes and upright stems reaching 2 to 3 feet in height. Leaves are flat or folded. It thrives on coarse sands and wet muck soils and grows so aggressively that it may become a serious weed. Palatability is good but it is less nutritious than many grasses. It is used to a limited extent for pasture and erosion control along the Gulf Coast.

Parthenium hysterophorus L. [syn. *Tanacetum parthenium* (L.) Sch. Bip.; *Chrysanthemum parthenium* (L.) Bernh.; *Matricaria parthenium* L, *M. parthenoides* Hort., *M. carpensis* Hort., *M. eximia* Hort., *M. odorata* Lam; *Pyrethrum parthenium* Smith] Compositae, is known as congress weed, carrot weed, star weed, feverfew, white top, chatak chandani, bitter weed, ramphool, garghas. It is believed to have entered India accidentally in the mid 1950s, and is now considered is one of the most feared noxious weed species (Rao 1956). Adverse effects of on humans and on animal health have been well documented. It is known to cause asthma, bronchits, dermatitis, and hay fever in man and livestock. The chemical analysis has indicated that all the plants parts including trichomes and pollen contain toxins called sesquiterpene lactones. The major components of toxic being parthenin and other phenolic acids such as caffeic acid, vanillic acid, ansic acid, p-anisic acid, chlorogenic acid, and parahydroxy benzoic acid are lethal to human beings and animals (Mahadevappa 1997; Oudhia 1998). Despite the fact that *Parthenium* is considered a toxic plant industrial uses are reported in the literatures (Sastri and Kavathekar 1990). A related species, *Parthenium argentatum* Gray (guayule) yields rubber which can substitute for *Hevea* rubber.

The word *parthenium* is derived from the Latin *parthenice* suggesting medicinal uses (Bailey 1960). John Lindley (1838) in *Flora Medica* describes the plant as follows: "*The whole plant is bitter and strong-scented, reckoned tonic, stimulating and anti-hysteric. It was once a popular remedy in ague. Its odour is said to be peculiarly disagree to bees and that insects may be easily kept at a distance by carrying a handful of the flower heads.*" In Homoeopathy system, allergies caused by *Parthenium* can be treated by a drug prepared from *Parthenium*. In Finland an infusion of Partenium is used in for consumption.

In the *Dictionary of Economic Plants in India Parthenium hysterophourus* is described as a weed found in Poona and is reported to be used as tonic, febrifuge, and emmenagogue. Root decoction is useful in dysentery (Singh et al. 1996). Mew et al. (1982) demonstrated that sublethal doses of parthenin exhibited antitumor activity in mice and that the drug could either cure mice completely or increase their survival time after they had been injected with cancer cells. Parthenium is also reported as promising remedy against hepatic amoebiasis (Sharma and Bhutani,1988). South American Indian uses a decoction of roots to cure amoebic dysentery (Uphof 1959) whereas parthenin, a toxin of *Parthenium*, is found pharmacologically active against neuralgia and certain types of rheumatism). In *Compendium of Indian Medicinal Plants* by Rastogi and Mehrotra (1991) parthenin induced dose-dependent damage to human leucocyte chromosomes in vitro and micronuclei formation in polychromatic erythrocytes of mice is reported (Dominguez and Sierra, 1970).

Parthenium is used as folk remedy in the Caribbean and Central America (Nabie et al. 1996). It is applied externally on skin disorders and decoction of the plant is often taken internally as a remedy for a wide variety of ailments (Dominguez and Sierra 1970; Morton 1981). In Jamaica the decoction is used as a flea-repellent both for dogs and other animals (Morton 1981).

Vasey grass

Gramineae, Poaceae *Paspalum urvillei* Steud.

Source: Magness et al. 1971

This is a warm season bunchgrass quite similar to Dallisgrass and introduced from South America before 1880. It is now common in the humid southeast, especially the Gulf Coast. It thrives both on wet sites and on well-drained soils. The erect stems may reach to 6 feet, with leaf blades up to 15 inches long and half an inch wide. Vasey grass is seldom planted but where growing is utilized for pasture and hay. It is easily overpastured. As hay, palatability is good and yields heavy with up to 4 cuttings per year possible.

Woody Fiber Crops

Stanley L. Krugman

INTRODUCTION

Unlike modern agriculture, forestry in the United States is not dependent on exotic germplasm. Some exotic woody germplasm is planted in forestry but such germplasm represents only a small percentage of the current planting program. In terms of modern forestry the United States is rich in woody plants with more than 2,000 different native species having potential use. Currently, less than a few hundred of these native species are actually utilized for their fiber while a great many more are harvested as a fuel source, for protection plantings, and for use as ornamentals. In the last 25 years, an array of these native woody plants has been investigated to a limited degree to determine their genetic variation.

With the increasing demand for more traditional wood products, including paper and fuelwood, there is a need and considerable opportunity in some parts of the United States to grow and utilize fast-growing, short-rotation woody trees. Various species and hybrids of poplars (*Populus* spp.) and several other native hardwoods have played this role. However, poplars are highly specific as to their site and growing requirements which restrict their potential use to selected areas. The same is true for the other hardwoods, such as American sycamore (*Platanus occidentalis* L.) and green ash (*Fraxinus pennsylvanica* Marsh.). Since the late 1960s, a number of additional woody species has been selected and tested under accelerated growing conditions. For this discussion, I will restrict my comments to two genera, Eucalyptus (*Eucalyptus* L.'Herit) and Royal paulownia (*Paulownia* Sieb. and Zucc.). Both are exotics, having been introduced in the United States during the 1800s. Both are fast growing hardwoods with many useful qualities. The full potential of these genera are not fully understood nor appreciated, yet there is considerable information that suggests that with a focused effort, both genera would make a useful contribution.

Eucalypts are restricted in range because all members of this genus are susceptible to low temperatures. Yet, with careful selection of species and proper seed source, there are genotypes that can be of considerable value and use. *Paulownia* has had relatively poor acceptance because it is considered difficult to grow and often has poor form. There is virtually no industrial experience with this genus in the United States because of relatively low volumes now available. Yet in Asia, especially in Japan and the People's Republic of China, it is widely used in fine furniture. It is widely grown in its native land of China for its timber value, and as a windbreak tree.

EUCALYPTUS SPP.

Members of this genus are among the most planted forest trees in the world. The genus comprises approximately 530 species and 140 varieties with new species and varieties still being described. It was introduced initially into California and the Hawaiian Islands about 1853. Eucalypts are today planted as ornamentals, as part of shelterbelts, and for fiber and fuelwood in California, Hawaii Arizona, Florida, and New Mexico. They have been planted in a number of southern states with very little success. Since members of this genus have been grown in the United States for over 100 years, why should it be considered a new crop? It is only in the last 25 years that serious studies have been undertaken to understand and identify the extent of the generic variation within this genus. The potential of this genus has not been fully exploited in the United States.

Early introductions were essentially random. Although a number of plantings took place in California during the late 1800s, most of the species and seed sources were eventually found to be unsuitable for timber products. Still, the various species found a use as a windbreak tree or as an ornamental. By the 1960s, more than 150 species were being grown in California alone as ornamentals because of their decorative flowers and pleasing form and shape.

A Eucalypts species introduction and testing center was established in south Florida in 1899 by what is now the USDA Forest Service. The goal of this center was to identify an array of new, fast-growing hardwood species. A few years later, a similar center was established in southern California. Both centers lasted approximately 10 years; but sudden low winter temperatures in both California and the southern United States abruptly ended the wide use of *Eucalyptus* at that rime. Since then, a large series of new species introductions have been carried out, usually with limited success. The collections were often poorly identified and seed source sampling was inadequate.

Investigations of the last 25 years have clearly demonstrated considerable genetic variation within this genus. Although no truly cold-hardy species have been identified, it is still possible to select for a degree of low temperature tolerance in certain species and seed sources. In field studies in California, a number of high-elevation seed sources from Australia withstood, in 1973, a cold wave occurring in late December and January when the temperatures went below freezing on 10 consecutive nights with a low of -7°C. In Florida, selected seed sources have tolerated temperatures as low as -12°C. With the proper genetic and management studies, it should be possible and feasible to match species and seed source to the appropriate growing conditions. In recent years, this has led to reports of fiber yields of 15 to 25 dry tons per hectare. For example, *Eucalyptus amplifolia* Naud. has been coppiced cultured through four rotations in northern Florida with annual yields reaching 23 dry tons per hectare. Somewhat similar high yields have been reported for *Eucalyptus saligna* Sm. in Hawaii. In each case, the key was the careful identification and selection of genetic material (species and seed sources) appropriate for given site conditions and the application of compatible management techniques. It is apparent from a number of current field tests that the full potential of this genus has not been exploited and many more seed source (provenance) investigations need to be initiated within a narrow range of growing conditions. While it is very unlikely that true cold-hardy Eucalypts will be found, there are many situations in which this genus will be useful. At this time, only approximately half of the species have been tested to any degree in the United States. There are some subgroups of the Eucalypts in which virtually little is known, even in Australia where it is native. What is needed is a better coordinated effort and a better understanding of the considerable variation in this genus.

PAULOWNIA

Although *Paulownia tomentosa* (Thunb.) Sieb. & Zucc. was introduced into the United States in about 1845, virtually little is known about other species of this genus in the United States, nor the extent of genetic variation in *Paulownia tomentosa*, the most northern species in Asia. Since its first introduction, mainly in the southern United States, *Paulownia tomentosa* is now found growing wild in many parts of the United States, including the western U.S. and even in the northeast as well as in the south. In China, its source of origin, yields of 36 to 53 cubic meters per hectare have been reported. It should be noted that this species is not grown for its biomass alone, but for its use as a quality furniture wood.

Many report this species as a weed tree for its poor form and rather large shade leaves. This is not surprising since there has been very little genetic selection of seed source for its adaptability to given sites, nor selection for form or growth rate. In the last 15 years, studies have been initiated to select from *Paulownia tomentosa* populations within the United States for improved growth and form. Still, current efforts to produce *Paulownia* spp. commercially have not been completely successful. In addition to a lack of appropriate plant material (seeds), optimum management techniques have not been applied.

While reviewing forest genetics activities in the People's Republic of China, both natural and planted stands of *Paulownia* spp. were studied. Currently, seven species and six varieties are commonly recognized. However, the Chinese list nine species of *Paulownia*. Many of the species tend to be subtropical and are not suitable for the continental United States. In 1986, four provenances each of *Paulownia elongate* (S.Y. Hu), *P. fargessii* (Franch), *P. fortunei* (Seem) Hemsl. and *P. tomentosa* collected in China were planted near Birmingham, Alabama; Tillman, South Carolina; Morganton, North Carolina; and the Garrett-Allegheny County area of Maryland. These species and provenances were selected as being good candidates for the southern and southeastern United States. On the whole, seedling survival after 2 years has been good with height growth ranging from 0.5 to 8 meters. It is too early to make any conclusion but it does appear that other *Paulownia* species can be grown in the United States. At 5 years, we will have an opportunity to evaluate form as well as height growth. As a comparison, *P. elongate* in a park in Peking had a height of 10.6 meters at age 6 while a roadside tree of *P. fortunei* near Kweilin, Kuangsi, had a height of 20.8 meters at age 11.

From the experience in China, *Paulownia* spp. prefer warm climates with 24°C to 30°C being the most favorable. *P. tomentosa* can withstand temperatures as low as -20°C, and *P. elongata* -15°C. Both *P. fortunei* and *P. fargessii* appear to be less cold hardy than *P. elongate*. Cold hardiness will need to be further determined under a number of growing conditions. Additional studies will be needed to determine appropriate management techniques for this genus. Yet, its rapid growth, attractive flower, and excellent wood quality make it a genus that needs to be considered for further use in the United States.

Pea, Southern

Cowpea, Black-eye pea, Callivance, Cherry bean, Frijol, China pea, Indian pea, Cornfield pea, Crowder pea

Leguminosae, Fabaceae *Vigna sinensis* (Torner) Savi

Source: Magness et al. 1971

This so-called pea is more closely related to the beans (*Phaseolus*) than to the peas (*Pisum*). it is an important food and stock-feed crop in the Southern States. Several slightly differing types are grown, as blackeye, brown eye, cream and cream crowder, differing in the flower color and color markings on the seeds. The plant needs warm weather, and is injured by any frost. It is bushy, or procumbent, twining but not climbing. Pods are 3 to 12 inches long and slender. Seeds are small, 1/6-1/4 inch in length. For food, they are harvested either at the green-shell state, while pods are still green, or as dry-shells, when ripe. Harvesting is usually by mowing and threshing in a viner, as with green peas. The pods may also be hand picked. For stock feed, the whole plant is harvested as hay, or pastured.

Season, bloom to harvest: Green-shell stage, 15 to 20 days. Dry-shell, 30 or more days.

Production in U.S.: 37,000 tons shelled dry; no data on green shell; 300,000 acres as feed and pasturage.

Use: Commercially, green-shell canned or frozen; dry-shell marketed dry.

Part of plant consumed: Seed only for food; whole plant for feed. Immature pods and seed may be used as snap beans.

Last update February 18, 1999 by ch

Pea, Winged

Leguminosae, Fabaceae *Tetragonolobus purpureus* Moench

Source: Magness et al. 1971

The plant is an annual trailer, with broad, ovate bean-like leaves. Pods are 2 to 3 inches long, somewhat rectangular in cross section, fleshy when immature. Winged pea is grown for the edible pods, and for the seeds, which are roasted as a substitute for coffee. Exposure is similar to that of snap or field beans. There are no data on production in the U.S., but it is very slight.

Peanut oil

Leguminosae *Arachis hypogaea* L.

Source: Magness et al. 1971

See Peanut for plant characteristics. Among edible vegetables oils, peanut oil is exceeded in world production only by soybean. World production of peanut oil, 1964-66, averaged 3,166,000 tons. In extracting the oil in the U.S., the cleaned nuts are passed through hullers or shellers to separate the kernels. The kernels, which contain 48 to 56 percent of oil, are then crushed, heated and pressed hot in hydraulic presses. The oil is used in the manufacture of margarines and shortenings, and as a salad and cooking oil. The press cake is used for cattle food.

Shelled peanuts crushed for oil annually in the U.S. averaged near 377 million pounds, 1964-66. Oil production averaged near 157 million pounds for the 3 years.

Sealy, R.L. and S. Bostic. 1993. Cliff brake fern: A native Texas fern with landscaping potential. p. 612-613. In: J. Janick and J.E. Simon (eds.), New crops. Wiley, New York.

Cliff Brake Fern: A Native Texas Fern with Landscaping Potential

Ramsey L. Sealy and Steve Bostic

Cliff Brake Fern [*Pellaea ovata* (Desv.) Weath.] is a native Texas fern that is found in nature on dry ledges and slopes of limestone outcroppings, calcareous rocks, or granite. It is frequently found on cliffs or at their bases; but also grows well in open rocky woodlands (Correll and Johnston 1979). Because of its tolerance to high temperatures, bright light, and alkaline conditions, cliff break fern might be well adapted to being incorporated into the xeriscape. Cliff break fern thrives in rich, well-drained soil (Hoshizaki 1975), and should be adaptable to many landscape situations.

Cliff Brake Fern has an attractive color, ranging from dark green to grayish-green (Jones 1987) and it has an interesting fine, open texture due to its peculiar rachis and costa structure (Lellinger 1985). Cliff break fern and other *Pellaea* spp. have been grown on trellises and in hanging baskets in greenhouses in the Northeast (Foster 1964), but its use in southern landscapes has been ignored. Because of the plant's apparent wide ecological adaptability and its ornamental qualities, *P. ovata* deserves consideration for use in the landscape and, in particular, in the xeriscape.

DESCRIPTION OF THE PLANT

P. ovata is a member of the Polypodiaceae, subfamily Gymnogrammeoidae, and tribe Cheilantheae (Tryon and Tryon 1973). Within the genus *Pellaea*, *P. ovata* is in the section Pellaea (Tryon and Tryon 1982).

P. ovata has slender rhizomes. Its leaves (fronds) may grow to 1 m or more in length and are divaricately bipinnate to tripinnate (Correll and Johnston 1979). There are 3 to 20 stalked pinnules on each pinna; the leaflets are 2 cm long and 1.5 cm wide and are ovate to oblong in shape with cordate to truncate bases (Correll and Johnston 1979) (Fig. 1). The petioles and rachises are pale tan-colored; the stalk is hard, dark, and polished (Hoshizaki 1975). The rachises and rachillae zigzag, often quite dramatically (Bailey and Bailey 1976). The zigzag pattern may all be in one plane or in several planes. Sori are borne in a marginal band along the blades and are covered by the reflexed margins of the pinnules (Bailey and Bailey 1976). The range of *P. ovata* is similar to that of several other American species of Pellaea, extending from the southwestern United States south to Argentina (Tryon and Tryon 1982).

The entire genus is adapted to relatively xeric conditions. The partially underground stems are covered with scales and have the capacity to survive light ground fires (Tryon and Tryon 1982). Further, the apogamous gametophytes do not require free water for fertilization (Tryon and Tryon 1982). New plants can be established during short moist periods because of rapid spore germination and sporophyte initiation (Tryon and Tryon 1982). *P. ovata* can tolerate and even thrive in moderate shade (as in open woodlands), but it may grow slowly under dense shade (Clute 1938). It is equally well adapted to full sun conditions (Hoshizaki 1975). *P. ovata* is native to areas with both very thin alkaline soils and areas with rich woodland soils (Clute 1938). *P. ovata* tolerates extremely hot summers (highs at 40°C or more) and can withstand at least brief periods of below freezing temperatures (periods of -17°C are reported with survival) (Hoshizaki 1975).

UTILITY IN THE LANDSCAPE

Several attributes recommend *P. ovata* as a xeriscape plant. These include its drought resistance and its tolerance of both alkaline soils and high temperatures. Cliff brake fern responds well to regular irrigation, but can thrive with neglect and occasional watering. We have observed that with even prolonged wilting, mature fronds of *P. ovata* revive with watering. Overwatering can kill cliff brake fern, and so it should not be placed with plants that have high water needs (Hoshizaki 1975). Since the fern is tolerant of both full sun and moderate shade, it can be used throughout the landscape in most light environments, except dense shade. Because it also grows well in rich woodland soils, *P. ovata* should be adaptable to many landscape schemes besides a xeriscape one. Some morphological characteristics make cliff break fern an interesting addition to the landscape (Fig. 2). The generic name *Pellaea* comes from a Greek word meaning "dusky" (Bailey and Bailey 1976), and the pinnules of *P. ovata* are somewhat to very glaucous. The small size of the leaflets (pinnules) and the open, zigzag character of the rachis allows *P. ovata* to lend an interesting open, light texture to the landscape. Cliff break fern can be effectively used in the landscape as a specimen plant, both potted or in the soil, and as part of a border, either by itself or in a mixed border.

Further popularization of *P. ovata* as a landscape plant will require determination of the limits of the fern's cold (freeze) tolerance, the extent of both drought and water-logging tolerance, information on the effect of different levels of shade on Cliff Break Fern's growth and survivability, and knowledge of the long-term adaptability of this new plant to the home landscape.

Pepper

Black, White, Pimienta

Piperaceae *Piper nigrum* L.

Source: Magness et al. 1971

Black pepper is the dried, unripe berry fruit of a perennial, tropical, woody vine. It may climb to 20 feet. The leaves are rather thick, broadly ovate-oblong or nearly round, and evergreen. The fruit is a small, globular drupe or berry, red in color. Powdered black pepper is the ground, entire fruit. White pepper is prepared by removing the outer skin of the fruit and grinding. It is less pungent than the black. Pepper is widely used in many forms of cookery. Desire for it was a strong motivation for searching for sea routes to India. Main commercial sources are now southern Asia and tropical Africa.

Pepper, Long

Piperaceae *Piper longum* L., *P. chaled* Hunter

Source: Magness et al. 1971

These two species are similar in growth habit and culture to black pepper.
The spikes are gathered when they begin to color red or yellow, and dried rapidly. They may be used directly in pickling and are also ground and used in preserves or curries. They are grown mainly in South Asia, and some are exported to Europe.

Griesbach, R.J. 2002. Development of *Phalaenopsis* Orchids for the Mass-Market. p. 458–465. In: J. Janick and A. Whipkey (eds.), Trends in new crops and new uses. ASHS Press, Alexandria, VA.

Development of *Phalaenopsis* Orchids for the Mass-Market

R.J. Griesbach

INTRODUCTION

It is widely recognized that potted *Phalaenopsis* production has increased tremendously in last few years. The specific statistics for *Phalaenopsis* are not available, for the US Department of Agriculture only keep records on total orchid production and sales. However, over 75% of all orchids sold are *Phalaenopsis* (American Orchid Society, pers. commun.). In 2000, wholesale orchid sales were approximately $100,000,000 (Fig. 1). The only crop with a higher value was poinsettia. During the last five years orchids sales has been increasing, unlike all the other ornamental crops (Fig. 2).

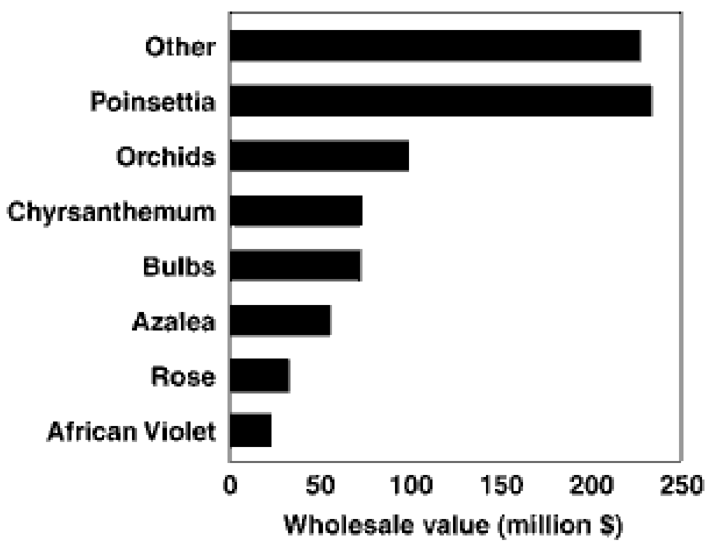

Fig. 1. Wholesale value of flowering potted plants within the United States for 2000 (USDA Agricultural Statistics).

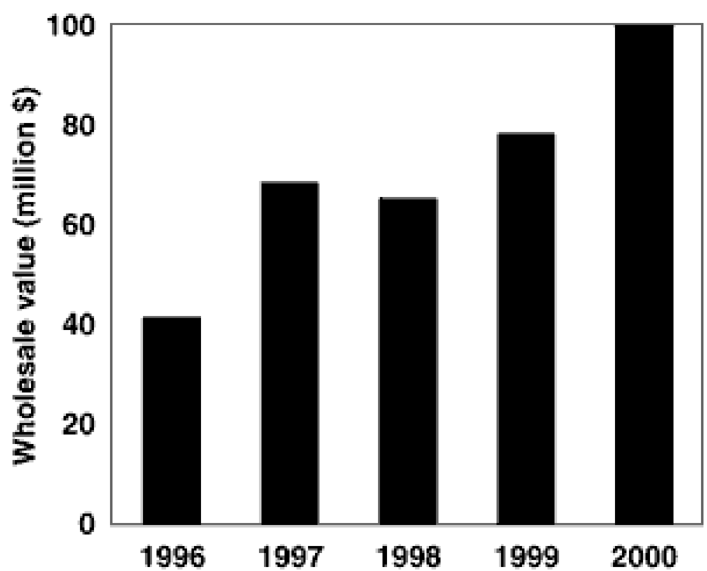

Fig. 2. Wholesale value of orchids within the United States for the last five years (USDA Agricultural Statistics).

Large scale, potted *Phalaenopsis* production is occurring in the Netherlands, Germany, China, Taiwan, United States, and Japan. In one cooperative venture, cultivar development is taking place in the Unites States; selected clones are being placed into tissue culture in Japan; mass proliferation of the tissue cultures is occurring in China; and the tissue cultured plants are being grown to maturity in the Netherlands. In 1957, James Shoemaker stated that "*orchid growing has not fully achieved the transition from a hobby to an industry*." Today, orchid growing is more than just an industry, it is an international business.

VICTORIAN BEGINNINGS

The development of hybrids reflects the preference of the consumer. As consumers' taste change, so does the type of hybrids produced and grown. During the Victorian period from 1830 to 1900, many homes had "parlor plants" (Martin 1988). During this period, the design of homes changed from a large single room to several smaller multiple-function rooms. Plants were grown in either the front or back rooms or parlors. The front parlor usually lacked heat and was extremely cold during the winter; while, the back parlor was typically overheated during the day and not heated at night. Many of the modern potted plants which we consider "new" were common house plants at this time. Several orchid species in the *Cattleya* Ldl. and *Dendrobium* Ldl. alliances were also common parlor plants.

The conditions in the Victorian home were not well suited to growing *Phalaenopsis* Bl. These orchids were considered a challenge to grow. James Veitch in his *Manual of Orchidaceous Plants* (1894) stated that "*the introduction of species of Phalaenopsis … has been one of the most difficult cultural problems horticulturists have been called upon to solve*." Because of the environmental conditions within the home, *Phalaenopsis* were predominantly grown in a conservatory or greenhouse.

Many homes in Europe at this time had greenhouses. In 1870, 50% of the middle and better class homes in London had attached greenhouses (Martin 1988). However in the United States, greenhouses were extremely expensive and rarely found. Because of this difference, *Phalaenopsis* were not as widely grown in the United States during the Victorian period.

The popularity of *Phalaenopsis* naturally led to the creation of many artificial hybrids. The first hybrid (P. Intermedia) was created in 1875 when John Seden at Veitch and Son's Nursery in England crossed *P. amabilis* (L.) Bl. with *P. equestris* Rchb. (Veitch 1886). The seed was sown at the base of the mother plant and only a single seedling survived which flowered a decade later in 1886. By 1900, an additional 13 primary hybrids were created and flowered. John Seden was responsible for creating all but one of these hybrids. The emphasis in hybridization at this time was to create exotic parlor plants.

The potential of artificial hybridization for creating new types was widely recognized, but the technical expertise required to germinate the seed and to raise the seedlings to maturity precluded its wide spread application. Only a few individuals were successful until 1909 (White 1942). In 1909, Hans Burgeff from Germany and Noel Bernard from France independently reported that orchid seeds germinated only in the presence of a symbiotic fungus. This discovery was used by Joseph Charlesworth and James Ramsbottom at the Charlesworth Company in England to develop a practical procedure to "symbiotically" germinate orchid seeds. In this procedure, a peat and sand mixture was sterilizing and then inoculated with the symbiotic fungus. After the fungus has penetrated the compost, the seed was sown on top. This symbiotic germination technology made it easier to produce hybrids, but large scale, commercial production of hybrids was still not possible. Many of the seeds in a capsule germinated, but few survived the process due to excessive fungal infection.

ORCHID TECHNOLOGY

Non-symbiotic Germination

Symbiotic germination methods were only used for a short time before being replaced by non-symbiotic germination procedures. In 1922, Lewis Knudson at Cornell University reported that the fungus was not required for germination if the seed was sown on agar containing appropriate salts and sugars. His Knudson C medium is still being used to germinate the seed of some species. With non-symbiotic germination technology, thousands of seedlings could be raised to maturity from a single seed capsule.

Besides the obvious potential in breeding, this technology was also extremely important for vegetative propagation. Unlike *Cattleya*, *Phalaenopsis* plants were difficult to import because they lacked water storage pseudobulbs. Many of the plants died in transit. Those plants which did survive were difficult to vegetatively propagate. The most desirable species (i.e. *P. amabilis*) produced a single stem that would produce only a few 'off-sets'. Non-symbiotic germination technology made it possible to produce very large quantities of plants.

By the time these new seed germination procedures were developed, the parlor plant craze had ended. Consumer preference shifted from potted plants to cut-flowers. Therefore, the emphasis in breeding focused on developing hybrids for this new market. Improved germplasm collected by Regnier in the Philippine Islands served as the genetic foundation for the cut-flower hybrids. Two improved forms of *P. amabilis* were collected. The *grandiflora* form of *P. amabilis* produced flowers that had fuller, rounder form with wider petals than the typical species. The *rimestandiana* form produced flowers that had the typical form and size but had tremendous substance. The *rimestandiana* forms that were used in breeding were later found to be tetraploid (Maurice Lecoufle pers. commun.). These two forms were originally recognized as distinct species.

Breeding Advances

The first major advance in breeding was made in 1920 by Dr. Jean Gratiot from France when he registered P. Gilles Gratiot. This hybrid, the result of a cross between the typical form of *P. amabilis* and the *rimestandiana* form, had extremely heavy substance. The second major advance in breeding came in 1927 when Henri Lecoufle at Vacherot and Lecoufle Company in France registered the hybrid between the *rimestandiana* and *grandiflora* forms of *P. amabilis*. This hybrid, P. Elisabethae, had the heavy substance of the *rimestandiana* from and the improved flower shape of the *grandiflora* form.

Through extensive in-breeding and out-crossing to *P. aphrodite* Rchb. superior hybrids were created, the most important of which was P. Doris. This hybrid was registered in 1940 by Duke Farms in New Jersey. P. Doris produced long, arching inflorescences on plants that were large and vigorous. The flowers were pure white, huge, and flat. Their heavy substance made them ideal for cut-flower production.

Production Protocols

Once cut-flower hybrids were developed, research began on developing commercial production protocols. The first experiments were preformed in the 1930s by H.O. Eversole in California (White 1942). He determined that *Phalaenopsis* grew the fastest and produced the most flowers in a sand-peat medium. Prior to this time, nearly all orchids were grown in living moss. Because of the difficulty in obtaining high quality peat, osmunda fiber became the medium of choice during the 1940s. Repotting orchids in osmunda fiber was both difficult and labor intensive. During the 1950s, independent research by O. Wesley Davidson at Rutgers University working with George Off at the Off Orchid Company and by Rod McLellan at the Rod McLellan Company resulted in the development of bark-based media. With these media, repotting was fast and easy. Today, the Rutger #3/Off mix is the most popular bark medium used.

Coupled with the development of improved potting media was the formulation of better fertilizers. Research on nutrition by Ratsek (1932), Evers and Laurie at Ohio State University (1940), Withner at Brooklyn College (1942), Fairborn at the Missouri Botanical (1944), Beaumont and Bowers at the University of Hawaii (1954), Davidson at Rutgers University (1957), and Sheehan at the University of Florida (1960) resulted in improved fertilizers. Before 1960, few growers fertilized their orchids. These studies showed that fertilization was critical for commercial production.

Another important research discovery was made by Gavino Rotor at Cornell University. In 1952, he reported that short days induced flowering in *P. amabilis* hybrids and that high temperatures inhibited flowering. All of this data was used to develop improved production protocols which increased the rate of plant growth and the yield of cut-flowers.

MARKET DEVELOPMENT

Between 1930 and 1950, the predominant cut-flower market was for white flowered hybrids. One of the reasons for the predominance of white flowers was the lack of quality hybrids in other colors. Pink cut-flower hybrids were developed during the 1950s. Interestingly, the genetic background of these pink hybrids was not significantly different than that of the white hybrids. The pink species (*P. schilleriana* Rchb. and *P. sanderiana* Rchb.) were not suitable for cut-flower production because of their thin substance. In addition, these species quickly wilted if the pollen was accidentally removed or disturbed during harvest. Many of the cut-flower pink hybrids that were developed actually arose from *P. amabilis*. *Phalaenopsis amabilis* is not completely white, but has a pink flush on the back of it's sepals and petals. Through inbreeding and intense selection, hybrids were eventually developed that were solid pink in color. These pink forms of *P. amabilis* (i.e. P. Doris) were then used in breeding with *P. schilleriana* and *P. sanderiana* to create quality hybrids.

By 1960, only a handful of closely related species (*P. aphrodite*, *amabilis*, *schilleriana*, and *sanderiana*) were in the background of nearly every hybrid created. The other species or "novelty" species were rarely used in breeding. Oscar Kirsch (1960) in Hawaii stated of novelty hybrids that "*many of these new creations would not be of value as commercial flower producers*." There were many reasons why they were of little value. First, the commercial market demanded cut-flower plants that produced long inflorescences with lots of large flowers. Novelty hybrids usually produced short inflorescences with a few small flowers. Second, the growers needed uniformity in both the product and production of the product. Populations of novelty hybrids generally contained plants that flowered at different times, had different growth habits and had different flower colors. Third, the cut-flower market wanted flowers that were uniform in color and not patterned. Many novelty hybrids produced flowers that had unusual colors.

In order to develop cut-flowers in an expanded range of pure colors without markings, the novelty species had to be used. Although the breeding protocol to create the "colored" cut-flower hybrids was obvious—cross the novelty species with the white, cut-flower hybrids and then backcross to the white parent—the problems associated with this approach were not. First, there were few novelty species in cultivation. Second, there was no experience on the genetic influence of the novelty species in breeding. Third, the modern primary hybrids were not very fertile due to chromosomal problems. The original primary hybrids made prior to 1900 used diploid forms of *P. amabilis*; while the modern recreation of these hybrids used tetraploid forms of *P. amabilis* (i.e. P. Doris).

The first novelty species to be used extensively in hybridization was *P. equestris*. This species was used to create a unique flower that had white petals and sepals with a red lip. The first *P. equestris* × *P. amabilis* hybrid was made by Seden in 1875 and had diploid parents. Its flowers were pale pink with a solid, dark red, lip. They were not flat and had poor substance and open shape. When a tetraploid, white, cut-flower hybrid was crossed with a diploid *P. equestris*, the results were quite different. These hybrids produced flowers that were nearly white with a pale red, stained lip. The flowers were reasonably large with heavy substance, but had poor shape. The most important of these hybrids was P. Sally Lowrey (*P. equestris* × P. Pua Kea). This hybrid was registered in 1954 by Oscar Kirsch in Hawaii. Through intensively backing-crossing of P. Sally Lowrey to white hybrids followed by sib-mating, improved forms were created that were pure white with dark red lips. In addition, these flowers had the improved form, size, and substance of the cut-flower hybrids.

During the 1960s, consumer preference shifted from cut-flowers back to potted plants. The parlor plant craze was reborn. Unlike Victorian homes, modern homes were ideally suited to growing *Phalaenopsis*. Novelty species were now used to create their own unique hybrids and not just for introducing color into cut-flowers. All of the species were re-introduced into cultivation and many were improved through intraspecific hybridization. In several instances, polyploid forms of the novelty species were created. These improved species were used to create primary hybrids that were far superior to those created at the turn-of-the-century.

Experimental crosses determine the genetic influence of the various species. For example, it was discovered that the brown spotting found on *P. amboinensis* J.J.Sm. flowers was not expressed in its hybrids with *P. amabilis*; while the spotting in *P. mannii* Rchb. was expressed. Additional studies showed that certain species combinations produced new characteristics. For example, when the solid colored *P. pulchra* Rchb. was crossed to hybrids with fine spotting, the progeny had large blotches of colors. All of this information and experience was used to create a wide range of unique hybrids.

PHALAENOPSIS DEVELOPMENT

Phalaenopsis grew in popularity and in the 1980s displaced *Cattleya* as the most popular orchid. At this time in Europe, a new, floral, marketing strategy was being developed. This strategy was aimed at the mass-market consumer and not at the conventional gardening hobbyist. In the Netherlands, a large-scale cooperative was created for growing and marketing all plants, including orchids. Individual growers specialized in a single crop, or even a single cultivar. The growers then jointly sold their product at an auction. In this manner, it was possible to supply wholesalers with a wide range of uniform, quality products throughout the year. Jan Post (1985) stated that in order to be commercially successful "*a pot plant market needs a lot of plants which no grower is able to handle and fulfill alone. Only with a large quantities from several growers will you create a orchid market for the consumer*."

The first orchid to be commercial marketed in this manner was *Vuylstekeara* Cambria 'Plush'. In 1975, Klass Schoone from the Netherlands began to propagate this clone for the mass-market. Since conventional methods for vegetative propagation were inadequate, Schoone turned to tissue culture. Orchids were the first plants to be commercially propagated through tissue culture. By 1985, over 100,000 tissue culture propagated plants of V. Cambria 'Plush' were being sold per year!

Tissue Culture Protocols

The first experiments in orchid tissue culture were carried out in Knudson's laboratory at Cornell University. In 1949, Gavino Rotor at Cornell University demonstrated that inflorescence nodes from *Phalaenopsis* could be induced to form a plantlet if aseptically placed on seed germination media. More than a decade later, Georges Morel (1960) at the Central Station for Plant Physiology in France reported that excised *Cymbidium* Sw. shoot tips could be induced to form multiple plantlets when cultured on seed germination media supplemented with phytohormones. Shortly after this report, Donald Wimber (1963) at Brookhaven National Laboratory developed a successful method of using tissue culture to commercial propagate *Cymbidium*.

Tissue culture techniques that were commercially successful for many orchids could not be used with *Phalaenopsis*. In *Phalaenopsis*, tissue culture propagation produced too much genetic variation. In some instances, over 50% of the propagated plants produced flowers that were significantly different than the mother plant. Therefore, mass-market *Phalaenopsis* were seed, and not vegetatively, propagated. Recently, tissue culture protocols specific for *Phalaenopsis* have been developed by Tse and others (1971) at the University of California, Intuwong and Sagawa (1974) at the University of Hawaii, Reisinger and others (1976) at the University of California, Zimmer and Pieper (1977) at the Technical University in Germany, Haas-von Schmude (1983) in Germany, Griesbach (1983) at the US Department of Agriculture, Homma and Asahira (1985) at Kyoto University in Japan, Tanaka (1987) at Kagawa University in Japan, Hinnen and others (1989) at the Agricultural University in the Netherlands, Tokuhara and Mii (1993) at Chiba University in Japan, Ernst (1994) at the University of California and Zhou (1995) at Sapporo Breweries in Japan, and Park and others (1996) at Shizuoka University in Japan. These methods, while generally successful, still can not be used to propagate all cultivars. In certain cultivars, these methods still produce too much variation. Due to the tremendous increase in uniformity with vegetatively propagated plants, the future mass-market *Phalaenopsis* will most like be tissue culture propagated and not seed propagated.

Breeding

Breeding for the mass-market was very different than breeding for the hobbyist or cut-flower markets. In the hobbyist and cut-flower markets, emphasis was placed exclusively on floral traits; while in the mass-market, vegetative characteristics were of nearly equal importance with floral traits.

The first *Phalaenopsis* that were sold in mass-market were cut-flower hybrids that were selected for more compact growth and flowering. The development of hybrids specifically for this market is in its infancy. Currently, *Phalaenopsis equestris* is being heavily used as parent. Unlike in breeding for cut-flowers, this species is not being used to introduce a single trait (i.e. red lip) into the white hybrids. Instead, the white hybrids are being used to introduce a single trait (i.e. better shape) into the species.

The first important hybrid in this line of breeding was P. Cassandra (*P. equestris* × *P. stuartiana*) which was made by Seden and registered by Veitch in 1899. P. Cassandra was remade many times, but the break through came in 1978 when Herb Hager at Herb Hager Orchids in California used P. Cassandra to make P. Be Glad. The other parent of P. Be Glad, P. Swiss Miss, was hybrid a between *P. equestris* and a white with a red lip, cut-flower hybrid. P. Be Glad produced flowers with greatly improved shape and size. The plants, however, were less floriferous and much larger in size.

The next step logical step in this line of breeding was obvious—backcross P. Be Glad to *P. equestris*. This hybrid, P. Be Tris, was registered in 1989 by Frank Smith at Krull-Smith Orchids in Florida. A triploid form of P. Be Tris was recently created by Amado and George Vasquez at Zuma Canyon Orchids in California. The tetraploid form of *P. equestris* which was used to create the triploid hybrid was produced through chemical treatment. During the 1970's, Robert J. Griesbach (1981) in cooperation with Arnold Klehm at Klehm Growers in Illinois developed procedures for using colchicine to double the chromosome number of *Phalaenopsis* seedlings. A colchicine-induced tetraploid form of *P. equestris* was seed propagated and distributed by Klehm Growers, the US Department of Agriculture and the American Orchid Society. Of the seed propagated tetraploids, *P. equestris* 'Riverbend' was the most widely distributed clone. The triploid forms of P. Be Tris are far superior to *P. equestris*, with more distinct coloration, better shape and heavier substance.

Production Protocols

Production protocols that were developed for cut-flowers were not the best for potted plant production. Extensive research in plant physiology by Sheehan (1960) at the University of Florida, Poole and Seeley (1978) at Cornell University, Krizek and Lawson (1979) at the US Department of Agriculture, Sakanishi and others (1979) at Oska University in Japan, Tanaka and others (1988) at Miyazaki University in Japan, Endo and Ikusiuma (1989) at Chiba University in Japan, Ota and others (1991) at Nagoya University in Japan, Doi and others (1992) at Kubota University in Japan, Kubota and Yoneda (1993) at Nihon University in Japan, Porat and others (1994) at the Hebrew University in Israel, and Wang (1995) at Texas A&M University helped to define the precise factors essential for maximum plant growth and development. The practical results of this research was the development of large-scale, production protocols (Fig. 3).

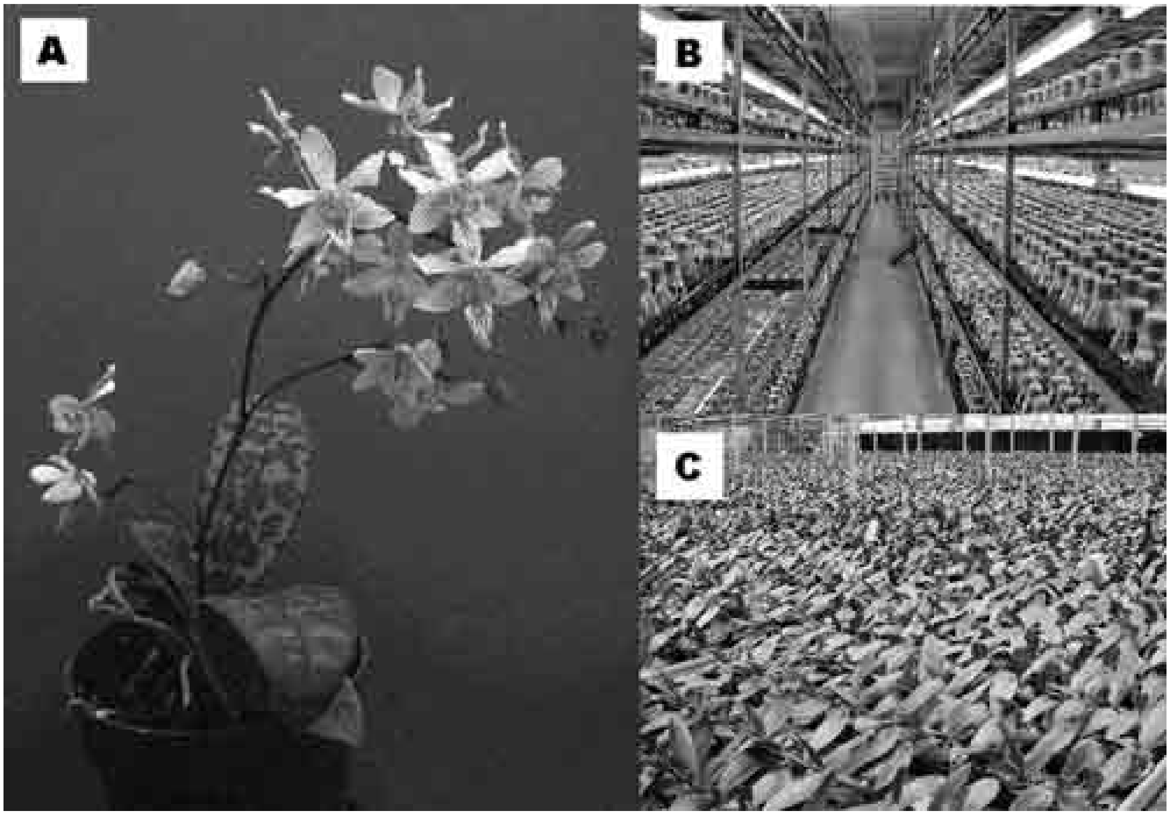

Fig. 3. *Phalenopsis* production. A) dwarf cultivar P. Hummingbird; B) Tissue culture propagation laboratory in Taiwan; and C) Production greenhouse in the Unites States.

FUTURE POTENTIAL

Phalaenopsis production is now international in scope. For example, in one operation breeding occurs in the United States. Selected clones are sent to Japan where tissue culture progation is initiated. Successful cultures are then sent to China for mass proliferation. In vitro grown plantlets are next sent to the Netherlands for greenhouse production. Finally, flowering plants are returned to the United States for sales. Very few *Phalaenopsis* are bred, propagated, flowered, and sold in the same country.

At this time, production does not meet the demand. It is widely expected that sales will increase as production increases. Demand for *Phalaenopsis* should continue well into the future as new types are developed. Based upon today’s breeding efforts, the cultivars of the future will have a compact growth habit, variegated foliage, fragrance, and be ever flowering.

Dry Edible Beans: A New Crop Opportunity for the East North Central Region

Glenn H. Sullivan and Lonni R. Davenport

Dry edible bean production in the United States increased from 0.8 million tonnes in 1970 to 1.5 million tonnes in 1990 (Table 1). Production expansion during this period was led by a 21% increase in domestic consumption and a 153% increase in export trade (USDA 1990). The most common commercial classes of dry beans grown in the United States include: small red, kidney, pinto, navy, and great northern (*Phaseolus vulgaris*); small lima (*P. lunatus*); and large lima (*P. limensis*). The largest share of domestic dry edible bean production in 1990 was comprised of pinto and navy beans, with 42 and 20% of total United States production, respectively (Table 2).

The dry bean industry is characterized by high regional concentration in production and processing (Fig. 1). However, production concentration is geographically dislocated from dry bean processing facilities. Dry bean processors are located predominantly in the eastern regions of the United States and Canada, while production expansion between 1970 and 1990 has accrued in the western regions (Table 1). This geographic dislocation between production and processing, combined with changing economic conditions within the industry, has forced dry bean processor to consider strategies for procuring supplies from areas with greater geo-economic relevance to their processing facilities and final demand.

PRODUCTION AND MARKET CONSIDERATIONS

With the exception of Michigan in the East North Central Region (ENCR), dry edible bean production has concentrated in the western regions of the United States (Table 1). Michigan led the nation in dry bean production in 1990, with about 17% of total production; followed by North Dakota and Nebraska with about 15% each. During the period 1970 to 1990, production in the West North Central Region (WNCR) increased 413%, followed by the Mountain Region (MR) at 96% (Table 1). Total dry bean production in the ENCR decreased 11.5% during this period.

Pinto beans comprise the largest volume of any dry bean class produced for human consumption in the United States (Table 2). Total pinto bean production increased 151% between 1970 and 1990, with North Dakota and Colorado accounting for almost half of the crop. Exports and rising domestic demand for ethnic foods have contributed significantly to continued production expansion in pinto beans.

Navy beans accounted for the second largest volume of dry edible bean production in 1990, however, their domestic share of total production has declined (Table 2). This decline resulted primarily from lower export demand in Canada and the United Kingdom since 1980. Michigan's overall decline in dry bean production between 1980 and 1990 was directly attributed to weaker market demand for navy beans. Michigan accounts for over 50% of all navy bean production in the United States.

Food service industry demand in the United States has generated new production opportunities for dry bean classes not previously grown in large quantities, including small red, small white, and pink beans (*P. vulgaris*); blackeye pea (*Vigna unguiculata*); and garbanzo/chickpea (*Cicer arietinum*). Next to pinto beans, these specialty dry bean classes collectively generated the highest rate of domestic production expansion between 1970 and 1990 (Table 2). The small red dry bean class currently exhibits the greatest demand growth, and the greatest potential for production expansion in the ENCR.

ECONOMIC CONSIDERATIONS

Total farm value of dry edible bean production in the United States was estimated at $906 million in 1990; up from $737 million in 1980 (USDA 1991). While producers in the ENCR accounted for only 17% of the farmgate value for all domestic dry bean production in 1990, they are strategically positioned geographically and economically to significantly expand production (Sullivan 1990). Nearly two-thirds of all dry bean processors are located in the eastern regions of the United States, with the largest concentration in the ENCR and Ontario, Canada (Fig. 1). In addition, western dry bean production and transportation costs since 1987 have continued to increase at rates greater than consumer prices, thus encouraging eastern processors to lower costs by developing supply alternatives in closer proximity to their processing operations.

Potential net returns from dry edible beans as an alternative crop favor production expansion in the ENCR (Westcott and Zepp 1989). At current yields, gross receipts of $576/acre ($1,423/ha) are possible. Net returns at this level compete favorably with maize and soybean production under midwestern conditions in most years. Assuming designation by the Secretary of Agriculture under the triple-base statutes of the 1990 Farm Bill, producers in the ENCR could further increase their competitive position. Producers could substitute dry bean crops for a portion of their program area without accruing future crop base penalties. Under this program provision, the breakeven price for dry edible bean production would be consistently lower for ENCR producers than for producers in western regions (Westcott and Zepp 1989). While dry bean prices have been well above $16.50 per hundredweight ($363.66/t) over the last ten years (Table 3), prices at this level would still generate net returns that are competitive with maize in the ENCR. By comparison, dry bean prices would have to consistently exceed $24 per hundredweight ($529/t) to profitably compete with maize production in most western regions. This price level would also encourage the expansion of dry bean imports into the United States.

FUTURE PROSPECTS

Studies conducted by the Purdue Center for New Crops, in cooperation with the Brooks Foods Division of Curtice-Burns, Inc., confirmed that market and production opportunities existed for selected dry bean classes in the ENCR; particularly for the small red bean class. These studies further confirmed that dry edible bean production expansion in the ENCR has not been slowed by economic factors, but rather by lack of cultivars adapted to regional climatic and cultural conditions.

A statewide research and development initiative is geared to expand dry edible bean production in Indiana. The Indiana Business Modernization and Technology Corporation, and the Indiana Commissioner of Agriculture's Value-Added Grants Program provided development grants to help accomplish the objectives of this program initiative. Brooks Foods has provided the industry leadership for developing, testing, multiplying and commercializing small red bean cultivars that can be adapted to farming conditions in Indiana and the ENCR. Promising cultivar selections were made and multiplied in cooperation with Asgrow Seed Company in 1990 for further field testing in 1991 and 1992. Seed multiplication for limited commercial plantings has been targeted for 1993, with full commercialization by Brooks Foods expected in 1994. Market and economic feasibility assessments indicate that these initiatives could increase dry edible bean production in the ENCR by 37 thousand tonnes annually (Sullivan 1990). This level of expansion translates into nearly 45 thousand acres (18,225 ha) of new production opportunities for growers.

Last update September 17, 1997 aw

Beans

(*Phaseolus* spp.)

The author of this chapter is D.G. Debouck (International Board for Plant Genetic Resources [IBPGR], Rome).

The author wishes to express his thanks to G.F. Freytag (USDA), J. León (University of Costa Rica), G. Ballesteros (University of Córdoba, Columbia), O. Toro (CIAT) and O. Youdivich. He also thanks the following institutions: IBPGR (Rome), CIAT (Colombia), IUCN (Switzerland), INIFAP (Mexico), ICTA (Guatemala), ICA (Colombia), INIAP (Ecuador), INIAA (Peru), CIF (Bolivia), INTA (Argentina) and the University of Costa Rica

Of the genus *Phaseolus sensu stricto*, which includes 55 species, five have been domesticated. The pre-Columbian peoples grew them for thousands of years as a main source of protein, since animals did not have an important role as a source of food or draught power, particularly in Mesoamerica.

As early as the pre-Columbian period, the kidney bean (*P. vulgaris* L.) had gained wider acceptance and was selected more intensively. The early chroniclers inform us that, in the Aztec and Incan empires, great importance was given to this species and it was used to pay tributes. It gained even more popularity after the conquest and, from 1880, with the exception of isolated studies the work on genetic improvement was mainly concentrated on this bean. This preferential treatment was detrimental to the other species which are of greater or comparable interest in modern agriculture, at least in areas that do not offer optimum ecological conditions for their development.

The ancestral form of *P. vulgaris* grows within the boundary between two climatic zones subtropical dry and tropical temperate where pre-Columbian societies established many settlements, a tact which may explain the acceptance of the species. To cover the greater part of the area occupied (except for certain Andean regions), the Pre-Columbians domesticated four other species.

The five ancestral forms were lianas which grew in different ecological niches. Biochemical studies have shown how *P. lunatus* was domesticated in several points of Mesoamerica and *P. vulgaris* in the Andes. Except in the latter region, uniformity in selection pressure led to a considerable similarity in evolutionary stock. With the exception of the tepary bean, the association with maize—although it was late in the Andes—also contributed to this standardization. The levels of evolution of the five species have been varied and there is a great potential for exploitation; for example, as regards the growth habit in *P. polyanthus* and the size and colour of the *P. acutifolius* seed. The ecological potential of these species would enable some of them to be developed even more profoundly than *P. vulgaris*.

At a time when the model of an agriculture which is both sustainable and productive has been accepted, beans deserve to be given renewed attention.

Phaseolus coccineus

Botanical name: *Phaseolus coccineus* L.

Family: Fabaceae

Common names: English: scarlet runner beans: Spanish: ayocote (name of Nahuatl origin, central Mexico), patol (Mexico [Zacatecas]), botil (Mexico [Chipas]), chomborote, piloy (high platear of Guatemala), cubá (Costa Rica)

This species has been cultivated in the high parts of Mesoamerica for many centuries. In pre-Columbian Mexico. the people of the Anahuac cultivated it extensively and ensured its distribution. Its introduction into southern Colombia (Antioquia and Nariño) and Europe (where it is known as scarlet runner bean and haricot d'Espagne) could have occurred in the seventeenth century before reaching other parts of the world. such as the Ethiopian highlands. It has been found in archaeological remains only in Mexico in Durango and Puebla. and wild only in Tamaulipas. Although archaeological information is very scarce. it could be assumed that its Mexican domestication took place in humid high zones.

Changes in maize varieties (earlier-maturing and with softer stems) and the use of fertilizers (for example, urea) and herbicides in maize yields led to the gradual abandonment of this crop in eastern Guatemala and in Costa Rica. It is reasonable to suppose that the same is happening in other areas of its cultivation. Because of its ecological niche *P. coccineus* has suffered heavy competition from exotic crops with a higher consumption and better market, for instance vetch, broad bean, cabbage, garlic and onion.

P. coccineus has been used in its nuclear area, particularly for its dry or green seeds. The consumption of young seeds enables the crop to be expanded to higher altitudes, since the fleshy root produces a second growth after light frosts (for example in Huehuetenango, Guatemala). The root of this legume has medicinal uses in Mexico and the flowers are also eaten. Its gaudy influorescences may be the reason for its recent expansion as an ornamental plant in Europe and the United States. The green pod is used as a vegetable in western Europe and the dry seeds (white seeds) are eaten in some traditional dishes.

Botanical description

A pluriannual species of great vegetative vigour with stems of several metres (only in a few modern cultivars are there shrubby forms) which emerge from a fleshy root. *P. coccineus* is easily distinguished by: its large seeds (the weight of 100 seeds is 80 to 170 g and 6 to 12 g for the wild form) and small, narrow, elliptical hilum; and its large influorescences (20 cm and in excess of 20 fruit-bearing stems) with scarlet, white or, more rarely, two-colour flowers. It carries out hypogeal germination, has a fleshy root which is divided and generally fusiform and which allows cotyledonary young shoots to resprout over several consecutive years. It flowers 50 days after sowing. with early varieties, or at the start of the rains, and continues to produce flowers over a long period, except in the shrubby varieties. In the majority of cases *P. coccineus* undergoes cross-pollination. assisted by its extrorse stigma and nectaries and through the action of bees and humming birds. Thus far, it is considered self compatible.

The seed of wild varieties is dispersed through explosive dehiscence of the pods during the dry period. In some wild populations there is a short latency; the seeds viability in natural conditions does not exceed three years.

Figure 3. Beans: A) *Phaseolus coccineus;* A1) legume; A2) seeds; B) *P. acutifolius*; B1) legume; B2) seeds

Ecology and phytogeography

Like *P. polyanthus, P. coccineus* tolerates higher precipitations than other species of *Phaseolus* (Table 3), provided that the soil has good drainage: that is with derivatives of volcanic ash, fine particles, etc. It grows at cooler temperatures than other cultivated species and is generally heliophytic. although it tolerates mists.

Table 3. Selected cultivated species of *Phaseolus:* altitude, daytime temperature, mean annual precipitation, duration of growth cycle from start to end of harvest, yield potential in tropical areas

Species	Altitude (m)	Temperature (°C)	Precipitation (mm/year)	Growth cycle (days)	Yield (kg/ha)
Phaseolus coccineus	1400–2800	12–22	400–2600	90–365	400–4000
Phaseolus acutifolius	50–1900	20–32	200–400	60–110	400–2000
Phaseolus lunatus	50–2800	16–26	0–2800	90–365	400–5000
Phaseolus polyanthus	800–2600	14–24	1000–2600	110–365	300–3500
Phaseolus vulgaris	50–3000	14–26	400–1600	70–330	400–5000

Its nuclear area extends from Durango to Veracruz and Puebla. In Guatemala. it is traditionally sown on the slopes of the Cuchumatanes range, on the high plateau of Huehuetenango up to Alta Verapaz and Sacatepéquez. and in the highest parts of the rest of Central America. The wild form of *P. coccineus* (although unable to be confirmed as ancestral throughout its distribution) extends from Chihuahua in Mexico to Panama, generally between 1400 and 2800 m in the humid high forest.

Genetic diversity

In its wild form, this species displays a great phenotypical variation in its current state of evolution. in contrast with the other wild species of the genus (there is some similarity with *P. augusti* of South America). Wild *P. coccineus* may be considered to be a complex of several forms, now in active speciation. throughout its distribution range. Some very differentiated forms, such as *P. glabellus*, may have become separated, constituting an early form of a group of which it is now difficult to distinguish all the variants. Allogamy is frequent in these plants, and the crossing of wild and cultivated forms, which have been displaced by humans, has changed the speciation patterns. Because of its active process of evolution, this species complex is not an easy task for the taxonomist but, by the same token, it offers great potential for the plant improver.

In addition to a group of four wild forms with scarlet flowers, mention should he made of another four forms with purple flowers. *P. polyanthus* is a related species at the boundary of the primary genetic stock of the scarlet runner bean, since in some cases it can be crossed with the later, as in Putumayo, Ecuador or in Imbabura, Colombia. Likewise, *P. vulgaris* may he considered to be at the boundary of the primary genetic stock of the scarlet runner bean.

There are only a few definite cultivars, particularly among the climbers; among the indeterminate shrubby cultivars, "Patol Blanco" may be mentioned and, among the determinate shrub cultivars, "Hammond's Dwarf".

There are risks of genetic erosion in areas where the traditional maize field has been changed, as some parts of Mexico (Chiapas, Oaxaca, Puebla and Veracruz), Guatemala and Costa Rica. Along with maize, the three species of bean (*P. coccineus*, *P. polyanthus* and *P. vulgaris*) and gourds were frequently sown in these areas. In the high plateau of Mexico (Durango, Zacatecas), the recent spread of the kidney bean may displace the "patoles" for reasons of cost.

P. coccineus material exists in collections of germplasm, mainly in Chapingo in Mexico (INIFAP), Pullman in the United States (USDA) and Palmira in Colombia (CIAT). The cultivated material has already been collected to a great extent, except in some areas of Guatemala (for example. Quiche), Honduras and Costa Rica. where it may be already too late to make such a collection.

For the wild material. it is necessary to collect around the great cities of Mesoamerica, particularly in the valley of Mexico, since these areas were a centre of diversity of the *P. coccineus*, complex which is very rich in forms. Many areas still remain to be explored, in view of material collected compared with the abundant herbarium material available. The complications involved in handling these forms ex situ mean that they need to he conserved in situ.

Cultivation practices

In most of its area *P. coccineus* is sown with maize and other varieties or species (*P. vulgaris, P. polyanthus*) following documented practices, since precipitations allow their association. In Durango and Zacatecas (Mexico), under heavy rain conditions it is sown alone, either in widely spaced rows or broadcast. depending on the type of ploughing. Manual harvesting is still common; the pods are gathered and left to dry in the sun before being beaten and the seeds are stored in sacks.

Estimation of the yield in cultivated herds is difficult, since farmers intercrop *P. coccineus* with other beans or harvest it periodically. It produces 400 to 1000 kg per hectare in the shrubby forms while, for climbing varieties, the yield can be much higher (Table 3). In the United Kingdom, for crops with young pods, more than 23 tonnes per hectare have been recorded.

Prospects for improvement

The scarlet runner bean has been used on many occasions for improving the common bean but only in very few cases has its own improvement been addressed, although specialists agree on the hardiness of the species against several fungi, bacteria and viruses.

The delayed production of climbing forms may be considered a limitation. The number of shrubby forms is not sufficiently high (especially of those with white seeds) and several of them have a low yield. Not all colours and seed stocks exist in these varieties, and this is particularly the case with shrubby forms. Floral abscission can at times be considerable—perhaps because of the lack of pollinators—and causes yield losses.

Many cultivars root easily and can be maintained over several years thanks to their fleshy root. Their large attractive flowers make insect pollination easy (this crop may be assumed to have a positive effect on local entomofauna). A hybrid scarlet runner bean could be developed; however, unlike the kidney bean or the tepary bean, it is not known whether there would be a strong heterosis effect.

The use of the scarlet runner bean to complement maize in silage deserves investigation since, as well as its fodder value, the plant can limit soil erosion. It may also be useful interspersed in young forest or fruit plantations (to give soil protection, fertilizing value or additional income).

Because of its type of germination. *P. coccineus* is a useful species for fighting the bean fly (*Ophiomyia phaseoli*) in the highlands of East Africa.

Phaseolus acutifolius

Botanical name: *Phaseolus acutifolius*

Family: Fabaceae

Common names. English: tepary bean: Mayan: xmayum (Mexico [Campeche]): Spanish tépari, (name of Opatan origin) (Mexico [Sonora]). escomite or escumite (Mexico [Chiapas]), frijol piñuelero (name of hybrid origin) (Costa Rica)

This species has been grown for a long time in Mesoamerica, mainly as a vegetable in desert zones or areas with a long dry period. Unlike the case of other cultivated species of the genus, *P. acutifolius* was first described in its wild form while the relationship with the cultivated form was recognized later Archaeological findings have shown that this species was grown in ancient times in the southeastern United States, where it apparently penetrated from Mexico 1200 years ago) and Puebla (where it existed 5000 years ago). Geographical distribution of the cultivated form extends from Arizona and New Mexico to Guanacaste, Costa Rica, on the dry subtropical slope of the Pacific. The distribution of *P. acutifolius* is sporadic, which is reflected in its market. The main product is a dry seed which is eaten because of its rich protein (17 to 27 percent) and carbohydrate content It is also used as a young tender string bean and as fodder after harvesting.

It is still not known precisely where the species was domesticated It should be noted that electrophoretic analyses of the phaseolin and isoenzymes indicate that the domesticated populations were few. Either because of its historic extinction, because the initial genetic base was already reduced at the time of its domestication or because of the autogamy of the species, the cultivated genetic potential does not seem to have been very extensive, to judge from its sub sequent development. Following are some of the causes that several authors have reported as having led to neglect of the tepary bean:

- the availability of cheap water in desert areas which enables the cultivation of fodder plants or garden produce and other vegetables of greater value (kidney bean, cowpea), as the tepary bean's yield remains the same or even diminishes with irrigation;
- the loss of eating traditions in indigenous communities;
- the shortage of demand on the big markets.

Its cultivation potential in desert areas is extensive and is still to be explored

Botanical description

P. acutifolius is a desert therophyte and is easily distinguished from other species of beans by its epigeal germination, sessile primary leaves, acute rhomboid folioles, pseudoracemes—with two to four fruit-bearing stems—small pink flowers (white in some cultivars) with very small triangular bracteoles and pods that have sutures marked with five to ten ovules Autogamy appears to be dominant Two wild forms are recognized: var. *acutifolius* with rhomboid folioles and var. *tenuifolius* with linear, sometimes sagittate, folioles. A third wild form appears sporadically with narrowly falcate folioles which. because they have different blastogenic characteristics from the var. *tenuifolius* and possess a certain incompatibility for crossing. could be considered a separate species (*P. parvifolius*).

Thc cultivated form, like the wild forms, has a short cycle, flowering 27 to 40 days after germination and ripening at 60 to 80 days. The plants wither completely (except *P. parvifolius*). In the wild forms, seeds are dispersed within a radius of 3 m by explosive dehiscence of the pods In some cultivars there is a brief postharvest latency of one month. The seeds of the wild plants germinate through the imbibition caused by the heavy desert rainfalls of the following year. However, only in some is germination staggered over three years.

Ecology and phytogeography

The cultivated form is found from 50 m to 1920 m above sea level. It requires an annual precipitation of 250 to 300 mm, although it is grown in Mexico in regions with a precipitation of 150 mm (Sonora) to 750 mm (Campeche). During the vegetative period, the daytime temperature can reach 20 to 32°C. It grows on well drained. sandy, muddy, sometimes organic soils with pH 6.7 to 7.1.

There is an ecological specialization in the wild forms of the tepary bean: var. *acutifolius* of Arizona, New Mexico, Lower California, Sonora, Chihuahua, Durango, Sinaloa and Jalisco occupies semi-sunny habitats with the mesquite on the banks of streams. while var. *tenuifolius* colonizes the sunny slopes with cacti and thorny shrubs in Arizona, New Mexico, Lower California. Sonora, Chihuahua, Durango, Sinaloa, Nayarit, Jalisco, Querétaro, Michoacán, Guerrero, Oaxaca and Jalapa. The cultivated form is a heliophyte and has characteristics that allow it to tolerate excessive sun.

Genetic diversity

Compared with the kidney bean, there is less seed variability. Basically two forms occur: one with a fairly small, rounded, white or black seed; and another with a larger-sized angular, rhombohedric seed that may be white, greenish white, grey, bay, dark yellow, mahogany, black or purple-mottled or coffee in colour. The average weight of 100 cultivated tepary bean seeds is between 10 and 20 g and, for the wild form, between 2 and 5 g. Two cultivars have been cited: one is white (Redfield) and another is dark yellow. Both result from mass selection. Although the cultivated and wild materials do not have a definite habitat, a desert environment is necessary. Whereas the wild varieties are generally climbers with a few guide shoots (2 to 4 m in length), there are two cultivated groups: the indeterminate shrubby varieties with short guide leaves and the indeterminate creepers with long guide leaves, which climb if they find support. The author knows only one escape variety. The secondary genetic stock is not well known: the kidney bean may be considered to be within the tertiary stock.

A good number of cultivars from which collections have been made mainly in Mexico appear to be no longer sown. It seems unlikely that many more cultivated forms will be found but it would be useful to re-examine the southern area of distribution. This examination is an example of a germplasm collection programme that has enabled a good part of the crop's variability to be saved. The two wild forms represent the major source of variation for future improvement of the species. As some plant species are threatened by overgrazing, it would be advisable to collect germplasm from Nayarit to Jalapa.

Cultivation practices

In the southern area of its distribution, the rural communities have conserved *P. acutifolius*, particularly because of its early maturity and reduced cultivation requirements. It is sown on the edge of maize fields, at the start of the rains to obtain the green bean and at the end of the rains to obtain the seed, or on plots around houses in virtually any period. In the northern area of its distribution (southeastern United States, northeastern Mexico), it is sown under heavy rain conditions in small fields with a favourable topography or on the edges of streams, generally alone or with some gourds and tolerated weeds. After the first heavy downpour, the land is ploughed and then sown in rows or broadcast following the second downpour. The plants are pulled up when they reach maturity and are left to dry in the sun. One week later they are trodden on a clean surface while the seeds are collected and winnowed with a basket. The seeds used to be stored in baskets or clay vessels (nowadays in tins or plastic bags), thus maintaining their germinating capacity for three years. In Campeche, to store seed for sowing, packets are made with the unopened pods and placed in contact with the smoke of embers.

Yields are estimated to be 200 to 900 kg per hectare, with wide variations depending on sowing density and rainfall. About 1000 to 2000 kg per hectare are obtained with fertilizer, with harvests of up to 4 tonnes per hectare.

Prospects for improvement

The tepary bean is considered to be a useful species for improving the kidney bean (it is not attacked by mildew or smut, *Xanthomonas phaseoli*), but no programmes have been carried out for improving the tepary bean itself. Unlike many leguminous vegetables, it gives an acceptable yield with less than 400 mm of annual precipitation. Its small seed size could be corrected by improving the species; the variability in colours and seed standards could also be increased. A pronounced heterosis is noticed when lines are crossed and there is a possibility of hybrid tepary beans being produced (it would be necessary to determine whether the secondary stock would make it possible to increase the flower's attractability to insects[1]). Some populations are susceptible to rust, oidium, mildew, root rot, leafminers, bruchids and leafhoppers. Some lines have good or excellent levels of resistance to these pests and diseases. In cultivation, the germplasm has proved susceptible to high temperatures, acidity, aluminum toxicity and common mosaic diseases.

Its potential for introduction into desert areas (the American tropics, the Sahel, the Near East, India) is considerable but it has not been exploited. For example, in July 1985, the author sent a small sample of tepary bean plants to Chincha in Peru for evaluation; in 1989 one of the tepary beans was already being sold under the name of cuarenteno in Chiclayo. In many areas its use as a cover plant or as a crop merged with millet (*Pennisetum* sp.), prickly pear (*Opuntia* sp.), mesquite (*Prosopis* sp.) and jojoba (*Simmondsia* sp.), for human or animal consumption, has not been exploited either. It should be possible to use it as a postharvest crop when temperatures are still favourable and residual humidity is low. One of the main reasons for promoting cultivation of the tepary bean is to limit the use of water in subdesert areas.

Research should be orientated towards increasing the collection of germplasm; distributing seed from gene banks to farmers; divulging information through agricultural extension services on the cultivation potential of the tepary bean in dry zones; setting up seed improvement projects; developing food technologies suited to leguminous vegetables (for example, industrial processing of proteins), which would free the farmer from market requirements; and promoting information on the methods of consumption in order to re-upgrade the use of this legume.

[1]No cytoplasmatic androsterility or agents re-establishing fertility have been recorded in *P acutifolius*.

Phaseolus lunatus

Botanical name: *Phaseolus lunatus* L.

Family: Fabaceae

Common names. English: butter bean, Lima bean, Burma bean, duffin bean, Rangoon bean

There are two main genetic stocks domesticated from two separate wild forms and with morphotypes from a different seed.

> **Common names of the small-seed cultivars** (24 to 70 g per 100 seeds). Mayan: ib (Mexico [Yucatán]); patashete (Mexico [Chiapas]); ixtapacal (Guatemala [Suchitepéquez]); Spanish: sieva, comba (Colombia [Guerrero]), furuna (Mexico [Jalapa]), chilipuca (El Salvador), kedeba (Costa Rica), frijol caballero (Cuba), haba (Puerto Rico, Panama), carauta (Colombia [Atlantic]), frijol de año (Colombia [Tolima]), guaracaro (Venezuela); French: pois souche (Haiti)

The Caribbean group is made up of small, round seed material distributed in that area.

> **Common names of the large-seed cultivars** (54 to 280 g per 100 seeds). Spanish: lima (because of its origin from the coast of Peru), torta (Colombia [Nariño, Huila], Ecuador [Imbabura, Azuay, Loja]), layo (Peru [Cajamarca]), pallar (Peru [Lambayeque, La Libertad, Lima, Ica, parts of the range]), palato (Bolivia [Chuquisacal), poroto manteca (Argentina)

Archaeological findings in Ancash, Peru, indicate that, after *Lagenaria siceraria*, the large-seed species were among the first to be cultivated (8 000 years ago), while the small-seed materials in Mesoamerica date back only 1 200 years. The large-seed material appeared 5 000 years ago on the coast of Peru, where they were of great nutritional and cultural value, particularly for the Mochican and Nazca peoples. Distribution of the wild form on the northern range (electrophoresis test results show that it is the ancestor of the Andean stock) suggests that domestication took place in this area and that it expanded towards the high parts of Ecuador and Colombia as well as towards the Peruvian coast and other high parts of Peru and Bolivia. Nowadays, the green seed in particular is eaten.

On the Peruvian coast, dulce de pallar, a kind of Lima bean conserve, is prepared from the dry seed. The aesthetic value of the seeds has enabled them to be used in recreation activities in peasant communities. The small-seed cultivars were domesticated from a wild form, possibly in Mesoamerica and in more recent times. The seeds are eaten dry (the Mayans of today prefer them refried) or green. In Asia the young plants or young leaves are consumed; in Madagascar they are used to prepare hay.

Among the reasons for the present marginalization of *P. lunatus*, apart from abandonment of the traditional diet with the rural exodus and changes in peasant customs, we should mention the presence of a cyanogenic glucoside which in some cultivars, if detoxification is omitted, may cause poisoning. Standardization in the consumption of leguminous vegetables (some varieties of common bean or cowpea) has been prejudicial to the Lima bean because of the presence of this glucoside. The small-seed cultivars, particularly under irrigation, suffer from the competition of soybean (and sometimes the cowpea because of its price). In the Peruvian Andes, Lima beans have heavy competition from the introduced lablab [*Lablab purpureus* (L.) Sweet] which is resistant to weevils, and the introduced pigeon pea [*Cajanus cajan* (L.) Mills], which is more tolerant of drought.

Botanical description

P. lunatus is a pluriannual species (except for a few modern cultivars) with epigeal germination and fibrous roots. Its ancestral forms come from low- or medium-altitude tropical deciduous forests. It is easily distinguished by its half-moon seeds (with the exception of a group of cultivars from the Caribbean that has a spherical seed). It is striated from the hilum and has: deltoid folioles; pseudoracemes with four to 12 fruit-bearing stems; small flowers, with a standard which is greenish (Mesoamerica) or purple (Andes); very small, roundish bracteoles; and smooth, falcate pods with three to six ovules. The two wild forms display marked differences but do not justify differentiated taxonomic treatment because of the considerable introgression among their genetic stocks. It is an autogamous species with an introrse stigma, but cross-pollination may exceed 32 percent.

The earliest genotypes flower 35 days after sowing and complete their cycle in around 100 days. Others may have two flowering cycles per year depending on the distribution of rainfall. In dry areas, the plants sprout from the lower part of the stem with the return of rainfall. In the majority of the traditional varieties, the guide leaves are long (3 to 6 m), indeterminate, creeping (and therefore useful as ground cover) or climbing.

The fibrous roots may attain several metres on filtering soils with deep humidity (Yucatán, coastal Peru), thus giving the plants great vegetative vigour (greater than maize) and a survival period of up to four years. In the wild populations. the seeds are dispersed through explosive dehiscence of the pods.

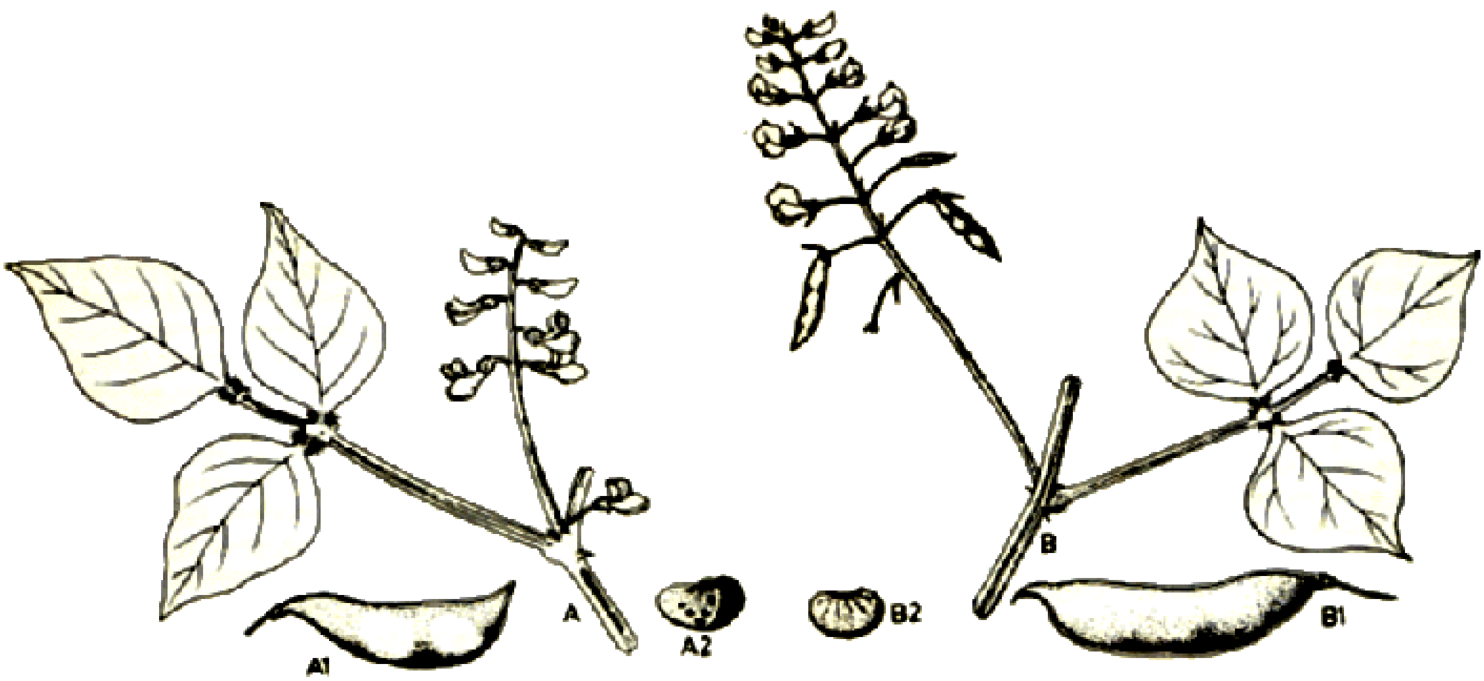

Figure 4. Beans: A) *Phaseolus lunatus*; A1) legume; A2) seed; B) *P. polyanthus*; B1) legume; B2) seed

Ecology and phytogeography

Although not strict, there is a certain distribution pattern of the forms. The small-seed wild form is found from Sinaloa in Mexico to Salta in Argentina, generally below 1600 m. The small-seed cultivars frequently grow at a lower altitude in the Pacific area of Mesoamerica, from Arizona in the United States to Choco on the western range of Colombia as well as the Ecuadoran coast, and from Yucatán and Colombia to Venezuela and in the Antilles. It also exists h northeastern Brazil and in Formosa, Argentina. The larger wild form is distributed in Ecuador and in the north of Peru between 320 and 2030 m. The large-seed cultivars are distributed in Peru from 50 to 2750m and in the high valleys of Chuquisaca and Cochabamba in Bolivia. Curiously, some also exist in the south of Brazil.

P. lunatus is a generally hardy species which prefers dry climates and deep soils (pH 6 to 7.2) with good drainage. Although it is true that some forms tolerate the climate of the lower tropics well, the species' exceptional altitude range should be mentioned, particularly in Peru where some forms withstand low temperatures (Table 3). *P. lunatus*, both cultivated and wild, is rather heliophytic.

Genetic diversity

The intraspecific variability of *P. lunatus* is particularly high in the groups of Siva and Gran Lima varieties and less in the Caribbean group. There are several commercial cultivars, particularly in California (for example. Henderson and Fordhook) and for domestic consumption (unripe green seeds in salads) in the United States. Relatives of the Andean wild form are *P. augusti* Harms, *P. bolivianus* Piper and *P. pachyrhiozoides* Harms. Of the cultivated species, the latter has the widest secondary stock.

There are numerous gene banks, mainly in Pullman in the United States (USDA), Chapingo in Mexico (INIFAP) and Palmira in Colombia (CIAT). Germplasm has been collected in order to save traditional material cultivated in several regions of the American tropics where varieties have rapidly disappeared. It could still be collected profitably in some parts of the Yucatán peninsula, northern Colombia, San Martin in Peru and in Paraguay.

In the case of wild material (particularly of the small-seed tone) many regions fall short for collecting specimens: Tamaulipas, Sinaloa, Michoacán, Oaxaca, Chiapas, Petén in Mexico, El Salvador, Nicaragua, Panama, Venezuela and easten1 Bolivia.

Cultivation practices

In the neotropical zones of America, it is very common to find from one to five *P. lunatus* plants in household vegetable gardens and on small plots, as it is customary for families to add a few green seeds to soups. In the Mayan Yucatán, this bean is traditionally sown as part of the slash-and-burn clearing system with maize, buul (*P. vulgaris*) and gourds. On the coast of Colombia, carauta is found on plots with maize, cassava and guandul. On the coast of Peru, it was frequently found broadcast on the banks of mountain streams where it absorbed the floodwaters. Similar practices may have existed in the *cinteño* valley in Bolivia before the introduction of the grapevine. Nowadays, in Chinca, Peru, it is sown as a commercial monoculture (white seeds) on ridges with irrigation. In many parts of the Andean range (in the dry inter-Andean valleys at 2000 m of Nariño, Colombia; Imbabura and Azuay in Ecuador; and Cajamarca in Peru) *P. lunatus* is frequently seen growing on old walls separating plots and roads or on landslides and slopes. The peasants thus use the spaces of least value. In other parts of Peru (Cajamarca, La Libertad), the Gran Lima types are sown around the edge of small farms. In some places, the plants behave spontaneously and cross with the wild forms that exist in the surrounding area (for example in Succhubamba, Cajamarca).

As it is sown almost individually in many family vegetable gardens. it is difficult to give figures for yield per area. Furthermore, periodic harvesting complicates the evaluation. In the shrubby forms, seed yields of 2000 kg per hectare have been recorded and, in climbing varieties, more than 3000 kg per hectare.

Prospects for improvement

Within the cultivated species, *P. lunatus* competes with *P. coccineus* through the genetic stock which is wider (primary and secondary) and differentiated into a very early form (for which there is genetic progress); it has a good rate of allogamy and heterosis has been found; consequently there are good prospects for improvement. *P. lunatus'* relatively late production, as well as that of the indeterminate creeping forms, may be compensated by exploiting the earlier shrubby forms. There is a wide variation in the glucoside content in the seed, and potential for improvement with types of less than 5 ppm, without any correlation with the colour of the tegument. The evaluation of cultivars to determine the glucoside content will make it possible to establish many materials in traditional areas of cultivation and consumption. Its hardiness and lengthy production may be advantages in adverse conditions where other leguminous vegetables do not prosper. The aesthetic value of the Gran Lima varieties may be considered in the development of handicrafts (which could be useful in remote parts of the Andes). The restoration of traditional dishes and uses (for example in recreation) would also contribute to the crop's promotion. The selection of varieties resistant to grub (*Acanthoscelides* sp.) and weevil (*Apion* sp.), particularly the Gran Lima, and of shrubby forms with a greater diversity of seeds (colour, shape) as well as the study of production techniques (the use of nettings, sowing on slopes, etc.) should be mentioned as research priorities.

Phaseolus polyanthus

Botanical name: *Phaseolus polyanthus* Greenman

Family: Fabaceae

Common names. Spanish: botil (Mexico [Chiapas]), piloya (Guatemala [Chimaltenango]), dzich (Guatemala [San Marcos]), piligüe (Guatemala [Alta Verapaz]), petaco (Colombia [Antioquía and western region]), cache (Colombia [Cauca, Huila and southern region]), matatropa (Colombia [Huila]), toda la vida (Ecuador, northern region of Peru).

The taxon *P. polyanthus* was recently acknowledged as a result of identification of its ancestral forms. There are no recordings of this legume on archaeological sites, in spite of the fact that the seeds found have been analysed thoroughly. The ecological conditions under which this species grows may not have been favourable for its preservation. Mention has been made of how old this crop must be in Mexico. In comparison with the wild forms and the other species, *P. polyanthus* is less evolved, which appears to be the result of its more recent domestication.

It has frequently been cultivated together with maize, gourds and two species of bean (*P. coccineus* and *P. vulgaris*) in Mesoamerican regions with a humid climate and at an intermediate altitude. Like the scarlet runner bean, this crop has been reduced with modification of the traditional maize field system in many parts of Mesoamerica. If peasants have to cease cultivating a species of bean, they keep the kidney bean, which generally obtains the best price. Among the other causes of its marginalization is the extension of coffee plantations and livestock rearing in its area of cultivation. As their incomes increased. peasants tended to abandon consumption of this legume. Traditionally, the green seed is preferred (either because it is easier to digest or because of its softer tegument) when the pod reaches physiological maturity and the dry seed is favoured less: it is eaten in soups. stews or even as a sweet (Amazon region).

Botanical description

Only pluriannual forms of *P. polyanthus* are known, which can live from two to tour years. In drier parts (for example, western Cajamarca, Peru) it tends to behave as an annual. It is easily distinguished from the other species by its epigeal germination; fibrous, fasciculate roots; inflorescences with six to 16 fruit-bearing stems; primary bracts and long, narrow bracteoles (giving the pseudoraceme the appearance of a spike); white or lilac flowers (purplish pink in the wild form); and terminal stigma. Its seed (70 to 100 g per 100 seeds for cultivated varieties and 16 to 25 g for wild forms) has a wide, elliptical hilum and the parahilum is frequently broken.

Ecology and phytogeography

P. polyanthus is distributed in intermediate altitudes (800 to 2600 m) in cool, damp climates with one dry period per year (Table 3); it has a long flowering period (two to five months) and can have two flowering and fruit-bearing periods per year if the rainy season is heavy (Colombia, Venezuela). It prefers deep, organic, damp and well-drained soils with pH 6.2 to 6.5 and it tolerates a degree of shade.

The cultivated form is found in Puebla, Veracruz, Oaxaca and Chiapas (Mexico). In Guatemala. it can be seen in Huehuetenango, San Marcos, Quezaltenango, Totonicapán, Baja and Alta Verapaz, Sololá, Chimaltenango and Sacatepéquez. It is also distributed in the upper parts of the Caribbean (Jamaica, Dominican Republic) and Costa Rica. It is cultivated in South America, where it is found in secondary vegetation, including wooded vegetation, from Mérida in Venezuela to Apurimac in Peru and in the western and central ranges of Colombia (the petaqueras of Antioquía), Ecuador (Azuay, Pichincha, Tungurahua) and northern Peru (Cajamarca, Amazon, Junín). To date, the wild form has been found only in the central-western part of Guatemala, where it is a liana that grows in the low, humid mountain forest; the possibility of it also occurring in the mountainous zone of the Jalisco-Michoacán boundary in Mexico should not be excluded.

Genetic diversity

This species is considered to be the least evolved of the cultivated *Phaseolus* species, hence it should have a greater potential for future development. There is little phenotypic variation (only the indeterminate climbing growth habit), including in the seeds. Normally it has orangy yellow seeds, but other colours do appear: reddish brown, bay, black and creamy white, for example. Seeds of the latter colour were found by the author in the Amazon region of Colombia and in Loja, Ecuador. It may have potential as a commercial crop in northern Peru and may compete as a plant with the caballeros (*P. vulgaris* with a large, round white seed), which do not produce in humid areas. Greater variation is seen in the seed where natural hybrids exist with *P. coccineus* (for example, in Putumayo, Colombia) and with *P. vulgaris* (for example in Tolima, Colombia) where colours may be combined with purple, coffee, etc. To date, there do not seem to be any properly recorded cultivars.

It is evident that *P. coccineus*, *P. polyanthus* and *P. vulgaris* are genetically close as a result of natural introgression among the species. However, each comes from a different and individualized ancestral form. The reason for this relationship should be found in the origin of the ancestral forms. Other species of the *P. coccineus* complex may also be considered to be close to the cache; the genetic stock of *P. polyanthus* is therefore wide.

An exact evaluation of genetic erosion in this species is difficult: in some parts of Guatemala (San Marcos, Chimaltenango) and Costa Rica, where the traditional maize field cultivation system has been modified, certain genotypes are disappearing; in others (Cauca, Tolima, Amazon region, in Colombia and Junín in Peru) it appears to extend into ruderal vegetations because peasants throw seed on roadsides and in smallholdings, etc. One farmer in Huila, Colombia, mentioned that it was the first seed that he sowed in the slash-and-burn system of Los Paez. The species' hardiness in humid environments provides food when the maize harvest is insufficient and explains its frequent presence in secondary forests in Colombia, Ecuador and northern Peru. It is even more difficult to evaluate erosion, as it is a predominantly allogamous species (although the local variation of this allogamy is not well known). However, it does seem useful to document the evolution of the native material in its areas of genetic cultivation in Mexico and Guatemala and to collect germplasm in appropriate cases. In the southern area of its distribution, where there seems to be less variation and erosion, collection would not seem to be urgent. The situation is different in the case of the wild ancestral form: its distribution area in central-western Guatemala is threatened by urbanization and agriculture (the primary forest where it grows is being cut down to set up coffee plantations). It is urgent to complete collection of germplasm and to ensure that at least some plant species are included in *in situ* conservation within the perimeter of natural parks. This method should also be considered for the few sites where there is natural introgression.

There are collections of this species, mainly in Chapingo in Mexico (INIFAP); Chimaltenango in Guatemala (ICTA); La Molina in Peru (INIAA); and Pullman in the United States (USDA). The widest collection is that of the CIAT in Palmira, Colombia.

Cultivation practices

The majority of the cultivation practices mentioned for the tepary bean in the high humid zones of Central America also apply to the cache bean. Although it is sown mixed with tepary beans, it frequently ripens a little earlier; separate harvesting (especially to eat it when green) is possible but is not always practiced. In the Andes it is frequent to see it in enclosures or in family vegetable gardens where it grows without any special care.

Prospects for improvement

A limiting factor appears to be the lesser digestibility of *P. lunatus* which has been verified in certain areas (Amazon region). The documentation of current consumption practices in peasant communities must be considered a priority before embarking on an investigation of its nutritional quality. It should be borne in mind that until the very recent past these beans were eaten several times a week. The lack of variation in seed colour is a problem which could be corrected partly with the distribution of germplasm from collections and through additional gatherings, particularly where there is introgression with *P. coccineus* and *P. vulgaris.* Variation in colour, type of seed and growth habits could be obtained through cross-breeding programmes that explore the primary and secondary genetic stock of *P. polyanthus.* Evaluation is still very much in its initial stage and is a priority for agrarian research. It would be very useful, since it is known that this species offers characteristics of resistance to several pests and diseases such as *Ascochyta* sp. (in the cool, humid parts of the Andes) and *Ophiomyia phaseoli* (in East Africa), respectively. There are genotypes ready for delivery to the farmer, particularly in conditions that are adverse to the kidney bean. The consumption of *P. lunatus* as a green seed could be recommended and recipes developed to improve preservation of the green seed. Its cultivation could also be encouraged in family vegetable gardens. Since the plant is attractive to livestock, it could be considered as a fodder crop in association with maize. In agrosilvicultural contexts (for instance in young plantations or hedges against erosion), it is possibly the best bean species to use. Its role in coffee plantations could also be considered from the point of view of fertilizing value and soil protection.

Conclusion

The bean was domesticated at a time when the current knowledge of molecular genetics and nutritional science was obviously not available to ensure selection of the material with the best evolutionary and nutritional potential. In addition to the kidney bean, four other species have been domesticated and have been maintained for thousands of years. It is not known whether the initial success of the kidney bean was due to its greater evolutionary potential compared with the other species or whether particular circumstances caused its domestication. Nor are all the reasons known for its promotion throughout the 200 years after 1492. Consequently, the germplasm collected of those species during the last 60 years, and the information relating to them, are possibly scarce in relation to what must have existed before the conquest. However, what has been able to be recovered is surprising and offers promise. In spite of all the changes that have occurred with the kidney bean since the fifteenth century, it has been difficult to modify its ecology drastically and the alterations that the latter may have suffered have had negative effects on species yield. Ought we not now give the neglected beans an opportunity?

Neglected Crops: 1492 from a Different Perspective. 1994. J.E. Hernándo Bermejo and J. León (eds.). Plant Production and Protection Series No. 26. FAO, Rome, Italy. p. 47-62.

Phragmites australis (Cav.) Trin. ex Steud.

Syn.: *Phragmites communes* Trin.
Phragmites vulgaris B.S.P.
Poaceae
Common reed

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Common reed provides high quality warm-season forage and is readily eaten by cattle and horses. However, it becomes tough and unpalatable after maturity. Animals grazing this grass during winter should be fed a protein concentrate. Extensively used in Mediterranean region and elsewhere for building dwellings, lattices, fences, arrows by Indians, and for weaving mats and carrying nets. Young shoots sometimes used as a vegetable. The stalks exude a manna-like gum which is eaten. The rhizomes and roots also serve as emergency food. In Russia they are harvested and processed into starch. A variegated form is grown as an ornamental. The reed is useful in the manufacture of pulps for rayon and paper. It contains over 50 percent cellulose and has a fibre

0.8–3.0 mm long and 5.0–30.5 μm in diameter. Pens for writing on parchment were cut and fashioned from this reed, and the stems were used as a linear measuring device. It is also useful in the production of homogeneous boards. It can be processed into a fine fibrous material suitable as a filler in upholstery. Flowering stalks yield a fiber suitable for rope making. It is also used for thatching and for making partitions, fences, coarse mats, baskets, sandals, etc. Thin stems are made into pens; panicles are used for making brooms and for decoration.

Folk Medicine

According to Hartwell (1967–1971), the plant is used in folk remedies for condylomata, indurated breast, mammary carcinomata, and leukemia. Reported to be alexeteric, diaphoretic, diuretic, emetic, refrigerant, sialogogue, stomachic, and sudorific, the common reed is a folk remedy for abscesses, arthritis, bronchitis, cancer, cholera, cough, diabetes, dropsy, dysuria, fever, flux, gout, hematuria, hemorrhage, hiccup, jaundice, leukemia, lung, nausea, rheumatism, sores, stomach, thirst, and typhoid.

Chemistry

Per 100 g, the reed is reported to contain (ZMB): 415 calories, 10.6 g protein, 2.1 g fat, 72.7 g total carbohydrate, 31.9 g fiber, 14.6 g ash, 480 mg Ca, 60 mg P, and 130 mg Mg. Leaves are reported to contain 17.1 g protein, 3.5 g fat, 63.7 g total carbohydrate, 27.4 g fiber, and 15.7 g ash. Stems are reported to contain 4.8 g protein, 0.8 g fat, 90.0 g total carbohydrate, 41.2 g fiber, and 4.4 g ash. According to Hagers Handbook (List and Horhammer, 1969–1979), the fresh herb contains 5.15 mg Vit. A/100 g, and 91.1 mg Vit. C as well as Vit. B_1, and B_2, the triterpene β-amyrin, taraxerol, and taraxeron ($C_{30}H_{48}O$). The rhizomes contain: moisture, 5.3; nitrogenous substances, 5.2; fat, 0.9; NFE, 50.8; CF, 32.0; sucrose, 5.2; reducing sugars, 1.1; and ash (rich in silica), 5.8%. Asparagine (0.1%) is also present. *P. communes* is rich in pentosans and may be used for the production of furfural; nodes and sheaths yield 6.6% and the underground parts over 13% of furfural. The pentosan content increases throughout the growing period and is maximum in the mature reed. The reed can be used also for the preparation of absolute alcohol, feed yeast and lactic acid. Analysis of the young grass gave: protein, 11.4; EE, 2.3; carbohydrates, 43.1; CF, 31.05; mineral matter (with high silica content), 10.8; calcium (CaO), 0.94; and phosphorus (P_2O_5) 0.39%. The reed is reported to contain a wax and a saponin. Leaves have a high ascorbic acid content (200 mg/100g).

Description

Perennial grass; culms erect, 2–4 m tall, occasionally up to 6 m, with stout creeping rhizomes, often also with stolons; leaf-blades broad, flat, 1.5–6 dm long, 1–6 cm broad, glabrous, green or glaucous, the sheaths overlapping; panicle tawny or purplish, 15–40 cm long, the branches ascending, rather densely flowered; spikelets 10–17 mm long, the florets exceeded by the hairs of the rachilla; first glume 2.5–5 mm long; second glume 5.7 mm long; lemmas glabrous, sharp-pointed, not bifid, with long hairs confined to rachilla joints; lowest floret staminate. Fl.

July–October.

Germplasm

There is considerable variability in glaucousness of leaves, shape and denseness of panicle and growth habit. The variegated form, or Spire-reed, is sold as an ornamental grass. Reported from the Eurosiberian Center of Diversity, reed or cvs thereof is reported to tolerate fire, frost, high pH, salt, weeds, and waterlogging.($2n$ = 48, 36, 54)

Distribution

Native to Eurasia, Africa, but now widespread throughout the world; throughout United States, Mexico, West Indies to Chile and Argentina, Australia.

Ecology

Grows in marshes and swamps, along streams, lakes, ponds, ditches, and wet wastelands, often weedy and very difficult to eradicate, as the stoloniferous rhizomes may reach 10 m or more in length. Grows best in firm mineral clays, and tolerates moderate salinity, where water level fluctuates from 15 cm below soil surface to 15 cm above. Tolerates burning if water is above soil surface, but burning is not essential for management. In Gulf Coast marsh rangelands, it is often co-dominate with Big cordgrass (*Spartina cynosuroides*). Ranging from Cool Temperate Steppe to Wet through Tropical Desert to Moist Forest Life Zones, reed is reported to tolerate annual precipitation of 3.1 to 24.1 dm (mean of 16 cases = 9.8) annual temperature of 6.6 to 26.6°C (mean of 16 cases = 14.8) and pH of 4.8 to 8.2 (mean of 12 cases = 6.2). (Duke, 1978, 1979)

Cultivation

Rarely if ever really cultivated. However, stands may be started by transplanting young plants or rooted stolons. Starts growth in February in southern locations, later further north. Foliage stays green until frost. New shoots grow from buds at nodes of old stems, stolons or rhizomes.

Harvesting

Giant reed cannot withstand prolonged heavy grazing. Its upright growth makes it easy for livestock to remove all the leaves. For maximum production, no more than 50% of current year's growth by weight should be grazed off during the growing season. Water control that lowers the water level but does not drain the area increases production. Grazing deferments of 60–90 days improve plant vigor. The straight hollow stems are cut in autumn and dried for arrowshafts, pipestems, loom rods, screens, roofing for houses and adobe huts, etc. Leaves are also gathered and used for weaving mats and other objects.

Yields and Economics

Though the plants grow profusely wherever they occur, few yield data are available. A very useful grass wherever it grows, especially in the Mediterranean region, North Africa, and western North America. Although used extensively locally, its products do not enter commercial markets.

Energy

Reed swamps in Europe produce 7.5–13.0 MT/ha/yr. According to the Phytomass files (Duke, 1981b), annual productivity ranges from 40 to 63 MT/ha. Reeds are currently being harvested from Swedish lakes at a cost of ca $50/MT (ca $2.86/GJ gross thermal value), which rises to $60/MT after transportation and final processing ($3.43/GJ gross thermal value). These costs are expected to diminish as machines and methods are optimised (Palz and Chartier, 1980).

Biotic Factors

Because of its extensive use, a great number of fungi have been reported on giant reed; however, none of them have seemed to have caused any great damage to the grass. Reported are the following fungi: *Belonioscypha vexata, Belonopsis excelsior, Bispora hamonis, Chaetomella atra, Cladosporium herbarum, Clasterosporium lindavianum, Claviceps purpurea, C. microcephala, Coniosporium arundinis, C. sorghi, Cyphella capula, Dinemasporium strigosum, Diplodina arundinacea, D. donacina, Epicoccum neglectum, Fomes fomentarius, Fusarium graminearum, Graphyllium dakotense, G. graminis, G. manitobiense, Hadrotrichum phragmitis, Helminthosporium fusiforme, Helotium robustius, Hendersonia arundinacea, H. fuckelii, H. graminicola, H. phragmitis, Hymenella arundinis, Lachnum acutipilum, Leptosphaeria arundinaceae, L. culmifraga, L. donacina, L. littoralis, L. phragmiticola, Leptostroma phragmitis, Lophiostoma arundinis, Lophiodermium arundinaceum, Melaconium echinosporum, M. sphaerospermum, Melanopsamma pomiformis, Meliola arundinis, Microdiplodia machlaiana, Mollisia arundinacea, M. riparia, Napicladium arundinaceum, Nervossia iowensis, Papularia sphaerosperma, Phyllosticta phragmitis, Piricularia grisea, Pirostoma circinans, Placosphaeria dothideoides, P. rimosa, Pleospora adscondita, Pseudographis phragmitis, Puccinia argentea, P. isiacea, P. invenusta, P. magnusiana, P. phragmitis (rubella), P. trabutii, Pythium debaryanum, P. ultimum, Rhabdospora arundinis, Rhopographus clavisporus, Scirrhia ramosa, Scolecotrichum graminis, S. maculicola, Selenophoma donacis, Sphaerella phragmitis, Stagonospora arenaria, S. dolosa, S. neglecta, S. graminella, S. simplicior, S. vexata, Tapesia hydrophila, Teichospora phragmitis, Torula herbarum, Trichobelonium kneiffii, Uromyces blandus, Ustilago grandis, U. hypodytes, Volutella therryana.* The nematode *Subanguina radicicola* has been isolated from this grass.

Phyllanthus Species: Sources of New Antiviral Compounds

David W. Unander, P.S. Venkateswaran, Irving Millman, Herbert H. Bryan, and Baruch S. Blumberg

INTRODUCTION

Phyllanthus has more than 700 species in at least 10 sub-genera (Holm-Nielsen 1979, Webster 1956-58). A survey of 300 ethnobotanical references of *Phyllanthus* spp. arranged taxonomically suggested some uses were clustered by subgenus. A summary of the number of species per sub-genus used traditionally in various places to treat possible symptoms of liver disease (such as jaundice) is presented in Table 1. Among the herbs of subgenus *Phyllanthus* used medicinally, we found that aqueous extracts of *P. amarus* Schum. & Thom., *P. debilis* Klein, *P. fraternus* Webster, *P. niruri* and *P. urinaria* L. all inhibited viral DNA polymerase (DNAp) of hepadnaviruses in vitro. (Hepadnaviruses include human hepatitis B virus and several animal hepatitis viruses.) Additionally, extracts of less common species in the same sub-genus, such as *P. mimicus* Webster or *P. odontadenius* Muell. Arg., also had such anti-DNAp activity. Extracts of species from sub-genera not reported as being used for symptoms of liver disease generally had much weaker inhibitory activity (data unpublished).

The ultimate goal of our research is to develop a therapy for carriers of hepatitis B virus (HBV) which would reduce the incidence of liver cancer. Since its identification (Blumberg et al. 1967, Blumberg 1977), the virus has been found to be associated with cirrhosis, chronic liver disease and primary liver cancer as well as acute serum hepatitis. More than 200 million people worldwide are estimated to be carriers, many of them asymptomatically (Ghendon 1987). A series of studies have shown that persistent HBV infection is associated with a greatly elevated risk of developing liver cancer (Beasley et al. 1981, Dodd and North 1987). Although a safe and effective vaccine exists, and is being vigorously promoted, there is no effective therapy for carriers.

Aqueous extracts of *P. amarus* collected near Madras, India, (initially published under the name *P. niruri* L.) inhibited viral DNAp in vitro. In addition, they eliminated detectable virus from the sera of woodchucks (*Marmota monax*) acutely or chronically infected with the woodchuck hepatitis virus (WHV) (Venkateswaran et al. 1987). Endogenous DNAp is packaged with viral DNA in hepadnaviruses like HBV or the closely related WHV. In a small clinical trial in India, administration of powdered *P. amarus* eliminated detectable antigen from the sera of 59% of the treated human carriers as compared to 4% of controls (carriers receiving a placebo) who cleared the virus naturally (Thyagarajan et al. 1988). Studies are in progress to characterize the compound(s) responsible for these effects.

SOURCES OF ANTI-DNAP VARIABILITY

In Experiment 1, plants of *P. urinaria* and *P. debilis* were grown in the greenhouse in a 2 x 2 factorial design comparing soils of differing fertility (fertilized regularly with a 0.04N-0.06P-0.07K solution vs. not fertilized) and different moisture and structure conditions (a commercial peat mix regularly watered vs. sand infrequently watered). Six month old plants were harvested, lyophilized and ground. Aqueous extracts were made using 5 g ground plant in 20 ml water at 60°C for two hours, mesh-filtered, centrifuged, and the supernatant passed through a 0.45 µm micropore filter (Nalgene 125, Nalge Co., Rochester, NY). Dried whole and ground plants and extracts were stored at -15°C. Extracts were made of two random samples of ground plant per treatment combination. Activity was expressed as µg of dry matter per ml of extract producing 50% inhibition of WHV DNAp, after Venkateswaran et al. (1987), and analyzed after testing for homogeneity of variance.

Various morphological variables (e.g., plant height weight, amount of branching), were significantly affected by differing soil conditions (data not shown). The only effects on inhibition of viral DNAp, however, were for gross soil fertility on *P. urinaria* (84 and 38 µg/ml for fertilized and unfertilized, respectively) and, in the pooled analysis, species (139 and 61 µg/ml for *P. debilis* and *P. urinaria*, respectively). Regression analyses showed significant effects on *P. urinaria* of available N or P or percent saturation of K. Genetic differences in viral DNAp inhibition were greater than any effects from soil conditions.

In Experiment 2, plants of *P. amarus* were grown in the greenhouse in a 2 x 3 factorial design comparing soil moisture and structure conditions as in experiment 1, and three levels of soil pH and in a 2 x 2 factorial comparing soil moisture and structure conditions and high vs, low Ca levels. *P. amarus* was commonly found in calcareous sites in Puerto Rico but much less commonly in other soils, so a preference for high pH, high Ca or both was hypothesized, and the effect of these variables on activity of plant extracts against WHV DNAp was tested. Media of average pH 5.5, 7.5 and 10.5 were made using aluminum sulphate, calcium sulphate and hydrated lime, respectively. The treatments in sand had mean pH values about one log unit greater than those in the peat mix (i.e., 11.5 vs. 10.5). To test the effect of Ca apart from pH, pulverized limestone was added or not added to the sand or peat mix. In this test, the pots with and without Ca had pH means of 8.0 and 7.0, respectively. Water samples taken from the bottom of pots during watering were used to follow pH. A more acidic treatment was also attempted, but *P. amarus* did not survive more than two weeks at about pH 4.5. In this experiment individual plants served as replicates with three replicates in the first test and two in the second. Extracts, assays and analyses were done as described.

Soil conditions significantly affected plant growth. Optimum growth seemed to be in soil slightly above neutral and with high Ca, as expected. For the effects of plant extracts on viral DNAp, soil pH as a main effect was non-significant. Using data from both tests, the linear regression of DNAp inhibition on soil pH showed an effect at P = 0.09. The R^2 value (0.11), however, suggested relatively little variability in the inhibition of viral DNAp was explained by pH. Soil moisture or structure significantly affected DNAp inhibition of plant extracts in the pH test (158 and 263 µg/ml for the sand and peat respectively). The interaction of moisture and pH had an effect at P = 0.10. Means over pH treatments ranged from 174-246 µg/ml with greatest activity at higher pH, over all six treatment combinations, means ranged from 85-332 µg/ml (greatest and least activity at high pH, sand and low pH, peat, respectively). Plants from high pH in sand were significantly stunted relative to other treatments, with average dry weight per plant of 1.7 g vs. an average for the other five treatments of 6.6 g. Plants at high soil pH in peat had mean inhibition values (262 µg/ml) similar to those at lower pH, illustrating the interaction observed between pH level and peat vs. sand. No regressions of DNAp inhibition on specific soil macronutrient data were significant. In the test examining high Ca vs. no Ca and sand vs. peat, neither main effect was significant

In Experiment 3, genetic differences among accessions were tested. Plants of *P. urinaria* from seed collected in India, the Ivory Coast Hawaii, Puerto Rico, Trinidad, Venezuela or Vietnam were grown randomized on one greenhouse bench using the same growing regime. Based on an analysis of extracts derived from two plants/seed source, there were highly significant differences among seed sources in inhibition, with means ranging from 70 to 532 µg/ml. This suggests that genetic variability for inhibition of DNAp exists in *P. urinaria*. Plants of *P. amarus* from seed collected from two sites in India and three sites in Puerto Rico were grown in a similar experiment with three plants/seed source but seed source was non-significant at P = 0.25, with means for viral DNAp inhibition ranging from 192 to 409 µg/ml. A third test using the same procedure examined different accessions of *P. amarus* from sites in Florida, India and Puerto Rico. No significant differences were found; means ranged from 122 to 163 µg/ml. These latter two tests were respectively grown in the winter and the summer.

CULTIVATION

Although common in the tropics, the *Phyllanthus* species of interest are generally small and often scattered in distribution. The only reference found which discussed cultivation (Kangsu Medical Institute) recommended fertile, well-drained soil for growing *P. urinaria*. To produce sufficient quantities for large scale extraction, a system was developed at the University of Florida Tropical Research and Education Center at Homestead, using black plastic mulch and trickle irrigation Since plants with the strongest inhibition of viral DNAp in our studies had consistently come from the warmest environments, a tropical site was desired. Southern Florida was chosen as being both tropical and efficient for shipment of harvested plant The soil at Homestead, which is a crushed oolitic limestone, was also considered well-suited to *P. amarus*. Wild plants of *P. amarus* were abundant in fallow fields around Homestead following periods of rain.

The first plot served as an experiment to establish *P. amarus* as a row crop and to test two fertility levels. Plots were fertilized with 560 or 1120 kg/ha 6N-5.2P-10K before mulching in a randomized block design with three replicates. Seed of *P. amarus* were sown using 1.5% cellulose gel (N-Gel, Hercules Co.) at 0.15 g seeds/liter (100 seedweight = 0.015 g). Approximately 50 cc of gell/hill were applied. Hills were holes set 30 cm apart in the mulch. Hills were in four rows spaced 30 cm apart on raised beds 1.7 m wide for a planting density of approximately 7,500 hills/ha.

Six months after planting, whole plants weighed an average of 7.5 g (lyophilized dry weight). Aqueous extracts were made as described. Extracts were made of shoots and roots by fertility treatment and replicate. The average DNAp inhibitory activity over all samples was 142 µg/ml. The two levels of fertility did not significantly affect viral DNAp inhibition. Roots were significantly more active than shoots (66 and 151 µg/ml respectively), but roots only accounted for about 10% of the total dry weight. This range of activity was consistent with earlier results obtained with plants collected in the wild (Venkateswaran et al. 1987). Cultivation, irrigation and fertilization thus did not reduce DNAp inhibitory activity over the far more laborious collection from the wild. Stand establishment measured as hills with any plants six months after planting, was only about 70% in this first plot. Variables affecting seed germination and longevity have not yet been well-characterized. Total potential production was estimated to be at least 40 kg/ha (dry weight) but should be substantially greater once stand establishment can be improved. At the rates used by Thyagarajan et al. (1988), 1.8 kg of dried whole plant would have provided a course of treatment for 100 persons.

CONCLUSIONS

P. amarus and closely related species appear to contain activity against the endogenous DNAp of hepadnaviruses. This may be the basis for traditional uses of these species against disease symptoms such as jaundice, which, retrospectively could, in at least some cases, have been caused by hepatitis B virus. This DNAp inhibitory activity was relatively unaffected by soil conditions, but differed among accessions, suggesting that genetic variability does exist for this trait. Plants proved easy to grow and biological activity of the cultivated material was equivalent to material collected from the wild.

Rocha S.F.R. and Lin Chau Ming. 1999. *Piper hispidinervum*: A Sustainable source of safrole. p. 479–481. In: J. Janick (ed.), Perspectives on new crops and new uses. ASHS Press, Alexandria, VA.

Piper hispidinervum: A Sustainable Source of Safrole

Sérgio F.R. Rocha and Lin Chau Ming

Piper hispidinervum (C. DC.), Piperaceae, is a promising source of sassafras oil, the source of safrol, currently derived from endangered plants of the Lauraceae such as *Ocotea pretios* Ness (Mez.), *Cinamomum petrophilum*, *C. mollissimum*, and *Sassafras albidum* Nutt. The essential oil of *P. hispidinervum* contains high levels (83–93%) of safrole in leaves which can be easily extracted by hydrodistillation.

SAFROLE

Safrol a phenolic ether (Tyler et al. 1982), is a colorless or slightly yellow liquid, $C_{10}H_{10}O_2$, molecular wt 162.18, with density of 1.096 at 20°C, and melting point about 11°C. The oil is insoluble in water, very soluble in alcohol, miscible with ether and chloroform. The DL_{50} (oral) is 1.950 mg/kg in rats and 2.350 mg/kg in mice (Budavaris 1989).

Sassafras oil is important to several products. It was used as an ingredient in popular beverages, such as "pinga com sassafras" in Brazil, and was once used as an ingredient for "root beer" in the United States. It has been used as a topical antiseptic and pediculicide, but it may be carcinogenic.

Safrole is an important raw material for the chemical industry because of two derivatives: heliotropin, which is widely used as a fragrance and flavoring agent, and piperonyl butoxide (PBO), a vital ingredient of pyrethroid insecticides. Natural pyrethrum in particular would not be an economical insecticide without the addiction of PBO as a synergist and the future of the natural pyrethrum industry is linked to the continued availability of PBO. Safrole has many fragrance applications in household products such as floor waxes, polishes, soaps, detergents, and cleaning agents.

Markets and Demand

Japan, Italy, and the United States are the most important markets for sassafras oil, and the total annual demand is estimated to be around 2,000 tonnes. Brazil has manufacturing capacity for both heliotropin and PBO (equivalent to about 500 t of sassafras oil), although a shortage of domestically produced oil has led to importations of oil from China. The worldwide sassafras oil price is US$4 to 6/kg.

The demand for sassafras oil is determined by the market for heliotropin and PBO. Heliotropin consumption is increasing, particularly in Eastern Europe, Asia, and some developing countries, and sassafras oil is the favorite raw material for its manufacture. If price rises markedly, synthetic heliotropin would become more attractive.

Sources

In Brasil, sassafras oil has been extracted commercially from *Ocotea pretiosa*, a perennial tree native to coastal tropical rainforests from Bahia to Santa Catarina, in Mata Atlantica. This species is also found in Colombia and Paraguay (Rizzini and Mors 1995). This was based on a discovery in l939 that wood distillation from a large tree in the state of Santa Catarina yielded a rich source of sassafras oil, containing 84% safrole. These trees were indiscriminately harvested, placing this species on the endangered list. Until the 1960s, Brazil was the major exporter of sassafras oil in the world, but production has declined with the depletion of this natural resource. Governmental restrictions in the late 1980s have resulted in a further decline in production and in the falling level of Brazilian exports. No significant replanting has ever occurred.

Vietnam has been exported sassafras oil since 1990 from wild trees of *Cinnamomum camphora*, but supplies from this source may be relatively short-lived. Current exports are estimated to be several hundred tonnes/year.

PIPER HISPIDINERVUM AS A SAFROLE SOURCE

In the early 1990s, certain forest shrubs of the Piperaceae, indigenous to the humid forests of Central America and Greater Amazonia, were found to contain high levels of safrole in their leaves. The Brazilian Amazon contains a wide variety of *Piper* species but attention had focused on *P. hispidinervum* and *P. callosum*, two species with high safrole content. Subsequently, *P. callosum* has been dropped in the research work in favor of the more promising *P. hispidinervum*.

This effort was carried out by Museu Paraense Emilio Goeldi in Belém in collaboration with the Center for Agroforestry Research (CPAF-EMBRAPA) in Acre.

Piper hispidinervum known as "pimenta-longa" in Brazil, has been described by Yunker (1972). It is a nodose, branching shrub with rather slender upper internodes, somewhat angular, mostly 1–3 cm long, glabrous or very sparsely pubescent, somewhat glandular dotted. Leaves are oblong-lanceolate or elliptic-oblong, with attenuately acuminate apex and inequilateral base. This species resembles *Piper aduncum* L. to some extent but differs in its scarcely scabrous leaves, glabrous stem, and short peduncle (Yunker 1972). Coppen (1995) suggests that this species is distributed throughout South America, and is especially prominent in the state of Acre in Brazil and may extend into Amazonas.

The species is most frequently found on degraded forest, bordering primary forest or farm land where it occurs as a colonizing "weed," either as a pure stand or along with other *Piper* species. On natural sites, plants develop initially into bushes and at an early stage they appear to inhibit growth of competing vegetation. As the plants age they become more tree-like, up to 10 m tall.

Pilot-scale distillations have been conduced to determine oil quality and yields and permit estimation annual productivity on a per hectare basis. The safrole content of the oil in unselected stock is about 85%, but a improvement to more than 90% is possible through selection. Leaves of *P. hispidinervum* in experimental plots of CPAF-EMBRAPA (Acre) contained 3% essential oils of which 93% is safrole.

Management and Culture

Mixed planting of *P. hispidinervum* with cash tree crops is a practical possibility and would be economically attractive as leaf harvesting would permit an early cash return. Another production possibility is sustainable management in natural vegetation since it occurs in high populations in several open areas bordering primary rainforest. Reforestation projects, in natural or deforested gaps, could take advantage of the vegetative and productive potential of *P. hispidinervum* since it is a pioneer species.

Piper hispidinervum offers excellent conditions for cultivation in areas with facilities for harvest, transport, and industrialization (Chaves 1994). Trials have been established at several sites in Brazil using both rooted cuttings and seedlings designed to provide information in both growth characteristics and biomasss yields (leaf + stem) under various planting and management regimes. Studies undertaken in laboratories of the Department of Horticulture, FCA–UNESP, Botucatu, demonstrated that this plant is positively photoblastic with 50% germination under sunlight but none in the dark.

Crop density studies in Acre state by Sousa et al. (1997) indicate that the highest biomass production was achieved at spacing of 70 × 70 cm. Essential oil yield was 0.3% in branches and 4.0% in leaves; safrole content was not evaluated.

Disease Susceptibility

In the early 1960s, Japanese immigrants to Brazil colonized the state of Pará, and initiated the culture of black-pepper (*Piper nigrum* L.) but it was an agronomic and economical disaster, due to fusarium disease caused by *Fusarium solani* f. sp. *piperis*. Poltronieri et al. (1997) evaluated the resistance of seedlings of *P. hispidinervum* to different isolates of this pathogen, and demonstrated resistance, indicating the possibility of commercial cropping in areas where black pepper had been decimated by the fusarium disease.

Cercospora is a potential pathogen of *P. hispidinervum*. In Xapuri (Acre state), plants infected by *Cercospora* had a reduction of 21% in essential oil produced, but the safrole content was unaffected (Siviero and Pimentel 1997).

FUTURE PROSPECTS

Forest preservation in developing countries is a controversial issue that involves many different interests. The worldwide demand for raw materials, such as safrole, offers an opportunity to these countries that have a source of products in their natural forests.

Forest preservation is best linked to local populations maintenance. In this context, *P. hispidinervum* is more than a new safrole source. The economical exploration of its productive potential could be an important step to assist in the maintenance of the Amazon rainforest, providing a new livelihood option. This might include culture as a crop but also sustainable management in natural vegetation, since this species occurs in high populations in several open areas such as in natural gaps in the forest and in areas bordering the primary rainforest. An integrated project based on this species among research institutes, universities, governmental, and non-governmental institutions could produce a sustainable alternative crop for the tropical rainforest.

Pine nut

Pinon, Pignolia

Pinaceae *Pinus edulis* Engelm.

***P. quadrifolia* Parl. ex Sudw.**

Source: Magness et al. 1971

The seeds of these species of *Pinus* are gathered from native trees for food by the Indians in southwestern U.S., and occasionally appear in markets. The trees are up to 40 feet, spreading, with stout branches, and with short needles not over 1.5 inches long. Cones are near globose or broad ovate, compact until mature. Seeds are about 0.5 inch long, elongated and angular. They are eaten directly, also used in confections under the name pignolia. The trees are not in cultivation.

Pinkroot

Spigelia marilandica L.

Figure 83.—Pinkroot (*Spigelia marilandica*)

Other common names.—Carolina pinkroot, Carolina pink, Maryland pink, Indian pink, starbloom, worm grass, wormweed, American wormroot.

Habitat and range.—This plant is found in rich woods from New Jersey to Florida and west to Texas and Wisconsin, but occurs principally in the Southern States. It is fast disappearing, however, from its native haunts.

Description.—Pinkroot is an herb with a simple erect stem from 6 inches to 1 1/2 feet high. The pointed leaves are stemless, from 2 to 4 inches long, and one-half to 2 inches wide. The rather showy flowers are produced from May to July in a 1-sided terminal spike. They are tube-shaped, narrowed below, and slightly contracted toward the top, where they terminate in five lanceshaped lobes. The outside and inside of the tube are bright scarlet and the lobes yellow.

The roots of other plants, especially that of the East Tennessee pinkroot (*Ruellia caroliniensis* (Walt,) Steud., syn. *R. ciliosa* Pursh), are often found mixed with the true pinkroot. The rootstock of this plant is larger and not as dark as that of *Spigelia marilandica,* and it has fewer and coarser roots

Part used.—The rootstock, collected after the flowering period.

Pinus elliottii Engelm.

Abietaceae
Slash pine

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

A major source of pulp and tall oils in the deep south of the United States. The wood is very hard, heavy, strong, coarse grained, and durable. It is used for construction and railroad ties. Terpin hydrate is the main synthetic product of turpentine used in pharmaceutical preparations, used as an expectorant in humans and for veterinary bronchitis (Morton, 1977). Other synthetics produced from pine are anethole, camphor, and dl-menthol. Tall oil rosin contains sterols, mainly sitosterol. Russians built a factory in 1968 to produce steroids from pine pulp extractives. They are also pioneering in the commercial production of vitamin A and E. Synthetic materials derived from turpentine are used in perfumery and to impart flavors suggestive of cinnamon, citrus, lemongrass, licorice, nutmeg, peppermint, and spearmint. Menthol from turpentine is added to cigarettes and cosmetic and toilet products (Morton, 1977).

Folk Medicine

Turpentine has long been used internally for catarrh, chronic bowel inflammation, colds, gonorrhea, leucorrhea, rheumatism, And various urinary complaints, rheumatism, and ulcers. Pine tar has been used for many ailments in the past, but lately it is prescribed only for external use in chronic and parasitic skin diseases. It shows up in several of the drugs I have resorted to in the futile efforts to cure my psoriasis. (I have had better luck in substituting rice flour for wheat flour with its glutin.)

Chemistry

Leaves yield ca 0.3% of a balsam scented oil compared to about 0.4% for longleaf pine. This leaf oil consists mostly of borneol, cadinene, camphene, and β-pinene. The natural oleoresin exudate from the resin ducts contains ca 66% resin acids, 25% turpentine, 7% nonvolatiles, and 2% water. Turpentine from slash pine contains 1-α-pinene, while that from longleaf contains some d-pinene. Pinene is the main constituent of turpentine. Dipentene and other monocyclic terpenes constitute 5–8% of gum and refined sulfate turpentine, 15–20% of wood and crude sulfate turpentine. Camphene constitutes 4–8% of wood turpentine, and 0% of gum turpentine. Rosin consists mostly of diterpene resin acids of the abietic (abietic, neoabietic, palustric, and dehydroabietic) and pimaric types (pimaric, isopimaric, and sandaracopimaric). Pine tar contains turpentine, resin, guaiacol, creosol, methylcreosol, phenol, phlorol, toluene, xylene, etc. Crude tall oil contains 40–60% resin acids, 40–55% fatty acids (mostly n-C_{18}, 75% monoenoic, and 25% dienoic, with traces of trienoic and saturates), and 5–10% neutral properties (17).

Toxicity

Raised in the southern US like me, Sam Page, of the FDA, tells me that as a child he was given oral doses (a couple of drops on the tongue) of turpentine as a mosquito repellant, an effective but dangerous application. My mom applied it to cuts and sores as a disinfectant, perhaps less dangerous. (Duke, 1984b)

Description

A fast-growing tree, 15–30 m tall, the trunk attaining a diameter of .6 to 1 m with short, thick branches. Outer bark dark gray, furrowed, breaking into oblong plates; inner bark red-brown. Needles, in 2s or 3s, 18 to 30 cm long. Cones (in spring) are rose-purple and 6 mm thick, the male 3.8 to 5 cm long, densely clustered; the female ca 1.25 cm long. Cones red-brown, maturing and dropping in the second fall, are 7.5 to 14 cm long, narrow-ovate, broadly ovate when open, each scale tipped with a short, straight or recurved spine. Seeds ovoid, 6 mm or more long, smooth, gray, with a glossy, brown, membranous wing 1.5 to 3.5 cm long (17).

Germplasm

Reported from the North American Center of Diversity, slash pine, or cvs thereof, is reported to tolerate hardpan, sand, slope, small fires, and waterlogging. Fast growing strains, resistant to pests and diseases, high in oleoresins, are being developed. When two seed orchards for improved strains were established in 1969, it was estimated that they would not impact the extractive industry for 40 or 50 years (Morton, 1977) ($2n = 24$)

Distribution

Native to southeast US (South Carolina to Florida, Alabama, Mississippi, and Louisiana). Cultivated and naturalized in east Texas. Widely planted in subtropical plantations, e.g. Brazil, India.

Ecology

Ranging from Warm Temperate through Subtropical Moist Forest Life Zones, slash pine is reported to tolerate annual precipitation of 11.2 to 16.0 dm (mean of 2 cases = 13.6), annual temperature of 18.8 to 23.3°C (mean of 2 cases = 21.0), and pH of 5 to 7.7 (mean of 2 cases = 6.4).

Cultivation

Seeds sprout about 2 weeks after planting. Discing the ground following natural or artificial seeding provides for a better, seed-soil contact. Tree can be propagated by grafting and air-layering (Morton, 1977). Not as fire resistant as the longleaf pine, slash pine farmers avoid burning until trees are 3.5–4.5 m tall.

Harvesting

Since 1910, pine oleoresins have been derived from heartwood chips (a lumbering by-product) and from stumps and roots. A ton of wood would yield about 5 gallons of turpentine spirits. Around 1930 more turpentine, rosin, etc. was derived from the wastes of the Kraft sulphate paper processing, a ton of sulphate pulp yielding ca 40 kg "tall oil". Trees begin to bear seed when about 10 years, not attaining full fertility until more than 20 years old.

Yields and Economics

Morton (1977) reported ca 7.5 million hectares in longleaf and slash pines, the two major sources of the resin and turpentine products sold in the US. Around 1935, slash pine replaced the longleaf pine as the leading source of oleoresin, formally called "naval stores". A single tree ca 30 cm in diameter, can average more than 5 kg gum a year over a four year period. Until about 1930, tapping was a main source (80%) of the pine gum produced in the US, down to 5% when Morton's

Major Medicinal Plants was published. By 1970, 40% of domestic rosin and 70% of domestic turpentine were byproducts of sulphate paper production (Morton, 1977).

Energy

Reports in India (Kaul et al, 1982) indicate that total biomass ranges from 169 MT/ha in 10 year old stands to 529 MT/ha in 40 year old stands, indicating annual productivity rates of ca 17 MT/ha/yr in the 10 year olds, 13 MT/ha/yr in the 40 year old stands. Aboveground biomass constituted 81–85% of the total. In Florida, Wang et al. (1982) estimate slash pine yields at 9.4 MT/ha/yr. Pine resins have heat values of 34,018–37,798 kj/kg. Fuel value of slash pine can be upgraded by increasing the resin content, thus increasing the energy content by as much as 12.7%. Wang et al tabulate selected properties of slash pine biomass with and without being resin soaked.

Table 1. Selected properties of slash pine biomass components collected from northcentral Florida.[z]

	Biomass property			
Biomass component	Heat of combustion[z] (kj/kg)	Density[y] (g/cm^3)	Moisture content[x] (%)	Ash content[x] (%)
Stemwood	19,749	0.51	99	0.3
Stembark	20,875	0.27	74	0.7
Branch	19,691	0.41	169	Not measured
Foliage	20,478	Not measured	153	1.9

[x]Bolt 2 = second 152 cm above the treatment site.
[w]Bolt 3 = the remaining merchantable bole to a 7.6 cm inside diameter.

Biotic Factors

According to Morton, seedlings are prey to the weevil, *Hylobius pales* and the pine webworm, *Tetralopha robustella.* Young and old trees are subject to fusiform rust (*Cronartium fusiforme*) and pitch canker (*Fusarium lateritium* forma *pini*). Mature trees are attacked by red heart (*Fomes pini*), butt rot (*Polyporus schweinitzii*) and root rot (*Fomes annosus*). Bark beetles (*Ips* spp.) cause much damage, especially during droughts. The black turpentine beetle (*Dendroctonus rerebrans*) breeds in stumps and attacks mainly trees that have been tapped for gum. Cones are attacked by the rust *Cronartium strobilinum* and the cone moth (*Dioryctria* sp.) (Morton, 1977). Browne (1968) lists the fungi *Amylostereum* sp., *Armillaria mellea, Cronartium conigenum, Dothistroma pini, Fomes annosus, Fomes noxius, Fusarium* spp., *Lophodermium pinastri, Macrophoma pinea, Peniophora sacrata, Peridermium harknessii, Physalospora rhodina, Phytophthora bochmeriae, Phytophthora cinnamomi, Polyporus tomentosus,* and *Sclerotinia fuckeliana,* and the coleoptera, *Aesiotes notabilis, Graphognathus leucoloma, Hylastes angustatus, Hylurgus ligniperda, Lipsanus iniquus, Perperus lateralis,* and *Pityophthorus pulicarius. Pineus laevis* is listed under hemiptera. Hymenoptera listed are *Atta* sp., *Neodiprion lecontei,* and *Sirex noctilio.* Lepidoptera listed include *Arachnographa micrastrella, Aroa melanoleuca, Hyalarctia huebneri, Lachriolepis nephopyropa, Lophodes sinistraria, Nudaurelia cytherea,* and *Rhyacionia subtropica*. Listed under aves are *Alisterus scapularis, Calyptorhynchus funereus,* and *Platycercus eximius,* and under mammalia, *Leggada minutoides, Lophuromys sikapusi, Macaca irus, Mus musculus, Otomys* spp., *Phacochoerus aethiopicus, Potamochoerus porcus, Rattus rattus, Rhabdomys pumilio, Sus scrofa, Sylvicapra grimmia, Thryonomys swinderianus, Tragelaphus scriptus, Trichosurus caninus, Trichosurus vulpecula,* and *Wallabia* sp. Among the nematodes, Golden (p.c. 1984) lists: *Belonolaimus euthychilus, B. gracilis, B. longicaudatus, Caucopaures* sp., *Helicotylenchus dihystera, Hoplolaimus galeatus, Meloidodera floridensis, Meloidogyne arenaria, Tylenchorhynchus claytoni,* and *Xiphinema americanum*.

White Pine

Pinus strobus L.

Figure 117.—White pine (*Pinus strobus*)

Other common names.—Northern pine, Weymouth pine, American white pine, American deal pine, soft deal pine, spruce pine.

Habitat and range.—The white pine native in this country occurs in woods from Canada south to Georgia and Iowa.

Description.—This large, handsome evergreen tree is sometimes 200 feet in height, with horizontal branches. The slender pale-green leaves or needles are borne five in a sheath and are from 2 to 5 inches long. The flowers are inconspicuous, and the drooping, cylindrical, cigar-shaped, resinous cones are about 5 inches long and about 1 inch in thickness until in fall when the scales spread out to permit the seeds to fall out. It requires two seasons for the cones to mature.

Part used.—The inner bark.

Plum, American

Rosaceae *Prunus* sp.

Source: Magness et al. 1971

Bailey, lists 14 species of native plums, several of which have contributed named varieties. Fruit of most species is gathered from the wild for making jams, and jellies. Hybrids of some of these species with the Japanese plums *P. triflora* are in some cases larger fruited and of a quality superior to that of the wild. However, there are apparently no commercial plantings of these improved kinds, though they are in home gardens, particularly in the Plains States. Various wild plums are called "Sloe."

Two species are in limited commercial production to provide fruit for jam. These are *P. maritima* Marsh., the Beach plum of coastal areas from New Brunswick to Virginia, and *P. subcordata* Benth. of California and Oregon. All the native plums have rather small, near globose fruits, produced on small trees or bushes.

Season, bloom to harvest: 70-120 days.

Production in U.S.: No data, possibly 100 tons commercially.

Use: Mainly jelly and jam. Some eaten fresh.

Part of fruit consumed: All except pit in fresh eating. Peel mainly removed after beating in making jelly and jam.

Beach Plum Small farm sustainability through crop diversification and value-added products.

Plum, Damson and Bullace

Rosaceae *Prunus insititia* L.

Source: Magness et al. 1971

These are small oval (the damsons) or round (the bullaces), firm fruited plums, produced on small trees, and used mainly for jelly and jam. They were grown in Europe before the Christian era and brought to America by the earliest settlers. The small, compact trees are hardy and disease resistant, and thrive better in eastern U.S. than other European plum types. The skin is very acid, making the fruits rather unsuitable for eating out of hand. However, they make highly esteemed jellies and jams, and are grown commercially for that purpose.

Season, bloom to harvest: 100-125 days.

Production in U.S.: No data. Possibly 2,000 tons.

Use: Jellies, jams, culinary.

Part of fruit consumed: Pulp in making jelly and jam, but whole fruit cooked prior to separating out seeds and peel.

Last update July 1, 1996 bha

Plum, Japanese

Rosaceae *Prunus salicina* Lindl.

Source: Magness et al. 1971

The Japanese plums were introduced into the U.S. during the latter part of the 19th century, and have become popular in our market. The fruit is medium to large for plums, 1.5 to over 2 inches in diameter. Shape is variable, but mostly conic to oval. Color generally light to dark red. Flesh generally soft and very juicy when ripe. Peel smooth, with waxy surface. Because these plums have high quality and will cross with American species they have been used in breeding to improve the quality of the hardy native types. Trees of Japanese plums are of medium size, and not very hardy to winter cold, hence commercial production is mainly in Calif.

Season, bloom to harvest: 60-160 days, depending on variety.

Production in U.S.: About 100,000 tons.

Use: Mainly fresh market.

Part of fruit consumed: Generally all except pit. Peel may be separated from pulp in mouth and not eaten.

Last update July 1, 1996 bha

Plum, prune, European type

Rosaceae *Prunus domestica* L.

Source: Magness et al. 1971

This group is the most important of the plums in the U.S. It includes all the prunes grown for drying and most of those canned, as well as a number of varieties mainly marketed fresh. Fruits are medium size, 1 to 1.5 inches diameter, globose to oval, and with a firm, meaty flesh. Peel is smooth, with a waxy surface and adheres to flesh. Trees are medium sized, usually held to 15-18 feet by pruning. Trees are of medium hardiness. Most of commercial U.S. production is in the Pacific States, New York and Michigan; but some plantings occur in all areas of U.S. except the South and the coldest areas. Important varieties include Sugar, Italian, Agen, Imperial, Epineuse.

See also plum oil.

Season, bloom to harvest: 130-160 days.

Production in U.S.: About 475,000 tons.

Use: Mainly dried, canned, fresh market. Prune juice is prepared from the dried fruit.

Part of fruit consumed: All except pit.

Reid, W. and K.L.B. Gast. 1993. The potential for domestication and utilization of native plums in Kansas. p. 520-523. In: J. Janick and J.E. Simon (eds.), New crops. Wiley, New York.

The Potential for Domestication and Utilization of Native Plums in Kansas

William Reid and Karen L.B. Gast

During the 19th century, Great Plains settlers demonstrated great interest in the domestication and utilization of North American plum species (*Prunus* spp.) (Bailey 1898; Goff 1897). In central and western Kansas, native plums represented the most reliable source of fresh fruit for many farm families (Kindscher 1987). By 1901, 305 native plum cultivars had been described, including 37 inter-specific hybrids (Waugh 1901). Interest in native plums waned during the 20th century, as mechanized farming and an increasingly efficient transportation system ushered in an age of agricultural specialization. By 1990, only five crops (wheat, maize, sorghum, soybeans, and hay) accounted for nearly 99% of the value of crops produced in Kansas (Byram 1990). Today, the decline in profits earned from producing traditional grain and forage crops has lead many farmers to search for new crops with greater profit potential. This search for agricultural diversification in the wheat belt has rekindled an interest in the domestication and utilization of native plums as a high value, speciality crop.

Eight species of native plum are found in Kansas, including *P. americana* Marsh., *P. angustifolia* Marsh., *P. besseyi* Bailey, *P. gracilis* Engelm. & Gray, *P. hortulana* Bailey, *P. mexicana* S. Wats., *P. munsoniana* Wight & Hedrick, and *P. rivularis* Scheele (Great Plains Flora Assn. 1986). Of these species, *P. americana*, *P. angustifolia*, *P. hortulana*, and *P. munsoniana*, are collected locally and processed into jams, jellies, and preserves in home kitchens. One species, *P. angustifolia*, has recently become the basis for a growing cottage industry in Kansas.

BOTANY

Prunus angustifolia can be found growing from Maryland to Florida in the east then westward to Kansas, Oklahoma, and Texas (Little 1977). The discontinuous distribution of *P. angustifolia* (Fig. 1) led Sargent (1965) to speculate that this species originated in the west and was moved eastward by native Americans and has since become naturalized in the southeastern United States.

Also known as the sandhill plum in Kansas (Stephens 1973), *P. angustifolia* forms large thickets in the sandy pastures of the central and western portions of the state. Large fruit size, small narrow leaves, and a dwarfed appearance led nineteenth century botanists to label the sandhill plum *P. angustifolia watsoni*, to distinguish it from the Chickasaw plum, *P. angustifolia*, common in southeastern states (Waugh 1903). Although modern botanists do not recognize the sandhill plum as a separate sub-species or botanical variety, the Kansas population of *P. angustifolia* seems uniquely adapted for growth in a climate characterized by high heat (40°C) and drought in summer and bitter cold (-30°C) in mid-winter.

The sandhill plum is a much-branched shrub usually less than 2 m high. Thickets up to 20 m across are quickly formed by root suckers. Bright yellow-green leaves that are folded lengthwise help make sandhill plum colonies easily recognizable in the prairies of Kansas. Leaves are simple, alternate, and narrowly elliptical. Twigs are slender, red, glabrous, and often end in a spine. Many branches grow in a distinctive zig-zag pattern. Small white flowers emerge in early April before leaf burst. Flowers have 5 white rounded petals, 20 stamens, and a single egg-shaped ovary. Fruits ripen from early July to late August. Fruits are globose, average 2.1 cm across, and vary in skin color from orange-yellow to deep red (Fig. 2).

GENETIC DIVERSITY

In 1990, we initiated a study to measure the genetic diversity of *P. angustifolia* in Kansas by establishing a planting of 120 seedlings. Bushes used in this study were produced from seed collected from a native plum population located near Pratt, Kansas in 1988. Fifty-nine bushes produced their first fruit crop in 1991. Fruit weight varied from 2.6 to 13.8 g and fruit skin color from yellow to dark red. The orange-yellow flesh of sandhill plums contained from 9.0 to 19.4% soluble solids and were highly acid averaging pH 3.2.

One bush produced fruit that averaged 2.7 cm in diameter as compared to 'Methley', a Japanese plum, which averaged 3.0 cm in diameter (Norton et al. 1990). However, fruit size in sandhill plum is strongly influenced by crop load (Fig. 3). Differences in total bush yield accounted for 44% of the variation in fruit size with the remaining variation in fruit size due to genetic differences.

The selection of sandhill plum cultivars high in soluble solids is very important to the Kansas plum processing industry. Our seedling sandhill plum population averaged 14.3% soluble solids compared to an average of 17% for 9 Japanese plum cultivars (Norton et al. 1990). We did identify individual sandhill plum bushes that produced fruit containing 19.4% soluble solids.

Fruit was harvested from our seedling planting from July 3 to Sept. 11 with the majority of fruit harvested during late July and early August. The harvest season per bush varied from 1 to 7 weeks and averaged 3.6 weeks. The heaviest yielding bushes had the longest harvest season and produced over 4 kg of fruit.

Bush form varied widely. In the year prior to our first fruit crop, bushes could be easily rated as either prostrate, spreading, bushy, or upright. Precocity in sandhill plum seems closely associated with the prostrate growth form. The highest yielding bushes in the first year of fruiting were those that grew nearly horizontally (Fig. 4) but this growth form is the least desirable horticulturally. Fruit-laden limbs dropping on the ground were more prone to fruit rots and were difficult to harvest.

Evidence of bacterial spot infection caused by *Xanthomomas campestris* pv. *pruni* (Smith) Dye could be found on all bushes in the planting. Disease severity increased with fruit yield because of the negative influence of fruit production on vegetative growth. Those bushes with little or no fruit crop were able to outgrow the spread of the bacterial infection.

POTENTIAL FOR DOMESTICATION

Cultivar Development

Observations of the small sample of sandhill plum germplasm described above indicate that sufficient genetic diversity exists within the species for rapid crop improvement. Increased fruit size and higher soluble solids would lead the list of objectives for developing sandhill plum cultivars suited for the processing industry. Additional crop improvement objectives should include a condensed ripening season, an upright growth form, and resistance to bacterial spot.

A limited search of rural Pratt County, Kansas identified two thickets of that produced ample quantities of sandhill plums averaging 2.6 and 2.7 cm in diameter. A more detailed search should yield a sufficient number of superior individuals to begin screening for possible commercial cultivars.

Rootstocks

Prolific root suckering by *P. angustifolia* will make the commercial culture of this plum on its own roots impractical. Fortunately, *P. angustifolia* is graft-compatible with many of the non-suckering rootstocks that have been developed for other diploid plum species (Okie 1987). Growth and yield responses of sandhill plums propagated onto these Prunus rootstocks are not documented.

Pest Problems

The sandhill plum is susceptible to many of the same pests that attack commercial peach and plum orchards. Plum curculio, *Conotrachelus nenuphar* Herbst, is the primary insect pest of sandhill plum. Fruit drop and fruit damage caused by this insect must be controlled if commercial plantings of the sandhill plum are to be successful. Major disease problems include brown rot [*Monilinia fructicola* (Wint.) Honey] of the fruit and bacterial leaf spot (*Xanthomonas campestris* pv. *pruni* (Smith) Dye). There seems to be little natural resistance to either of these diseases within *P. angustifolia*. However, bacterial spot resistance has been identified in *P. cerarsifera* Ehrh. (Byrne 1989).

Chemical controls for the major pests of sandhill plum are widely available. Since sandhill plum is legally a plum, growers may apply any pesticide registered for use on European and Japanese plums for control of insect, disease, and weed pests.

Mechanical Harvest

Acceptance of sandhill plum as a crop in Kansas would depend in part on the availability of mechanical harvesting equipment. Fortunately, the dimensions and growth habit of the sandhill plum are close to those of the highbush blueberry. Harvesters developed for the blueberry industry should be easily adapted to sandhill plum harvest.

SANDHILL PLUM PRODUCT DEVELOPMENT

Sandhill plum jelly has been a regional favorite ever since the early settlers discovered abundant plum thickets on the Kansas prairie (Kindscher 1987). Until recently, sandhill plum jams and jellies were produced only in rural family kitchens for home consumption. With the rapid rise of consumer interest in regional and/or speciality foods, two Kansas food companies have begun manufacturing sandhill plum products for distribution nationally. Fruit is collected from uncultivated thickets and purchased for $1.10/kg. Products manufactured from the sandhill plum are marketed as uniquely Kansan and command as much as $17.50/kg.

Sandhill plums make distinctive fruit products that are often described as pleasingly tart with an apricot-like flavor. Besides the traditional jams and jellies, four additional Sandhill plum products have been developed by the Value-Added Center at Kansas State University. These include a pancake syrup, a fruit topping for ice-cream, a naturally sweetened fruit spread, and an artificially sweetened fruit spread. The manufacturing process for all six Sandhill plum products is outlined in Fig. 5.

CONCLUSIONS

Continued expansion of the sandhill plum industry will depend on the domestication of *P. angustifolia*. The rich genetic diversity found both within this species and among all native Kansas plums offer tremendous opportunities for crop development. Improvements in fruit size, soluble solids, and bush form can be made rapidly through careful examination of seedling populations. The domesticated Sandhill plum of the future is envisioned as a bush fruit adaptable to mechanical harvest with technology borrowed from the blueberry industry. Successful domestication and market development will provide Kansas farmers with an additional crop and allow them to reap the economic benefits of agricultural diversification.

Singh, B.P. and Wayne F. Whitehead. 1999. Pointed gourd: Potential for temperate climates. p. 397–399. In: J. Janick (ed.), Perspectives on new crops and new uses. ASHS Press, Alexandria, VA.

Pointed Gourd: Potential for Temperate Climates

Bharat P. Singh and Wayne F. Whitehead

Pointed gourd (*Trichosanthes dioica* Roxb., Cucurbitaceae) is a tropical vegetable crop with origin in the Indian subcontinent. It is known by the name of *parwal*, *palwal*, or *parmal* in different parts of India and Bangladesh and is one of the important vegetables of this region. The fruit is the edible part of the plant which is cooked in various ways either alone or in combination with other vegetables or meats. Pointed gourd is rich in vitamin and contains 9.0 mg Mg, 2.6 mg Na, 83.0 mg K, 1.1 mg Cu, and 17.0 mg S per 100 g edible part (Singh 1989). It is purported that pointed gourd possesses the medicinal property of lowering total cholesterol and blood sugar. These claims are supported by preliminary clinical trials with rats (Chandra-Sekar et al. 1988) and rabbits (Sharma and Pant 1988; Sharma et al. 1988).

BOTANY

The plant is a perennial, dioecious, and grows as a vine (Fig. 1). Roots are tuberous with long taproot system. Vines are pencil thick in size with dark green cordate simple leaves. Flowers are tubular white with 16–19 days initiation to anthesis time for pistillate flowers and 10–14 days for staminate flowers. Stigma remains viable for approximately 14 hours and 40–70% of flowers set fruit (Singh et al. 1989). Based on shape, size and striation, fruits can be grouped into 4 categories: (1) long, dark green with white stripes, 10–13 cm long, (2) thick, dark green with very pale green stripes, 10–16 cm long, (3) roundish, dark green with white stripe, 5–8 cm long, and (4) tapering, green and striped, 5–8 cm long (Singh 1989).

Fig. 1. Pointed gourd trained on a fence wire trellis.

CULTIVATION

The pointed gourd is usually propagated through vine cuttings and root suckers. Seeds are not used in planting because of poor germination and inability to determine the sex of plants before flowering. As a result, crop established from seed may contain 50% nonfruiting male plants. To propagate from root suckers, tuberous roots of pointed gourd are dug in the early spring, subdivided, and replanted. Both pre-rooted and fresh vine cuttings are used for propagation. Vine cuttings made in the fall of previous year and rooted during winter are planted when danger from frost is over in the spring in order to obtain a crop in the same year. Current year vine cuttings are also planted to establish the crop during the summer, but optimum plant yield is only obtained during the next year. Fresh vines used for field planting should have 8–10 nodes per cutting and should be partially or fully defoliated to check transpiration. The distance between plants is kept between 1.5–2.0 m × 1.5–2.0 m depending on the method of training of vines (Singh 1989; Yadav 1989). A female:male ratio of 9:1 is optimum for ensuring maximum fruit set (Maurya et al. 1985).

Pointed gourd prefers a well-drained sandy loam soil with good fertility. Das et al. (1987) reported maximum early as well as total yield at N:P rates of 90:60 kg/ha, while Kumar et al. (1990) obtained maximum number of fruits/plant when both N and P were applied at the rate of 60 kg/ha.

Vines require training on some form of aerial support system to achieve maximum fruit production (Prasad and Singh 1987; Yadav et al. 1989). Singh (1989) reported 14% higher yield on vines trained on bower system compared to those growing on the ground. In tropics, pointed gourd produces maximum yields for 3–4 years, after which yielding potential gradually declines (Samalo and Parida 1983).

To determine whether pointed gourd can be grown successfully in temperate climates, a study was initiated in 1994 at the Fort Valley State University in Georgia. Cuttings of male and female vines were obtained from the Department of Vegetable Crops, Narendra Deva University of Agriculture and Technology, Faizabad, India with the assistance of National Bureau of Plant Genetic Resources, New Delhi, India, and National Germplasm Resources Laboratory, Beltsville, Maryland. Cuttings were first multiplied in the greenhouse under mist. Rooted cuttings were planted in the field in six 12 m long rows during April 1995. Planting distance was 1.52 m in the row and 1.83 m between rows. Thus, planting density amounted to 3,595 plants/ha, of which 3,236 were female and 359 male (female:male ratio 9:1). Vines were trained on trellises made of 1.52 m high fence wire. Plants were cut back to the ground level before frost and roots covered with straw to safeguard from cold during winter. Vines sprouted from over-wintered roots during subsequent years in spring when the average soil temperature reached above 12.5°C.

HARVESTING AND YIELD

Pointed gourd vines produced limited number of fruits during 1995, however, full scale fruiting only began in 1996. Fruits were produced for harvest from the beginning of July and continued to the middle of October. There was a continuous increase in the number of fruits produced during the first 4 weeks, thereafter, variation among weekly fruit numbers was dependent on the environmental conditions (Fig. 2). Plants produced fruits for harvesting for 15 weeks in 1996 and 17 weeks in 1997. Harvesting was carried out twice a week to obtain fruits at proper maturity for cooking. Over matured fruits developed hard seeds, rendering them less desirable. It took approximately 15 days for fruits to reach the marketable size from fruit-set. Seasonal pattern for the fresh and dry fruit yield /plant was similar to the fruit number/plant. Total fruit number, fresh and dry yields on per plant basis were higher in 1997 than 1996 (Table 1). Fresh fruit yields/ ha for 1996 and 1997 were 16.2 and 21.0 t, respectively. These yield levels compare favorably to those reported from the Indian subcontinent (Singh 1989).

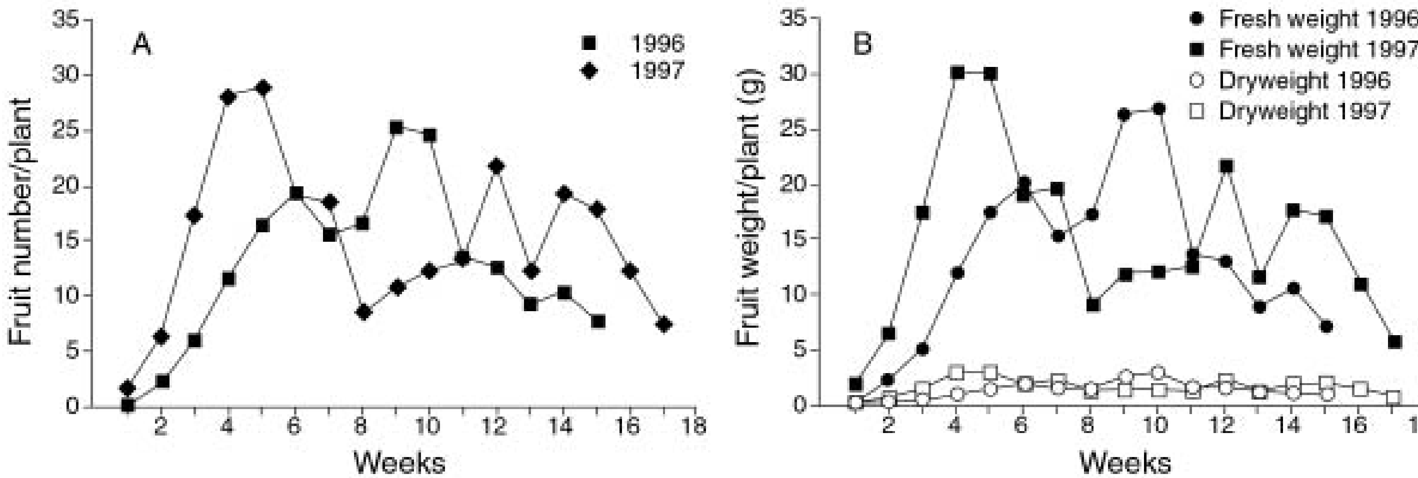

Fig. 2. (A) Per plant fruit number, and (B) fresh and dry weight of pointed gourd on a weekly basis in Georgia during 1996 and 1997.

Table 1. Total fruit number, fruit fresh and dry yields of pointed gourd in Georgia during 1996 and 1997.

Year	Total fruit number		Fresh fruit yield		Dry fruit yield	
	Per plant	Per ha	Per plant (kg)	Per ha (t)	Per plant (kg)	Per ha (t)
1996	190	614,840	5.0	16.2	0.5	1.6
1997	254	821,944	6.5	21.0	0.7	2.3

PROSPECT FOR THE CROP IN THE UNITED STATES

Two main factors will determine the prospect of pointed gourd in the United States: (1) the ability of the plant to adapt to the temperate climate, and (2) market demand for the crop. Research conducted in Georgia clearly demonstrate that pointed gourd can overwinter successfully and produce fruit for approximately 16 weeks during summer with yield comparable to that reported from India. The demand for this vegetable from ethnic minorities from the Indian subcontinent is also high and occasional imports are sold for US $9–10/kg in International Farmers Markets and ethnic grocery stores. However, since fruit harvest is spread over a long period, pointed gourd appears only suited for production on small areas. Price of this commodity produced locally would probably be similar or higher than the imports. The labor employed in manually harvesting these small sized fruits will have to be paid at a higher rate in the US than the exporting countries offsetting any transportation cost advantage from producing the crop locally. Therefore, pointed gourd provides most opportunity to small farmers living close to metropolitan cities where it can be grown as U-Pick or for supply to International Farmers Markets and ethnic grocery stores. The crop also has potential for production in home gardens where it can provide a nutritious vegetable for an extended period.

Seneca-Snakeroot

Polygala senega L.

Other common names.—Senega snakeroot, Seneca root, rattlesnake-root, mountain flax.

Figure 94.—Seneca-snakeroot (*Polygala senega*)

Habitat and range.—This native p]ant is found in rocky woods and hillsides from New Brunswick and western New England to Minnesota and the Canadian Rocky Mountains, and south along the Allegheny Mountains to North Carolina and west to Missouri.

Description.—The root of this plant sends up a number of smooth, slender, erect stems (as many as 15 or 20 or more), sometimes slightly tinged with red, from 6 inches to a foot in height, and generally unbranched. The lance-shaped, stemless leaves are thin in texture and from 1 to 2 inches long. The flowering spikes are borne in May and June on the ends of the stems and consist of rather crowded, small whitish, insignificant flowers. The lower flowers develop first and have already fruited when the upper flowers open.

A modified form of Seneca-snakeroot occurring in the North Central States is distinguished by its taller stems and broader leaves.

Part used.—The root, collected in autumn.

Pomarrosa Malay

Malay apple, Pomarrosa Americana

Myrtaceae *Eugenia malaccensis* L.

Source: Magness et al. 1971

Tropical evergreen tree to 35 feet in height. The fruits are pear-shaped, 4 inches long, 3 inches wide and are reddish pink with longitudinal stripes and splashes of darker red. The fruit flesh is thick, white, dry and surrounds a large seed. The fruits may be eaten fresh or used to make jelly, but are usually stewed with some flavoring material such as cloves.

Populus deltoides Bartr. ex Marsh.

Salicaceae
Eastern cottonwood

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

The timber is used principally for lumber, veneer, pulpwood, excelsior, and fuel (Laver, 1981). Widely used in the US and Canada for shelterbelt and amenity plantings (Ag. Handbook 450). Recently, it has been championed as one of the leading potential species for silviculture biomass production. Salicylic acid, derivable from this species, is now synthesized and selling at ca $2.50 to $3.00 per kilo. Salicylic acid in technical form is used as a coupling agent in dye intermediates, in the foundry industry as a curing agent in the production of shell molding compounds, as an agent for retarding the vulcanization process in rubber, as a preservative for glues and leather goods, and in alkyl/alkyd resins and latex paints (CMR, Dec. 13, 1982).

Folk Medicine

The bark tincture has been used to treat rheumatism, gout, and scurvy and infections of the chest, kidneys, and stomach. The buds have been used as a vulnerary and pectoral. In Europe, the fresh flowers are steeped in cold water to purify the blood. Used by Amerindians as a folk cancer remedy. Ojibwa used aspen buds, stewed in bear fat, for earache, bronchitis, or cough. Bella Coola decocted the rotten leaves as an herbal bath for general body pain and used the buds in poultices for hip or lung pain. Carrier chewed the root to apply as a hemostat and decocted the buds for colds and respiratory problems. Chippewa decocted the buds for colds and respiratory problems; heart ailments, sprains, and strains, and the root for backache, female problems, metrorrhea, and weakness. Delaware used the bark for female ailments. Nanticoke used bark for sprains. Ojibwa used the down like cotton on wounds. Potawatomi cooked buds in tallow to make an ointment for eczema and sores. "Tacamahaca" was used by Amerindians for maturing tumors. Smoky Mountain settlers used the buds like the Indians to make a salve for myalgia and soreness (Duke, 1983c).

Chemistry

The bark contains salicortin, salicin, salicyl alcohol, pyrocatechin, α-salicyloylsalicin, grandidentatin, grandidentoside, populoside, trichocarposide, and 6-methyldihydroquercetin. Leaves contain salicortin, salicin, salicyl alcohol, pyrocatechin, 1-0-p-cumaroyl-β-D-glycoside, populoside, α-salicyloylsalicin, chrysin-7-glucoside, and deltoidin (2-0-salicyloylsalicin). Tremulacin, brenzcatechin, and quercetin-3,3'-dimethyethes are also reported (List and Horhammer, 1969–1979).

Description

Large tree to 20–30(-50) m tall, diam. 0.5 to 2 m; bark grayish-green and smooth at first, later blackish and furrowed. Leaves broadly deltoid, 8–15 cm long, nearly as broad, glabrous on both sides, short-acuminate, dentate with incurved glandular or callous tipped teeth; bases truncate to subcordate, with 2–3 basal glands; petiole strongly flattened laterally. Bracts of aments fringed or fimbriate, the divisions narrow. Staminate aments 7.5–12.5 cm long, thick, stamens ca 60 or more, anthers red. Pistillate aments green and slender, 2–3 dm long; ovaries glabrous; stigmas 3 or 4. Capsules ovoid, 6–10 mm long, glabrous, green, the peduncle 3–10 mm long; seeds cottony (Brown and Brown, 1972).

Germplasm

Reported from the North American Center of Diversity, eastern cottonwood, or cvs thereof, is reported to tolerate frost, heavy soil, sand, slope, and waterlogging. Because of its intolerance to competition and the absence of suitable seedbeds under existing stands, it does not usually succeed itself (Laver, 1981).

Distribution

Quebec to North Dakota, south to Florida and Texas (Ag. Handbook 450).

Ecology

Estimated to range from Warm Temperate Dry to Moist through Cold Temperate Dry to Moist Forest Life Zones, eastern cottonwood is reported to tolerate annual precipitation of 6 to 15 dm, annual temperature of 8 to 14°C, and pH of 4.5 to 8. Said to persist on infertile sands, fine sandy loams, and fairly stiff clays, but thrives on moist well-drained, fine sandy loams or silts close to streams (Laver, 1981).

Cultivation

Seeds are microbiotic, but,with proper drying and cold storage in sealed containers, their viability can be maintained for several years. Natural seed regeneration can be obtained on moist sites with exacting site preparation. Seed should not be covered nor pressed into the soil of the seedbed. Young seedlings are very susceptible to drying out, and the seedbed must be kept water-saturated for germination and at least one month thereafter (ca 1 oz seed per 100 ft^2 seedbed; or about 300 seeds per sq ft) for broadcast, 100 seeds per linear foot for drilling. About 4 weeks after germination, beds should be thinned to 20 plants per square foot. Nursery beds are often stream sterilized or fumigated with methyl bromide to help control damping off. Finely divided sphagnum moss is a good medium for culturing poplar seedlings in the greenhouse (Ag. Handbook 450).

Harvesting

In the Lower Mississippi Valley, seed ripening and dispersal takes place from mid-May through late August, while in the Northeastern US, it occurs slightly later. Cottonwoods produce large seed crops nearly every year.

Yields and Economics

Geyer studied two provenances of cottonwood germplasm, one from Missouri, the other from Nebraska. At Tuttle Creek, Kansas (Eudora soil series, silty-clay loam, pH 7.5, 2.0% organic matter, 146 kg available P/ha, 560 kg exchangeable kg/ha; annual precipitation 838 mm, annual mean temperature 13°C) the Missouri germplasm produced 24,000 kg/ha ovendry biomass over four years spaced at 0.3 by 1.2 m, 29,400 kg/ha spaced at 0.6 by 1.2 m, and 27,100 kg/ha spaced at 1.2 by 1.2 m. This averages out to annual biomass production of 6 MT/ha at 0.3 by 1.2, 7 MT/ha at 0.6 by 1.2, and 7 MT/ha at 1.2 by 1.2 m. At the sandier Milford site (cass fine sandy loam, pH 7.7, 0.6% organic matter, 22 kg P and 336 kg K; annual precipitation 787 mm, the Missouri germplasm produced 22,000 kg/ha ovendry biomass spaced at 0.3 by 1.2 m, 20,600 kg/ha spaced at 0.6 by 1.2, and 21,100 kg/ha spaced at 1.2 by 1.2. Annual biomass production (aboveground) thus averages out to about 6 MT/ha at 0.3 by 1.2, 5 MT/ha at 0.6 by 1.2, and 5 MT/ha at 1.2 by 1.2 m. Biennial harvests were made in December when no leaves were on the trees. The stumps sprouted vigorously the following spring. Bark accounted for about 28% of the small parts of the tree on a dry weight basis, 16% of the large parts, running about 19% for the whole tree. The heat of combustion for the small parts was 4,695 cal/g, 4,416 for the large parts. At Tuttle Creek, the Nebraska germplasm produced 27,400 kg/ha ovendry biomass over four years spaced at 0.3 by 1.2 m, 25,800 kg/ha spaced at 0.6 by 1.2 m, and 28,000 kg/ha spaced at 1.2 by 1.2 m, averaging 7 MT/ha/yr at 0.3 by 1.2, 6 MT at 0.6 by 1.2 and 7 MT at 1.2 by 1.2 m. At the sandier Milford site, the Nebraska germplasm produced 28,200 kg/ha ovendry biomass spaced at 0.3 by 1.2 m, 28,500 kg/ha spaced at 0.6 by 1.2, and 24,000 kg/ha spaced at 1.2 by 1.2 averaging out to about 7 MT/ha/yr at 0.3 by 1.2, 7 MT at 0.6 by 1.2, and 6 MT at 1.2 by 1.2 m. Bark accounted for about 41% of the small parts of the tree on a dry weight basis, 23% of the large parts, running about 28% for the whole tree. The heat of combustion for the small parts was 4,385 cal/g, 4,288 for the large parts. Average annual of several species tested in eastern Kansas ran from 3.6 to 6.7 ovendry MT/ha, with close spacings producing the greatest tonnage, greater than those reported from similar studies in southeastern and northeastern US. Geyer compares these studies with similar studies in Pennsylvania, spaced at 0.6 by 0.6 m, yielding 0.6 MT/ha in year 1, 3.7 in year 2, 6.0 in year 3, and 6.2 in year 4. Another Kansas study showed 5.8 MT/ha/yr in 3 year old Populus 'Tristis No. l' (Geyer, 1981). Henry and Salo (1981) calculate the energetic cost of a silvicultural biomass farm as 1.67 billion (10^9) Btu for supervision, 0.53 for field supply, 7.87 for harvesting, 8.78 for handling the biomass, 17.32 for transport of the biomass, 112.48 for irrigation, 128.33 for fertilizaton and cultivation for a total consumption of ca 277 10^9 Btu, returning 4,250 x 10^9 Btu as energy, for a net gain of 3,972 x 10^9 Btu. (For a farm designed to have an annual production of 250,000 ovendry tons of biomass, enough to support an electric power plant of ca 50 MW.)

Energy

According to the phytomass files (Duke, 1981b), annual productivity in *Populus* ranges from 3 to 22 MT/ha. Fast growing poplars in Sweden, harvested young, have given biomass yields of 14–28 MT/ha. The maximum possible production of fast growing poplars, with optimum fertilization and moisture, is 44 MT/ha in the Netherlands, but normal production levels are closer to 6 (Palz and Chartier, 1980). The MAI of ca 22 MT DM/ha have been reported for hybrid poplars in Sweden, Henry and Salo (1981) assume that silvicultural energy farms in Louisiana will generate 15.3 times as much energy as they consume, compared to 10.6 times in Wisconsin. Here we see the 10:1 ratio we saw also in oilseeds, much higher than the average energetic yields for conventional crops.

Biotic Factors

Agriculture Handbook No. 165 lists the following as affecting this species: *Agrobacterium tumefaciens, Cercospora populina, C. populicola, C. reducta, Ciborinia confundens, Cryptodiaporthe salicina, Dothichiza populea, Fomes applanatus, F. igniarius, Graphium rubrum, Hypoxylon* spp., *Marssonina populi, Melampsora abietis-canadensis, M. medusae, M. occidentalis, Melanconis occulta, Mycosphaerella macularis, M. populifolia, M. populorum, Nectria* sp., *Phoradendron flavescens* var. *macrophyllum, Phyllosticta intermixta, P. maculans,* *Phymatotrichum omnivorum, Physalospora obtusa, Pleurotus ostreatus, Polyporus* spp., *Septoria populi, S. populicola, Steccherinum ochraceum, Stigmina* sp. *Taphrina aurea, T. johansonii, Trametes hispida, Uncinula salicis, Valsa nivea, V. sordida, Venturia tremulae*. In addition, Browne (1968) lists the following as affecting this species: Bacteria: *Aplanobacter populi*. Fungi: *Armillaria mellea, Cladosporium subsessile, Cryptodiaporthe populea, Drepanopeziza populorum, D. punctiformia, Fomes fomentarius, Ilypoxylon pruinatum, Leucostoma niveum, Melampsora laricipopulina, M. populnea, Mycosphaerella populorum, Nectria coccinea, N. ditissima, N. galligena, N. haematococca, Neofabraea populi, Oxyporus populinus, Pezicula populi, Phellinus igniarius, Phyllosticta populina, Septotinia populiperda, Trametes sauveolens, Venturia macularis. Coleoptera: Capnodis miliaris, Chrysomela interrupta, C. scripta, Tragocephala variegata, Zeugophora abnormis, Z. scutellaris.* Diptera: *Phytagromyza populicola*. Hemiptera: *Pemphigus populitransversus, Phloemyzus passerini.* Hymenoptera: *Pontania bozemani, Trichiocampus viminalis.* Lepidoptera: *Acronicta lepusculina, Choristoneura conflictana, Leucoma salicis, Nymphalis antiopa, Paranthrene tabaniformis, Sesia tibialis.* Mammalia: *Capra hircus, Oryctolagus cuniculus* (Browne, 1968). Adults and larvae of the cottonwood leaf beetle (*Chrysomela scripta*) feed on the foliage and succulent stems of seedlings, killing or retarding growth in plantations and nurseries. Equally injurious are cottonwood twig borers (*Gypsonoma haimbachiana*) and cotton root and stem borers (*Paranthrene dollii*). Borers of the southern and central states (*Plectrodera scalator*) and the poplar borer (*Saperda calcarata*), found principally in the northern part of the range, cause lumber defects (Laver, 1981).

Prickly-Ash

(1) *Zanthoxylum americanum* Mill.; (2) *Z. clava-herculis* L.

Synonyms.—(1) *Xanthoxylum fraxineum* Willd.; (2) *X. carolinianum* Lam.; *Fagara clava-herculis* (L.) Small.

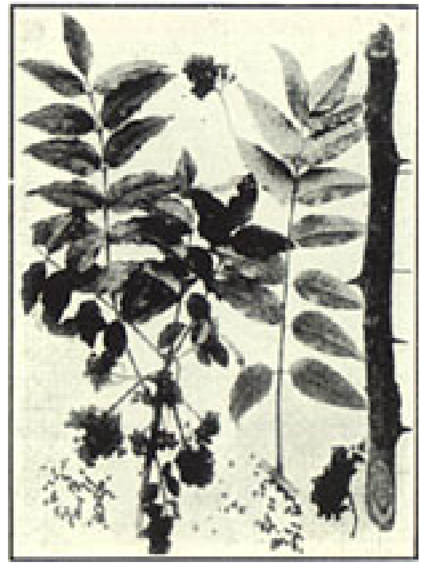

Figure 87.—Southern, prickly-ash (*Zanthoxylum clava-herculis*)

Other common names.—Common prickly-ash, northern prickly-ash, toothache tree, toothache bush, yellowwood, angelica tree, pellitory-bark, suterberry; (2) southern prickly-ash, Hercules-club, toothache tree, yellow Hercules, yellowthorn, yellowwood, yellow prickly-ash, prickly yellowwood, West Indian yellowwood, sea ash, pepperwood, wild orange.

Habitat and range.—The common, or northern, prickly-ash is common in woods, thickets, and along river banks from Virginia, Missouri, and Kansas northward to Canada, while the southern prickly-ash grows along streams from southern Virginia to Florida and west to Texas and Arkansas.

Description.—(1) The common or northern prickly-ash is generally a shrub from 10 to 12 feet high, rarely exceeding 25 feet. Its leaflets are from 5 to 11 in number and from 1 1/2 to 2 inches long. The greenish-yellow flowers appear about April or May, before the leaves are borne in dense, stemless clusters from the axils of the branches. The branches have brown, cone-shaped prickles, and the bark, leaves, and pods are highly aromatic.

(2) The southern prickly-ash is taller than the northern species, but seldom attains a greater height than 45 feet. Its leaves consist of 5 to 17 leaflets from 1 1/2 to 3 inches long, and its small, greenish flowers appear in June after the leaves are out, borne in large clusters at the ends of the branches. The entire tree is furnished with sharp spines or prickles.

Part used.—The bark of both species.

Jatropha curcas L.

Euphorbiaceae
Physic nut, Purging nut

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

According to Ochse (1980), "the young leaves may be safely eaten, steamed or stewed." They are favored for cooking with goat meat, said to counteract the peculiar smell. Though purgative, the nuts are sometimes roasted and dangerously eaten. In India, pounded leaves are applied near horses' eyes to repel flies. The oil has been used for illumination, soap, candles, adulteration of olive oil, and making Turkey red oil. Nuts can be strung on grass and burned like candlenuts (Watt and Breyer-Brandwijk, 1962). Mexicans grow the shrub as a host for the lac insect. Ashes of the burned root are used as a salt substitute (Morton, 1981). Agaceta et al. (1981) conclude that it has strong molluscicidal activity. Duke and Wain (1981) list it for homicide, piscicide, and raticide as well. The latex was strongly inhibitory to watermelon mosaic virus (Tewari and Shukla, 1982). Bark used as a fish poison (Watt and Breyer-Brandwijk, 1962). In South Sudan, the seed as well as the fruit is used as a contraceptive (List and Horhammer, 1969–1979). Sap stains linen and can be used for marking (Mitchell and Rook, 1979). Little, Woodbury, and Wadsworth (1974) list the species as a honey plant.

Folk Medicine

According to Hartwell, the extracts are used in folk remedies for cancer. Reported to be abortifacient, anodyne, antiseptic, cicatrizant, depurative, diuretic, emetic, hemostat, lactagogue, narcotic, purgative, rubefacient, styptic, vermifuge, and vulnerary, physic nut is a folk remedy for alopecia, anasorca, ascites, burns, carbuncles, convulsions, cough, dermatitis, diarrhea, dropsy, dysentery, dyspepsia, eczema, erysipelas, fever, gonorrhea, hernia, incontinence, inflammation, jaundice, neuralgia, paralysis, parturition, pleurisy, pneumonia, rash, rheumatism, scabies, sciatica, sores, stomachache, syphilis, tetanus, thrush, tumors, ulcers, uterosis, whitlows, yaws, and yellow fever (Duke and Wain, 1981; List and Horhammer, 1969–1979). Latex applied topically to bee and wasp stings (Watt and Breyer-Brandwijk, 1962). Mauritians massage ascitic limbs with the oil. Cameroon natives apply the leaf decoction in arthritis (Watt and Breyer-Brandwijk, 1962). Colombians drink the leaf decoction for venereal disease (Morton, 1981). Bahamans drink the decoction for heartburn. Costa Ricans poultice leaves onto erysipelas and splenosis. Guatemalans place heated leaves on the breast as a lactagogue. Cubans apply the latex to toothache. Colombians and Costa Ricans apply the latex to burns, hemorrhoids, ringworm, and ulcers. Barbadians use the leaf tea for marasmus, Panamanians for jaundice. Venezuelans take the root decoction for dysentery (Morton, 1981). Seeds are used also for dropsy, gout, paralysis, and skin ailments (Watt and Breyer-Brandwijk, 1962). Leaves are regarded as antiparasitic, applied to scabies; rubefacient for paralysis, rheumatism; also applied to hard tumors (Hartwell, 1967–1971). Latex used to dress sores and ulcers and inflamed tongues (Perry, 1980). Seed is viewed as aperient; the seed oil emetic, laxative, purgative, for skin ailments. Root is used in decoction as a mouthwash for bleeding gums and toothache. Otherwise used for eczema, ringworm, and scabies (Perry, 1980; Duke and Ayensu, 1984). We received a letter from the Medicial Research Center of the University of the West Indies shortly after the death of Jamacian singer Robert Morley, "I just want you to know that this is not because of Bob Morley's illness, why I am revealing this ... my dream was: this old lady came to me in my sleep with a dish in her hands; she handed the dish to me filled with some nuts. I said to her, "What were those?" She did not answer. I said to her, "PHYSIC NUTS." She said to me, "This is the cure for cancer." We found this Jamaican dream rather interesting. Four antitumor compounds, including jatropham and jatrophone, are reported from other species of Jatropha (Duke and Ayensu, 1984). Homeopathically used for cold sweats, colic, collapse, cramps, cyanosis, diarrhea, leg cramps.

Chemistry

Per 100 g, the seed is reported to contain 6.6 g H_2O, 18.2 g protein, 38.0 g fat, 33.5 g total carbohydrate, 15.5 g fiber, and 4.5 g ash (Duke and Atchley, 1983). Leaves, which show antileukemic activity, contain α-amyrin, β-sitosterol, stigmasterol, and campesterol, 7-keto-β-sitosterol, stigmast-5-ene-3-β, 7-α-diol, and stigmast-5-ene-3 β, 7 β-diol (Morton, 1981). Leaves contain isovitexin and vitexin. From the drug (nut?) saccharose, raffinose, stachyose, glucose, fructose, galactose, protein, and an oil, largely of oleic- and linoleic-acids (List and

Horhammer, 1969–1979), curcasin, arachidic-, linoleic-, myristic-, oleic-, palmitic-, and stearic-acids are also reported (Perry, 1980).

Toxicity

The poisoning is irritant, with acute abdominal pain and nausea about 1/2 hour following ingestion. Diarrhea and nausea continue but are not usually serious. Depression and collapse may occur, especially in children. Two seeds are strong purgative. Four to five seed are said to have caused death, but the roasted seed is said to be nearly innocuous. Bark, fruit, leaf, root, and wood are all reported to contain HCN (Watt and Breyer-Brandwijk, 1962). Seeds contain the dangerous toxalbumin curcin, rendering them potentially fatally toxic.

Description

Shrub or tree to 6 m, with spreading branches and stubby twigs, with a milky or yellowish rufescent exudate. Leaves deciduous, alternate but apically crowded, ovate, acute to acuminate, basally cordate, 3 to 5-lobed in outline, 6–40 cm long, 6–35 cm broad, the petioles 2.5–7.5 cm long. Flowers several to many in greenish cymes, yellowish, bell-shaped; sepals 5, broadly deltoid. Male flowers many with 10 stamens, 5 united at the base only, 5 united into a column. Female flowers borne singly, with elliptic 3-celled, triovulate ovary with 3 spreading bifurcate stigmata. Capsules, 2.5–4 cm long, finally drying and splitting into 3 valves, all or two of which commonly have an oblong black seed, these ca 2 x 1 cm (Morton, 1977; Little et al., 1974).

Germplasm

Reported from the Central and South American Centers of Diversity, physic nut, or cvs thereof, is reported to tolerate Slope. There is an endemic species in Madagascars *J. mahafalensis*, with equal energetic promise. ($2n = 22$)

Distribution

Though native to America, the species is almost pantropical now, widely planted as a medicinal plant which soon tends to establish itself. It is listed, e.g., as a weed in Brazil, Fiji, Honduras, India, Jamaica, Panama, Puerto Rico, and Salvador (Holm et al, 1979).

Ecology

Ranging from Tropical Very Dry to Moist through Subtropical Thorn to Wet Forest Life Zones, physic nut is reported to tolerate annual precipitation of 4.8 to 23.8 dm (mean of 60 cases = 14.3) and annual temperature of 18.0 to 28.5°C (mean of 45 cases = 25.2).

Cultivation

Grows readily, from cuttings or seeds. Cuttings strike root so easily that the plant can be used as an energy-producing living fence post.

Harvesting

For medicinal purposes, the seeds are harvested as needed. For energy purposes, seeds might be harvested all at once, the active medicinal compounds might be extracted from the seed, before or after the oil, leaving the oil cake for biomass or manure.

Yields and Economics

According to Gaydou et al (1982), seed yields approach 6–8 MT/ha with ca 37% oil. They calculate that such yields could produce the equivalent of 2,100–2,800 liters fuel oil/ha (see table under Energy). In Madagascar, they have ca 10,000 ha of purging nut, each producing ca 24 hl oil/ha for a potential production of 240,000 hl (Gaydou, et al, 1982).

Energy

The clear oil expressed from the seed has been used for illumination and lubricating, and more recently has been suggested for energetic purposes, one ton of nuts yielding 70 kg refined petroleum, 40 kg "gasoil leger" (light fuel oil), 40 kg regular fuel oil, 34 kg dry tar/pitch/rosin, 270 kg coke-like char, and 200 kg ammoniacal water, natural gas, creosote, etc. In a startling study, Gaydou et al. (1982) compare several possible energy species with potential to grow in Malagasy. Oil palm was considered energetically most promising.

	Crop production MT/ha	Fuel production /ha	Energetic equivalent kwh/ha
Elaeis guineensis	18–20	3,600–4,000	33,900–37,700
Jatropha curcas	6–8	2,100–2,800	19,800–26,400
Aleurites fordii	4–6	1,800–2,700	17,000–25,500
Saccharum officinarum	35	2,450	16,000
Ricinus communis	3–5	1,200–2,000	11,300–18,900
Manihot eaculenta	6	1,020	6,600

Biotic Factors

Agriculture Handbook No. 165 lists the following as affecting *Jatropha curcas*: *Clitocybe tabescens* (root rot), *Colletotrichum gloeosporioides* (leaf spot), and *Phakopsora jatrophicola* (rust).

Purple Trillium

Trillium erectum L.

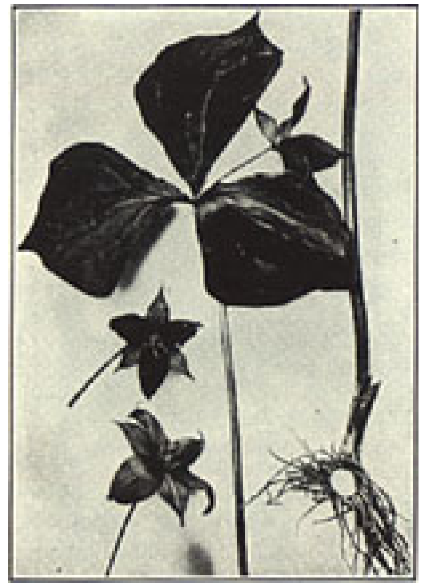

Figure 90.—Purple trillium (*Trillium erectum*)

Other common names.—Bethroot, trillium, red trillium, purple trillium, ill-scented trillium, birthroot, birthwort, bathwort, bathflower, red wake-robin, purple wake-robin, ill-scented wake-robin, red-benjamin, bumblebee root, daffy-downdilly, dishcloth, Indian balm, Indian shamrock, nosebleed, squawflower, squawroot, wood lily, truelove. Many of these names are applied also to other species of trillium.

Habitat and range.—This is a native plant growing in rich soil in damp, shady woods from Canada south to Georgia, Alabama, and Missouri.

Description.—Purple trillium is a low-growing plant from 8 to 16 inches in height, with a rather stout stem having three leaves arranged in a circle near the top. These are from 3 to 7 inches in length and of about the same width and are practically stemless. The flower, which appears from April to June, is borne singly at the end of the stem on a slender stalk. Its parts are arranged in threes which feature serves to identify the plant. The three petals, which are 1 1/4 inches long and one-half inch wide, are dark purple pink, greenish, or white. The flower has an unpleasant odor. It is followed by a reddish berry.

Part used.—The root, collected toward the close of summer.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

White Oak

Quercus alba L.

Other common names.—Stone oak, stave-oak.

White oak

Figure 116.—White oak (*Quercus alba*)

Habitat and range.—The white oak is found in woods from Maine to Minnesota and south to Florida and Texas but is most abundant in the North Central and Middle Atlantic States.

Description.—This tree is usually from 60 to 80 feet high, but in dense woods it sometimes reaches a height of 150 feet. The trunk attains a diameter of 3 to 4 feet with many wide-spreading branches. The leaves are red and hairy when young, becoming smooth and thin when older. In autumn they turn a beautiful red. The leaves are 4 to 7 inches long, borne on short stems, and are usually divided into five to nine lobes. When the leaves appear the very small greenish or yellowish flowers are produced. The male flowers are borne in slender, usually drooping spikelike clusters and the female flowers singly. The acorns mature in the autumn.

Part used.—The bark, preferably that from trunks or branches 10 to 25 years old, which should be collected in the spring. The outer layer is first scraped off.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Samanea saman (Jacq.) Merr.

Mimosaceae
Rain tree

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

With a checkerd nomenclature, under *Enterolobium* in the Wealth of India, *Pithecellobium* in Common Trees of Puerto Rico, and Samanea in Woody Plants of Ghana, the rain tree is apparently widely traveled. Perhaps one of its most important uses in Latin America is as a shade tree, especially in parks, pastures, and roadsides. Improved growth, nutritive quality, protein content, and yield have been demonstrated by *Axonopus compressus*, a tropical forage grass, grown under *Samanea*. "The benefit by association was presumptively attributed to nitrogen made available in the soil by excretion or decomposition of the leguminous nodules." (Allen and Allen, 1981). The tree house in Walt Disney's "Swiss Family Robinson" was built in a rain tree 60 m tall with a canopy 80 m in diameter. Simon Bolivar is said to have encamped his entire liberation army under the "saman de guerra" near Maracay, Venezuela. In Malagasy, it is grown as shade tree for cacao, coffee, patchouly, and vanilla. In Indonesia, it is recommended for nutmeg but not for tea. In Uganda, it is considered good for coffee, bad for tea. According to NAS (1980a), "Grass grows right up to the trunk because this species' leaflets fold together at night and in wet weather, allowing the rain to fall through." Like *Acacia, Ceratonia, Prosopis,* and *Tamarindus*, this produces copious pods with a sweet pulp, attractive to children and animals alike. Pods can be ground up and converted to fodder or for that matter alcohol as an energy source. A lemon-like beverage can be made from the pulp. The wood is soft, lightweight (spec. grav. 0.44; 720–880 kg/m^3) of medium to coarse texture, fairly strong, takes a beautiful finish but is often cross-grained and difficult to work. It is used for furniture, general construction, and interior trim, for boxes and crates, panelling, plywood, and veneer. Central American oxcart wheels are made from cross sections of trunks. It is used for boat building in Hawaii, where it is also famous for making "monkeypod" bowls. Shavings from the wood are used for making hats in the Philippines. The tree yields a gum of inferior quality which could be used as a poor man's substitute for gum arabic. Like most other mimosaceous trees, this is an important honey plant. Rain tree is one host of the lac insect, which, however, produces a poor quality lac, reddish and rather brittle (C.S.I.R., 1948–1976).

Folk Medicine

According to Hartwell (1967–1971), the root decoction is used in hot baths for stomach cancer in Venezuela. Rain tree is a folk remedy for colds, diarrhea, headache, intestinal ailments, and stomachache (Duke and Wain, 1981). The alcholic extract of the leaves inhibits *Mycobacterium tuberculosis* (Perry, 1980). The alkaloid fraction of the leaves is effective on the CNS and PNS. In Colombia, the fruit decoction is used as a CNS-sedative. The leaf infusion is used as a laxative (Garcia-Barriga, 1975). In the West Indies, seeds are chewed for sore throat (Ayensu, 1981).

Chemistry

Per 100 g, the green leaf is reported to contain 47.8 g H_2O, 10.2 g protein, 2.1 g fat, 22.2 g insoluble carbohydrate, 15.7 g fiber, and 2.0 g ash. On an oven-dry basis, the leaves contain ca 3.2% N. Gohl, 1981 tabulates as follows:

		As % of dry matter						
	DM	CP	CF	Ash	EE	NFF	Ca	P
Fresh twigs, late vegetative, Malaysia	38.9	24.7	22.1	4.4	2.8	46.0	0.55	0.26
Fresh leaves, Thailand	39.1	22.1	29.4	6.0	7.0	35.5	1.42	0.21
Fresh leaves, Trinidad	34.4	30.0	29.0	3.5	3.5	34.0		
Pods, Jamaica	79.5	12.8	14.5	2.4	0.7	69.6	0.29	0.32
Pods, fallen, Trinidad	85.0	18.0	10.9	4.6	1.4	65.1		
Seeds, Jamaica	86.5	31.6	14.0	4.3	6.0	44.1	0.16	0.34

Whole pods contain: moisture, 15.3; ash, 3.2; fat, 2.1; protein, 12.7; 11.4; and carbohydrates, 55.3%. Kernels contain: moisture, 16.1; ash, 3.0; fat, 1.3; protein, 10.6; CF, 10.8; and carbohydrates, 42.0%. The bark contains two alkaloids—$C_8H_{17}ON$ and $C_{17}H_{36}ON_3$ (pithecolobine; LD_{50} in mice 40–225 μg/kg)—and a saponin (samarin), which yields on hydrolysis an aglucone of the formula $C_{23}H_{36}O_4$, arabinose, glucose and rhamnose. Samarin is an irritant to isolated intestine. Other constituents identified in the bark are gallic acid, glucose, sucrose, fatty acids and a phytosterol. Wood contains: lignin, 30.44; cellulose, 50.89; α-cellulose, 38.35; and ash, 0.27% (C.S.I.R., 1948–1976). Hager's Handbook (List and Horhammer, 1969–1979) reports hexacosanol, lupeol, α-spinasterol, octaconsanolic acid, α-spinasterol-β-D-glucoside, α-spinasterone, and lupeone from the rind, hentriacontane and octacosanol from the leaves; α-spinasterol, and its β-D-glucoside, palmitic, and stearic acid from the seed kernel, three flavonoids and kaempferol from the testae, and α-spinasterol and octacosabolic acid from the wood.

Description

Large umbraculiform tree to as much as 60 m tall, the crown to 80 m broad, covering 1/5 hectare, trunk to 1.5 m DBH, unarmed, with gray rough furrowed bark. Leaves alternate, evergreen, bipinnate, 25–40 cm long, with 2–6 pairs of pinnae, each of which bears 6–16 paired stalkless leaflets, with a glandular dot between each pair. Flower heads clustered near the end of twigs, each cluster on a green hairy stalk 7–10 cm long, with many small tubular pinkish-green flowers, calyx and corolla 5-toothed. The many stamen united to form a tube near their bases, seed pods oblong, flat, arcuate, black, 20–30 cm long, with a raised border, each with several oblong reddish-brown seeds ca one cm long.

Germplasm

Reported from the South American Center of Diversity, rain tree, or cvs thereof, is reported to tolerate drought, poor soils, waterlogging and weeds. ($2n = 26$)

Distribution

Native from the Yucatan Peninsula and Guatemala to Peru, Bolivia, and Brazil. Widely planted and naturalized elsewhere in continental tropical America from Mexico southward, throughout the West Indies (except Bahamas), and in Old World tropics. Grown also in southern Florida (Little and Wadsworth, 1964).

Ecology

Ranging from Subtropical Very Dry to Moist through Tropical Dry to Moist Forest Life Zones, rain tree is reported to tolerate annual precipitation of 6 to 25 dm (mean of 49 cases = 14.0), annual temperature of 21.6 to 28.5°C (mean of 36 cases = 25.8), and pH of 6 to 7.

Cultivation

Easily propagated from seeds and cuttings. Young specimens transplant easily.

Harvesting

Lopped for forage or timber at any time, it can be maintained at any height by periodical pruning.

Yields and Economics

A full grown tree 15 years old is said to yield ca 200–275 kg pods per season, which translates to 10 MT/pods, if we can crowd 50 productive trees to the hectare. A single tree 5 years old has been said to yield nearly 550 kg green forage (assuming 50% moisture = ca 275 kg DM). Assuming 50 trees to the hectare, that translates to nearly 14 mT forage in leaves.

Energy

According to figures in the Wealth of India, 10 MT pods would yield 1150 liters of absolute alcohol, roughly 5–10 barrels ethanol/ha/yr. It is reportedly used as an alcohol source in Colombia. Use of the wood as a fuel is not often reported. In the Philippines, Quisumbing (1951) reports the branches and trunk are used as firewood.

Biotic Factors

Browne (1968) lists: Fungi. *Fomes annularis, Ganoderma australe, Ganoderma lucidum.* Coleoptera. *Anomala antiqua, Apate monachus, Lepropus chrysochlorus, Oncideres tessellata.* Hemiptera. *Ferrisia virgata, Hemiberlesia lataniae, Icerya aegyptiaca, Icerya formicarum, Kerria lacca, Ptyelus flavescens, Rastrococcus iceryoides.* Isoptera. *Coptotermes amanii*. Lepidoptera. *Attacus atlas, Homona coffearia, Indarbela quadrinotata, Melisomimas metallics.* Mammalia. *Callosciurus caniceps.* Also occuring on *Samanea saman* are *Hypomyces haematococcus;* root knot nematodes, *Meloidogyne* sp.; and the leaf spot *Microstroma pithecolobii.*

Rauvolfia serpentina

Contributor: Pankaj Oudhia

Copyright (c) 2002. All Rights Reserved. Quotation from this document should cite and acknowledge the contributor.

Scientific Name: *Rauvolfia serpentina* (L.) Benth. ex Kurz. (Syn. *Ophioxylon sepentinum* L.)

English Name: Rauvolfia root, serpentine

Trade Name: Serpentine Roots

Common (Indian) Names:
Assamese: Arachoritita
Bengali: Chandra
Hindi: Chandrabhaga, Chota-chand, Sarpagandha
Canarase: Sarpangandha, Sarpagandhi, Shivanabhiballi, Sutranavi, Patalagandhi
Malyalma: Churannavilpori, Suvapavalporiyam
Marathi: Harkaya: Harki
Oriya: Patalagarur, Sanochado
Sanskrit: Sarpagandha, Chandrika, Patalguruda
Tamil: Chevanamalpodi
Telugu: Patalaguni, Patalagaruda, Sarpagandha

Family: Apocynaceae

Habitat: Moist forests shady places near rain-forest.

Status: The natural reserves of this plant are declining, especially after reports of its medicinal properties appeared in literatures. International Union for the Conservation of Nature and Natural Resources (IUCN) has kept this plant under endangered status.

Distribution: The snake-weed genus includes about 50 species, this has fairly wide area of distribution, including the tropical part of the Himalayas, the Indian peninsula, Sri Lanka, Burma, and Indonesia.

Related Species

Rauvolfia tetraphylla L. (Syn. *R. canescens* L.; *R. heterophylla* Roem. and Schult.). In Hindi, it is named Barachandrika. Found in Bihar, Orissa, Chhattisgarh, Madhya Pradesh, West Bengal, Andhra Pradesh, Tamil Nadu, and Kerala states of India. Native to West Indies. Its roots are often used as an adulterant of *R. serpentina*.

Rauvolfia vomitoria Afzel. and *R. caffra*. Both are African species. Having medicinal properties similar to R. serpentina but with low total alkaloid content and also low in serpentina.

Botany: An erect perennial shrub with a long, irregularly, nodular, yellowish root stock.

Leaves: In whorls of 3, thin, lanceolate, acute, bright green above and pale beneath.

Flowers: in irregular corymbose cymes, white, often tinged with violet.

Fruit: Drupe, single or didymous, shining black, the inflorescenece with red pedicels and calyx and white corolla.

Flowering Time: March to May in Indian conditions.

Natural Components: The root contains ophioxylin (an alkaloid having orange colored crystalline principle), resin, starch and wax. The total alkaloid yield is 0.8%. Five crystalline alkaloids isolated are ajmaline, ajmalicine, serpentine, serpentinine, and yohimbine.

Useful Parts: Roots and leaves.

Medicinal Properties and Uses: According to Ayurveda root is bitter, acrid, heating, sharp, pungent and anthelminic. Drug Rauvolfia consists of air-dried roots. Rauvolfia preparations are used as antihypertensive and as sedative. It is also used for the treatment of various central nervous system disorders associated with psychosis, schizophrenia, insanity, insomnia, and epilepsy.

Ayurvedic Preparations: Sarpagandha ghanavati, sarpagandha yoga, Sarpagandha churna, Mahesvari vati etc.

Cultivation: This plant is under cultivation in India, Sri Lanka, and Java. Experiments on cultivation are in progress in the United States.

Climate: it grows luxuriantly well where the rainfall is 2500 mm or more. The areas having more equable climatic variations seem to be more suited than the areas having higher climatic variations.

Soil: It prefers soil with plenty of humus and rich in nitrogenous and organic matter with good drainage. Alkaline soils are not suitable for commercial cultivation.

Propagation: Can be propagated both through seeds and vegetatively, but propagation by seed is preferred.

Seed Rate: 10 kg/ha.

Nutrients: Generally organic cultivation is practiced. Initially before sowing 10–15 tonnes of farm yard manures/ha are used.

Spacing: 45 × 30 cm.

Plant Protection: Serious and major infestation of any insect of diseases have not been reported.

Maturity Period: 3 Years. At this time the subaerial parts dry and main root reach a depth of 0.9

meters.

Average Yield: 2700 to 3300 kg dried roots/ha and 8–10 kg seed.

Rhizophora mangle L.

Rhizophoraceae
Red mangrove

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Timber of the mangrove is used for cabinetry, construction, piling, poles, posts, shipbuilding, and wharves. Duke (1972) notes that in Panama it is being studied for its telephone pole potential. In the Choco it is being exploited for the pulp industry. Cattle will eat mangrove leaf meal after $CaCO_3$ has been added to raise the pH. Morton (1965) even describes a wine made from mangrove leaf and raisin. Amerindians ate the starchy interior of the fruit and hypocotyl during hard times (Morton, 1965). Dried hypocotyls have been smoked like cigars. Dried leaves have been used in Florida as a tobacco substitute. African children use the dried fruits as whistles (Irvine, 1961). In Costa Rica, concentrated bark extracts are used to stain floors and furniture, a habit shared with Africa's Ashantis. Cuna Indians make fishing lines from the brown branches. Although some have speculated that Rhizophora plantings can be used to extend or preserve precarious shores. Hou resurrects a quote suggesting the contrary "mangrove follows the silting up of a coastal area rather than precedes and initiates the accumulation of mud or other soil...it establishes itself merely on accrescent coasts" (Hou, 1958). Morton (1965), however, notes that the American Sugar Company introduced it in 1902 as a soil retainer on the mud flats of Molokai. According to Garcia-Barriga (1975) Kino de Colombia, resin from the red mangrove, has several medicinal uses.

Folk Medicine

One Cali doctor reports a cure of throat cancer, with gargles of mangrove bark (Garcia-Barriga, 1975). Reported to be astringent, emmenagogue, expectorant, hemostat, styptic, and tonic, red mangrove is a folk remedy for angina, asthma, backache, boils, ciguatera, convulsions, diarrhea, dysentery, dyspepsia, elephantiasis, enuresis, epistaxis, eye ailments, fever, filariasis, hemoptysis, hemorrhage, inflammation, jaundice, leprosy, lesions, leucorrhea, malignancies, scrofula, short wind, sores, sorethroat, syphilis, tuberculosis, uterorrhagia, and wounds (Duke and Wain, 1981; Morton, 1981).

Chemistry

Per 100 g, the leaf is reported to contain, 10.7 g protein, 3.4 g fat, 77.0 g total carbohydrate, 14.5 g fiber, and 8.9 g ash (Duke and Atchley, 1983 in ed). Per 100 g, the leaf meal is reported to contain 5.6 g H_2O, 7.5 g protein, 3.6 g fat, 59.3 g NFE, 13.9 g fiber, 10.1 g ash, 1.350 mg Ca, 140 mg P, 15.2 mg Fe, 650 mg K, 600 µg β-carotene equivalent, 88 mg Mg, 30 mg Mn, 3.5 mg Cu, 0.52 mg Co, 4.3 mg Zn, 54 mg I, 13 mg thiamine, 19 mg riboflavin, 240 mg niacin, 32 mg folic acid, 5.3 mg pantothenic acid, and 46.0 mg choline (Morton, 1965). I suspect that the vitamins are off by a magnitude or two. Something is wrong with the amino acid figures as well, but perhaps the proportions are worth repeating, arginine 1.1 : lysine 0.9 : methionine 0.421 cystine 0.301 : glycine 0.801. Another analysis of the leaf tablets shows, per 100 g, 790 mg S, 8.3 mg Cu, 920 mg Na, 8.3 mg B, 224 µg chlorophyll, 0.68 µg folic acid, 5.2 ppm cobalt, and 144 ppm F (Morton, 1965). Fresh leaves contain 65.6% moisture and ca 0.1% chlorophyll. Dry bark contains 10–40% tannin, aerial roots ca 10.5%.

Description

Tree 5–20(-30) m tall, 20–50(-70) cm in diameter with arching stilt roots 2–4.5 m high. Bark gray or gray-brown, smooth and thin on small trunks, becoming furrowed and thick; inner bark reddish or pinkish. Leaves opposite or elliptical, acute at tip and base, entire, without visible veins, thick, leathery, glabrous, 6–12 cm long, 2.5–6 cm wide, shiny green upper surface, yellow-green, black-dotted underneath. Petiole 1.5–2 cm long. Stipules paired, leaving ring scar. Flowers mostly 2–4 on forked stalk 4–7 cm long in leaf axil, pale yellow, ca 2 cm across. Bell-shaped hypanthium ca 5 mm long with 4 widely spreading, narrow, leathery, pale yellow sepals 12 mm long; petals 4, 1 cm long, curved downward, whitish but turning brown, cottony on inner side; stamens 8, stalkless. Ovary inferior conical, 2-celled with 2 ovules each cell; style slender; stigma 2-lobed. Berry, ovoid, 3 cm long, dark brown. Seed 1, viviparous, becoming cigar-shaped, to 25 cm long and 12 mm in diameter (Little, 1983).

Germplasm

Reported from the African, American, and Polynesian Centers of Diversity, red mangrove, or cvs thereof, is reported to tolerate diseases, insects, pests, salt, and waterlogging (NAS, 1980a, Little, 1983). ($2n$ = 36 in other species of Rhizophora)

Distribution

Tropical America from Bermuda through West Indies to Florida. Northern Mexico south to Brazil and Ecuador including Galapagos Islands and north-western Peru. Western Africa from Senegal to Nigeria; Angola, Melanesia, Polynesia (Little, 1983).

Ecology

Estimated to range from Tropical Moist to Rain through Subtropical Moist to Rain Forest Life Zones, red mangrove is reported to tolerate annual precipitation of 14.9 to 23.0 dm (mean of 7 cases = 18.8), annual temperature of 21.6 to 25.6°C (mean of 6 cases = 23.5), and estimated pH of 6.0 to 8.5. Mostly on brackish and saline silt of depositing shorelines.

Cultivation

Since natural regeneration is so good, this species is not often cultivated, but it has been planted, for example, to stabilize the banks of brackish aquaculture enclosures. Direct seeding yields ca 90% survival in Rhizophora and Avicennia. Air-layering and the planting of propagules have both been successful in Florida (NAS, 1980a).

Harvesting

No data available.

Yields and Economics

In Florida, red mangrove is said to fix 4 MT carbon/ha/yr (Murry and Benemann, 1981). Cannell (1982) cites data showing that *Rhizophora mangle* spaced at 1,100 trees/ha, averaged 7–8 m tall, and an LAI of 4.4. The stem wood and bark on a DM basis weighed 28 MT/ha, proproots 14.4 MT, the branches 12.7, the foliage 7.8, and the roots estimated at 50 MT/ha for a total standing biomass of ca 113 MT/ha. The current annual increment (CAI) of stem wood and stem bark was 3.07 MT/ha/yr, foliage 4.75 (Cannell, 1982). Litterfall was 0.84 g/m^2/day wood, 1.3 g/m^2/day leaves. Thus the annual foliage fall was close to 5 MT/ha/yr. These data were taken in a mangrove swamp in Puerto Rico. Standing biomass of the Pacific mangrove (*R. brevistyla*), from the more fertile Pacific side of Panama, was 280 MT/ha. (Duke, 1981b).

Energy

Following the phytomass files (Duke, 1981b), annual productivity is estimated to range from 5 to 20 MT/ha (with 9 reported in Puerto Pico). Wood (sp. grav. 0.9–1.2), an important source of charcoal, described as excellent for fuel and charcoal (Little, 1983).

Biotic Factors

Durable in the soil but susceptible to attack by dry-wood termites (Little, 1983). Morton (1965) reports a Cerospora (sic) leaf spot in Florida. Agriculture Handbook No. 165 notes *Anthostomella rhizomorphae* on leaves.

Rheum spp.

Polygonaceae

Chinese rhubarb, Garden rhubarb, Pie-plant, Rhubarb, Wild rhubarb

We have information from several sources:

Midwest Vegetable Production Guide for Commercial Growers 2000

Magness, J.R., G.M. Markle, C.C. Compton. 1971. Food and feed crops of the United States.

Rhubarb—Cooperative Extension Service, Purdue University, West Lafayette, Indiana.

Smooth Sumac

Rhus glabra L.

Figure 98.—Smooth sumac (*Rhus glabra*)

Other common names.—Mountain sumac, upland sumac, scarlet sumac, sleek sumac, white sumac, Pennsylvania sumac, shoemake, vinegar tree.

Habitat and range.—Smooth sumac occurs in dry soil thickets and waste grounds from Nova Scotia to British Columbia and south to Florida, Mississippi, and Arizona.

Description.—Although sometimes attaining the height of a small tree, the smooth sumac is more frequently found as a rather handsome shrub 2 to 12 feet high, with smooth, brownish-gray trunk and branches. Its leaves are very long from 1 to 3 feet, and consist of from 11 to 31 leaflets, each leaflet being about 2 to 4 inches in length and about half as wide, lance-shaped, pointed, sharply toothed and whitened beneath. From June to August the plant bears greenish yellow flowers in dense pyramidal clusters at the ends of the branches. These are followed by roundish, flattened fruits or berries, covered with short, crimson hairs. Each fruit contains a smooth, 1-seeded stone.

Part used.—The leaves, bark, and berries, the latter being gathered while the downy covering ia still on them, which gives the berries their sour taste.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Joublan, J.P., M. Berti, H. Serri, R. Wilckens, F. Hevia, and I. Figueroa. 1996. Wild rose germplasm evaluation in Chile. p. 584-588. In: J. Janick (ed.), Progress in new crops. ASHS Press, Arlington, VA.

Wild Rose Germplasm Evaluation in Chile*

Jean Paul Joublan, Marisol Berti, Humberto Serri, Rosemarie Wilckens, Felicitas Hevia, and Inés Figueroa

A number of *Rosa* species (Rosaceae) native to southern Europe and North Africa were introduced to Chile by Spanish colonizers. These species are now widely distributed in Chile from Santiago (33°S) to Aisen (45°S) and from sea level to 2000 m (Navas 1976; Hoffmann et al. 1992). Chile annually exports between 3600 to 4500 t of dehydrated rosehips to Europe.

Rose hips are the enlarged floral cups (receptacles) which surround numerous small, hard dry fruits (achenes) commonly called seeds. Rose hips are bright orange and oval and become fleshy but are not true fruits (Fig. 1). They are collected from the wild by peasants and their families. Rose hips are brought to the processing plant where they are dehydrated and seeds are removed; dry pulp is exported, mainly, to European countries. The dry pulp is used in herbal teas and marmelades and has been used as a pigment for laying hens and broiler chickens (Burgos 1976; Cortés 1976; Larraín 1978). It contains large amounts of vitamin C (1000-2000 mg/100g), riboflavin, pectins, nicotinic acid, and malic acid (Israel and Benado 1977). The vitamin C content varies with the site of collection, harvest date, and dehydration methods (Galeb 1976; Ziegler et al. 1986).

The achenes are a by-product of pulp extraction and have been used to feed pigs, hens, chickens, and chinchilla rabbits (Villagrán 1976; Moraga 1978; Peña 1978; Fuente et al. 1979; Seitz 1979; Barbet 1987; Voullieme and Hiriart 1978, 1980a, b). Achenes contain 8% oil composed by oleic, linoleic, linolenic, and transretinoic acids (Soto 1978). This oil is used in the cosmetic industry and is reported to accelerate the regeneration of damaged tissue, and promote wound healing (Valladares et al. 1985, 1986).

Information about the *Rosa* species that exist in Chile is scarce. "Rosa mosqueta" is the common name used for at least three species [*Rosa moschata*, *R. rubiginosa* (= *eglanteria*) and *R. canina*] which are collected from the wild. Morphological differences are evident in the wild material indicating that more than one species and probably several subspecies and ecotypes have developed since introduction. The objective of this study was to evaluate differences in characteristics, size, pulp thickness, and vitamin C of rose hips from wild material existing between latitudes 36° and 38°S where most processing plants exist.

METHODOLOGY

Rose hips and shoots were collected at 30 locations between Cauquenes (36°S) and Perquenco (38°S), Chile, and brought to the University of Concepción, Chillán. Locations sampled were at altitudes from 0 to about 2000 m. Forty hips were collected from each plant sampled and 20 hips were used to measured diameter, length, pulp thickness and the other 20 were used to determine weight, and industrial pulp yield. Vitamin C content was obtained from a sample of 20 hips, homogeneous in color. Samples were frozen and ascorbic acid content was measured according to the AOAC method (1969).

RESULTS

Preliminary results determined that rose hips were very variable among and within locations. All fruits collected from locations in the northern part of the sampled areas had thorns on fruit pedicels and some sparcely distributed thorns in the fruits. Clearly most plants South of Angol (42°S) did not have thorns in the fruit pedicel. Thorns in fruit pedicels have been used to classified species. According to Navas (1976), *R. canina* pedicels are glabrous and *R. rubiginosa* has thorns on the pedicels, and *R. moschata* has pubescent pedicels. Flowers are needed for a definitive classification.

Average hip length and diameter vary between 13 to 24 mm and 9 to 14 mm, respectively. Pulp thickness vary between 2.3 to 1.1 mm and mean fruit weight vary between 2.5 to 2.7 g (Table 1). Industrial pulp yield (kg of fresh fruit needed to produce 1 kg of dry pulp) vary between 2.7 to 5.3 kg. Neighboring plants differ significantly in their fruit length, diameter, pulp thickness, weight, and industrial pulp yield. Ascorbic acid content varied among locations, but this was related directly with the moisture content of the fruits (Table 1). Variability in data collected is influenced by the environment and the genetic background. Further evaluations will be performed to select plants with the desired characteristics for commercial planting, management, and industrial processing. Selection is an important goal for processing companies because they would receive a more uniform product that could have a better industrial yield.

Rue

Herb of Grace

Rutaceae *Ruta graveolens* L.

ADDRESS>Source: Magness et al. 1971

The plant is a perennial herb, woody at the base, up to 2 feet in height. The leaves are much divided and have a very strong odor. In ancient times rue was much used as a flavoring and for medicinal purposes. It is now used to some extent by people who like bitter flavors in cookery and beverages. The volatile oil, distilled from the whole plant, is used in aromatic vinegar and toilet preparations.

Sorrel, Garden

Sourgrass

Polygonaceae *Rumex acetosa* L.

Source: Magness et al. 1971

Garden sorrel is a perennial plant, the roots of which persist for several years. It is grown to a limited extent for the leaves, gathered in early spring and used as greens or pot herbs. The stems are erect, reaching 3 or more feet in height. Rosette leaves are thin, light green and oblong. Stem leaves are narrow and pointed. All leaves are glabrous and have a tart flavor.

Season, start of growth to first harvest: About 4 weeks.

Production in U.S.: No data; very limited.

Use: As pot herbs. Part consumed: Young leaves.

Last update June 28, 1996 bha

Sorrel, French

Polygonaceae *Rumex scutalus* L.

Source: Magness et al. 1971

French sorrel differs from garden sorrel, which see, in that the stems are more branched and less upright. The leaves are somewhat fleshy. Rosette leaves have long petioles and are somewhat heart-shaped, while stem leaves are more pointed on short petioles.

Season, from start of growth to first harvest: 2 months, but harvested throughout the summer.

Production in U.S.: No data, very limited.

Use: As pot herb.

Part consumed: Leaves only.

Safflower seed oil

Carthamus tinctorius L.

Compositae or Asteraceae

Source: Magness et al. 1971

Production of sallower seed for oil has increased greatly in the U.S. during the past 20 years, from about 17,000 acres in 1949 to over 300,000 acres in 1968. The plant is a branching annual with spiny leaves that are nearly as broad as long. Seeds are borne partially exposed in globular heads, with 15 to 50 seeds per head and 1 to 5 heads per plant. Seeds are elongated, 0.25 to 0.33 inch long and a third as much in diameter. The seed contains 32 to 40 percent oil. The seed coats are fibrous, so seeds are decorticated before pressing or putting through expellers to obtain the oil. Most of the oil is used for edible purposes, but it is also comparable to linseed oil for industrial use. The press cake is a valuable high protein feed supplement for cattle, sheep and poultry.

Salsify

Oyster plant, Vegetable oyster

Compositae, Asteraceae *Tragopogon porrifolius* L.

Source: Magness et al. 1971

Salsify is grown for its edible roots, which when cooked have a flavor resembling that of oysters. Although naturally a perennial, the crop is produced as an annual. The leaves are smooth and very long and slender. The roots are white, long and slender, about I inch diameter at the crown, 10 inches to a foot long, and tapering. Cultural conditions are similar to carrots, but plants have a smaller leaf surface and require a longer growing season than carrots.

Season, seeding to harvest: 4 months or more.

Production in the U.S.: 34 acres reported in 1954 census.

More in home gardens.

Use: As cooked vegetable. Part of plant consumed: Roots only.

Elderberry

Caprifoliaceae *Sambucus* sp.

Eastern elderberry *S. canadensis* L.

Western elderberry *S. coerulea* Raf.

Source: Magness et al. 1971

Elderberry plants are large shrubs, or small trees, sometimes up to 20 feet, cultivated to a limited extent in the U.S. for the fruit. Leaves are large and compound. Stems are hollow or pithy. Fruits are produced in large flat clusters 6 to 9 inches across. Individual berries are small, about 0.16 to 0.25 inch diameter, globose, with prominent seeds. Colors vary from red to blue-black. Fruits are harvested from wild in considerable quantities. There are a few commercial plantings of a selected variety named Adams.

Season, bloom to harvest: 60 to 90 days.

Production in U.S.: No data. About 500 tons.

Use: Culinary, jelly, wine.

Part consumed: All in culinary, juice in jelly and wine.

Last update February 18, 1999 by ch

Sand dropseed

Gramineae, Poaceae *Sporobolus cryptandrus* (Torr.) A. Gray

Source: Magness et al. 1971

This is a tufted, native bunchgrass abundant in the Southern Plains and from Idaho and Oregon southward. It is most prevalent on sandy soil. Plants are 2 to 3 feet tall, with solid stems and rather numerous leaves up to 12 inches long and 0.25 inch wide. Roots are coarse and deep-penetrating. The plants produce a fairly large amount of foliage which is eaten readily by livestock while green, but sparingly when ripe. If not overgrazed, stands tend to increase in density. It produces seed in abundance and is useful for reseeding depleted range land. Its relatively low palatability, however, limits its overall usefulness.

Last update June 28, 1996 bha

Sassafras

Sassafras variifolium (Salisb.) Kuntze.

Synonyms.—*Sassafras officinale* Nees and Eberm.; *S. sassafras* (L.) Karst.

Other common names.—Ague tree, saxifrax, cinnamonwood, saloop, smelling-stick.

Habitat and range.—Sassafras is a native tree, growing in rich woods from southern Maine to Ontario, Michigan, and Kansas and south to Florida and Texas.

Figure 92.—Sassafras (*Sassafras variifolium*)

Description.—The sassafras occurs in the North as a shrub, but in the Southern States it sometimes attains a height of 100 feet. The leaves are variable in shape, some with three lobes and others with but one lobe on the side, shaped like a mitten. The yellowish green, fragrant flowers are borne in clusters which appear in early spring. Male and female flowers are borne on different trees. The fruit, which ripens in September, is about the size of a pea, dark blue, 1-seeded and is borne on a thick red stalk. All parts of the tree are aromatic

Part used.—The bark of the root, which is in reasonably constant demand collected in spring or autumn. The outer layer is discarded. The production of sassafras oil by distillation of the root and root bark is a small industry in the southeastern section of the country.*

Sesbania

Sesban

Leguminosae , Fabaceae *Sesbania exaltata* (Raf.) Rydb.

Source: Magness et al. 1971

This is an upright-growing annual legume reaching to 8 feet, grown only for turning under as a soil-improving crop. It produces a heavy tonnage for this purpose. On irrigated lands in the Southwest it is extensively grown as a summer crop and turned under prior to planting winter vegetables. It is grown mainly in areas of high summer temperatures.

Akee, Seso Vegetal

Sapindaceae *Blighia sapida* Koen.

Source: Magness et al. 1971

Tropical evergreen tree of medium size. The flowers are produced laterally in racemes. The trivalved fruits turn yellow and red as they ripen. The mature fruit splits open along 3 sutures exposing the 3 large, shiny, black seeds attached to a white or milky-white aril. The firm and oily aril is the edible portion and is consumed fresh or is cooked and used as a vegetable. Only naturally opened fruits can be eaten. (unripe fruits are poisonous.)

Last update March 3, 1999 by ch

Sindora supa Merrill

Caesalpiniaceae
Supa

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Freshly cut trees are said to yield ca 10 liters of a nondrying, limpid, light yellow, homogeneous, aromatic, slightly fluorescent oil, probably a mixture of sesquiterpenes. The oil is valued for illumination, for making varnishes, paints, and transparent paper, and for the adulteration of other oils. The oil is also used for caulking boats. Supa, the wood of this species, is prized for interior house trim, naval construction, furniture, and cabinetmaking. The sap-wood is cream-colored or pinkish; freshly cut heartwood is yellow, aging upon exposure to reddish brown. Difficult to work, the heavy wood is valued for its durability and pleasant aroma (Allen and Allen, 1981).

Folk Medicine

Supa oil is a popular folk remedy for eczema, herpes, ulcers, and other skin diseases in the Philippines.

Chemistry

"The oil is ... probably a mixture of sesquiterpenes." (Quisumbing, 1951).

Description

Deciduous, straight, unbuttressed, unarmed, tree to 30 m tall. Leaves paripinnate, ca 15 cm long, with three pairs of leaflets, these elliptic, glabrous, coriaceous, 3.5–9 cm long, 2.5–5 cm broad. Flowers small, pedicellate in axillary or terminal panicles 10–15 cm long. Sepals 4, valvate; petal 1; stamens 9–10; anthers dorsifixed, longitudinally dehiscent. Pods broadly ovate, ca 4 cm long, 6 cm broad, opically beaked, basally rounded, with evenly spaced spinelike thorns. Seeds 1–3, black, shiny, with a large fleshy aril (Allen and Allen, 1981).

Germplasm

Reported from the Indochina-Indonesian Center of Diversity (endemic to Philippines), supa, or cvs thereof, is reported to tolerate slope. (x = 12 ?)

Distribution

Endemic to the Philippines, found in low- to medium-altitude forests in Albay, Carmarines, Nueva Ecija, and Quezon provinces in Luzon and in Mindoro (Quisumbing, 1951).

Ecology

Judging by its distributions I would guess that this is a species of the Tropical Moist Forest Life Zone.

Cultivation

The tree is not currently cultivated, apparently being harvested from the wild.

Harvesting

As Burkill (1966) puts it, the wood oil is obtained by the wasteful method of hacking the trunk and by cutting cavities in its base and subsequently firing them to increase the flow... The resin is formed in the wood at all depths, a circumstance which encourages the exploiter to destroy the tree more completely on account of his gain in going deeply.

Yields and Economics

Trees said to yield 10 liters oil each.

Energy

If the tree has been called the kerosene tree, perhaps this tree merits further study. If 100 trees per ha each yielded 10 liters "kerosene"/year renewably, the trees possibly merit as much attention as the "diesel" tree of Calvin, said to yield 40 liters a year.

Biotic Factors

Allen and Allen (1981) note that, so far, reports indicate no rhizobial nodules in these species, as might be expected in most caesalpinioids.

Skirret

Umbelliferae, Apiaceae *Sium sisarum* L.

Source: Magness et al. 1971

Skirret is a vegetable grown for its edible roots. The plant grows to 3 to 4 feet high and bas compound, pinnate leaves. The roots grow in clusters, like sweet potatoes; but are longer, somewhat cylindrical, and somewhat jointed. They have a sweet taste and are tender if well grown, but have a woody, nonedible core. Plants are usually grown from seed, which may be started in beds and transplanted to the field, or may be field sown.

Season, seeding to harvest: 6 to 8 months.

Production in the U.S.: No data, very minor.

Use: As cooked vegetable.

Part consumed: Fleshy, tuberous roots.

Last update June 28, 1996 bha

Skunkcabbage

Spathyema foetida (L.) Raf.

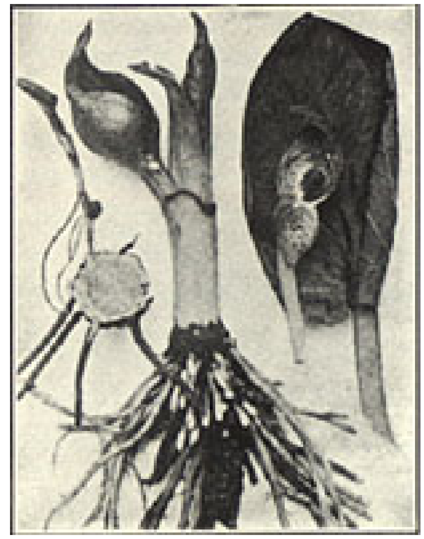

Figure 95.—Skunkcabbage (*Spathyema foetida*)

Synonym.—*Symplocarpus foetidus* (L.) Nutt.

Other common names.—Skunkweed, polecat weed, swamp cabbage, meadow cabbage, collard, fetid hellebore, stinking poke, pockweed.

Habitat and range.—Swamps and other wet places from Canada to Florida, Iowa, and Minnesota abound with this ill-smelling herb.

Description.—Skunkcabbage is a curious plant, the most striking characteristic of which is its rank, offensive odor. It is one of the very earliest of spring flowers appearing in February and March. The hood-shaped flower, which appears before the leaves, is oddly shaped and is not easily described, but its form is we]l shown in the illustration. The edges of the leaf are rolled inward, hiding the spadix inside, which is roundish and completely covered with numerous, dull-purple flowers. The leaves, which appear after the flower, are numerous and very large about 1 to 3 feet in length and about 1 foot in width. The rootstock and root when bruised have the characteristic odor of the plant.

Part used.—The rootstock with the roots, collected early in spring after the flower appears or after the seeds have ripened. It should be dried either in its entire state or deprived of its roots and sliced crosswise. It loses its value with age and should not be kept longer than one year.

Slippery Elm

Ulmus fulva Michx.

Other common names.—Moose elm, red elm, Indian elm, rock elm, sweet elm.

Habitat and range.—This tree is native in woods, along streams, and on hills from Quebec to North Dakota and south to Florida and Texas. It is more common in the western part of its range.

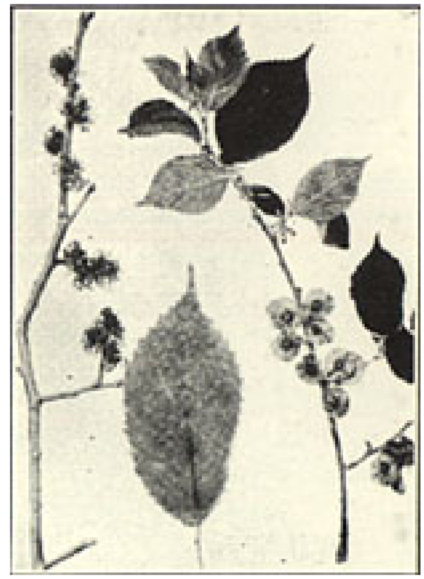

Figure 96.—Slippery elm (*Ulmus fulva*)

Description.—The usual height of the slippery elm is from 40 to 50 feet, with a trunk about 2 1/2 feet in diameter. In open woods and fields it is spreading and irregular in growth, but in dense woods it grows tall and straight, branching some distance from the ground. The bark is very rough, even the small branches are rough, and the twigs are furnished with rough hairs. The rather large leaves, which are from 4 to 8 inches long, are supported by short, downy stalks. The small, bell-shaped flowers appear in dense clusters in early spring, before the leaves, and are followed by flattened and circular winged fruits. Each fruit consists of a single seed surrounded by a thin, winged margin, which aids its dispersion by the wind.

Part used.—The inner bark. The whole bark is shaved from the tree, and after the outer bark is removed the inner portion is dried usually under pressure so that it will remain flat.

Soybean oil

Soya

Leguminosae, Fabaceae *Glycine max* (L.) Merr.

Source: Magness et al. 1971

The soybean bas become the most important source of vegetable oil in the U.S. Quantity of beans crushed for oil averaged about 485 million bushels, 1964-66, producing 2,820,000 tons of oil. Production of oil has trebled in the past 20 years. The plant is a bushy, hairy annual herb up to 3 feet. The hairy pods grow in small clusters, axillary along the stem, and each contains 2 to 4 seeds. Seeds are variable in size, generally about 0.25 inch long. Pods are closed until seeds are threshed out. The seeds contain up to 25 percent of drying oil. The oil is extracted either with solvents, hydraulic presses or experers, the latter two methods involving heating. Much soybean oil is used as salad and cooking oil and for the manufacture of margarine. Large quantities are also used in industry. The press cake is a high protein feed. The beans and plants are also important livestock feeds.

Sphaeranthus indicus

Contributor: Pankaj Oudhia

Copyright (c) 2002. All Rights Reserved. Quotation from this document should cite and acknowledge the contributor.

Sphaeranthus indicus L.

Common (Indian) Names
Sanskrit: mahamundi, mundi, hapus,
Hindi, Bengali, Marathi & Gujerati: mundi, gorkhmundi,
Telugu: boddatarupa, boddasoramu
Tamil: kottak aranthai
Malyali: mirangani
Riya: murisa, bokashungi
Punjabi: ghundi, khamadrus
Santal: belaunja
Undari: mundi

Family: Asteraceae

Habitat: Common rabi weed found in rice fields.

Distribution: Throughout India, Sri Lanka, Africa and Australia.

Related Species: *Sphaeranthus africanus* L. (Sanskrit-Sveta Hapusa; Malyali-Velutha adakkamaniyan)

Botany: A much branched, strongly-scented annual with winged stem and the wings toothed. Leaves obovate-oblong, narrowed at the base, dentate and serrate. Flowers compound heads, globose avoid, Flowering time November to January in Indian conditions; glandular hairy. Achene staled.

Useful Parts: Root, bark, leaves, flowers, and seeds.

Medicinal Properties and Uses: According to Ayurveda, this herb is hot, laxative, digestible, tonic, fattening, alterative, anthelmintic and alexipharmic. It is used in insanity, tuberculosis, indigestion, bronchitis, spleen diseases, elephantiasis, anaemia, pain in uterus and vagina, piles, asthma, leucoderma, dysentery, vomiting, hemicrania, etc. Methyl chavicol, α-ionone, d-cadinene, p-methoxy cinnamaldehyde as major constituents and α-terpinene,citral, geraniol, geranyl acetate, β-ionene, sphaerene as minor constituents of essential oil have been identified.

Ayurvedic Preparations: Mundi Churna, Mundi panchang swarasa, Mundi kvatha.

Other uses: Leaves eaten as pot-herb. The herb used as a fish poison and stuffed into hole of crabs to kill them. Aqueous extract is poisonous to American cockroaches. Plants yield an essential oil and a fatty oil. The plant is used as a soil fertility indicator.

Spinacia oleracea L.

Chenopodiaceae

Spinach

We have information from several sources:

Midwest Vegetable Production Guide for Commercial Growers 2000

Magness, J.R., G.M. Markle, C.C. Compton. 1971. Food and feed crops of the United States.

Spinach, New Zealand

Aizoaceae *Tetragonia tetragonioides* (Pall.) O. Kuntze

Source: Magness et al. 1971

New Zealand spinach is used in the same manner as spinach, but the plant is very different. It reaches a height of 1 to 2 feet, and is much branched, spreading to 3 to 4 feet across. In home gardens, tender shoots, tips, and leaves are cut and used throughout the summer. Commercially, whole plants are usually cut above the ground when small. New growth from the cut stem base will produce a later crop. The plant is adapted to warmer growing conditions than spinach, and will produce summer greens where spinach will not. Leaves are generally similar in appearance to spinach.

Season, seeding to first harvest: 2 months.

Production in the U.S.: No data. Minor as compared to spinach, Mainly in home gardens.

Use: As pot herb or greens.

Part consumed: Young leaves and stem tips.

Leszczyñska-Borys, H., M.W. Borys, and J.L. Galván S. 1999. *Spiranthes*: Terrestrial orchid with ornamental potential. p. 431–432. In: J. Janick (ed.), Perspectives on new crops and new uses. ASHS Press, Alexandria, VA.

Spiranthes: Terrestrial Orchid with Ornamental Potential

Helena Leszczyñska-Borys, Michal W. Borys, and J.L. Galván S.

Terrestrial orchids are rarely cultivated (Bailey 1914; Oszkinis 1991). The genus *Spiranthes* L.C. Rich. is represented by 150–200 species, mostly in the subtropical and tropical regions of the American Continent (Orpet 1914; Peña 1990). Some species are hardy and are found in the United States and Poland (Bailey 1914; Orpet 1914; Szafer et al. 1953; Peña 1990). None of the species has found horticultural application in Mexico, although the wealth of terrestrial orchids, their presence in a range of contrasting environmental conditions, and their esthetic values suggest various ornamental uses.

BOTANY

The genus *Spiranthes* (Orpet 1914), is characterized as "hardy native, easily transplated, flowering biennially, late summer and early autumn." Bailey (1914) concludes that "few species have any value; some of the hardy species are advertised by dealers of the native plants and by collectors." The name *Spiranthes* derives from Greek and refers to the twisted spikes (Bailey 1914), hence the common name "Ladies' Tresses." Martínez (1979) mentions a common name *ya áxchi* (Mayan) for *S. acaulis* (Sm.) Cog. and Rzedowski and Equihua (1987) report two names *coyol cimarrón* and *cutzis* for *S. aurantiaca* (Llave & Lex.) Hemsl from the Valley of Mexico. Peña (1990) describes 17 species of *Spiranthes* from the Valley of Mexico. Among them is *Spiranthes cinnabarina* (Llave & Lex.) Hemsl. [syn. *Dichromanthus cinnabarinus* (Lex.) Garay and

Stenorrhynchos cinnabarinus (Lex.) Lindl.]. *Spiranthes cinnabarina* (Llave & Lex.) Hemsl. occurs in the Valley of Mexico, in sod and in dry brush land, at 2250–2600 m above sea level (Peña 1990). The scape and inflorescence are attractive and suggest uses as a bedding plant, pot plant, or cut flower (Fig. 1).

Fig. 1. Flowering stem of *Spiranthes cinnabarina*.

Wild plants of *S. cinnabarina* were examined that were growing inside the property of the Universidad Popular Autonoma del Estado de Puebla, in Cholula, Puebla, Mexico (19°N 2100 m above sea level) where the Centro de Investigación Universitaria and the Germplasm Bank of Flowering Bulb Species are located. The climate is temperate, subhumid, with rainfall in the summer. Precipitation in the driest month is below 40 mm. The winter precipitation is less than 5% of the annual total (798 mm). The temperatures of the coldest month range from –3° to 18°C. The dry season has spells of precipitation, sometimes extending for three days. The wet season presents frequent spells of hot weather, lasting from two to three weeks. Rainfall is usually brief and intense. Evaporation rate exceeds precipitation almost three times, resulting in rapid development of soil water deficit due to sandy volcanic soils.

The first group of wild *S. cinnabarina* was found in partial shade accompanied by pasture plants, under *Eucalyptus* trees. The dry remains of grasses were burned yearly, leaving ashes and unburned remains, an old system of agriculture in Mexico, still commonly used by farmers and gardeners. The second group of wild plants, in the pasture in the open field at the same location, were growing in a layer of 5–10 cm of accumulated organic matter which contained residues from a steel factory. The third group, forming part of the collection in the Germplasm Bank, was situated in the same area, in beds, in the open field, in sandy, volcanic soil containing some added organic matter.

Spiranthes cinnabarina is an herbaceous, perennial plant that is adapted to a range of soil physical conditions. This species, when found in localities with frequent rainfall or where water accumulates, gave higher shoots, larger inflorescences and more brillant orange coloration. It is adapted to xerophytic conditions and extended spells of drought during the vegetative season, suggesting landscaping uses especially in urban areas. This species develops fleshy, fasciculated roots at a depth of 20 to 30 cm. The fleshy root system may explain the species tolerance to transplanting, characteristic of the genus (Orpet 1914).

CULTURE AND USE

The growing season is determined by the start of the rainy season, and the dormancy of the bud located upon a short, underground shoot. The dormancy period usually begins in the second half of October and lasts until May or June.

Trimmed bare root plants in the flower bud stage or with 30% of flowers opened can be air dried for 3 days, and then successfully transplanted. At the beginning of the growing season when plants were transplanted at the rosette stage (5–6 leaves) only one out of 108 plants was lost; when transplanted at the flowering stage bare root all 50 plants survived.

Plants grown in pots, flowered yearly for three years. The plant diameter at flowering stage ranges from 20–30 cm. The scape is covered with several bracts, being longer at their base. The inflorescence is a spike whose dimensions vary with the soil, water conditions, and solar radiation.

The plant can be grown in mass in parks, gardens, and urban areas in beds or pots. The medium height flowering scapes have orange flowers that turn to coffee-black starting at the base of the spike. Although this is a disadvantage for cut flowers, in group plantings the black flowers provide a contrast to the upper orange flowers which is attractive. At the end of the growing season the dead, above ground parts, should be trimmed.

The stems are resistant to winds. Both the "bud," and the open flower are attractive in color and form. The inflorescence, slowly opens from the base to the apex but its esthetic value is lost when more than 70–75% of the spike is opened. The remains of the flowers do not abscise but remain attached to the spike. Low scape height for group planting and, for use as a pot plant would be desired. A low scape genotype has been found and is currently under observation.

The stem can be used as a cut flower and for arrangements. The stem should be cut above the third leaf. The individual flowers opened continually. The stems held in water, without preservative, in a room of northern exposition (19°C day, 16°C night), lasted 10–14 days. Inflorescences wilted, after the stem was cut at noon, in full sun, but regained normal rigidity easily when the stem was placed in water within an hour. However, the inflorescence bent if the time from cutting to placing in a vase exceeded 1 h.

Picea spp.

Pinaceae
Spruce

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Although the bruised shoots may be malodorous, those of some species have been used to make spruce beer, popular in the Canadian backwoods (Fernald et al., 1958). Millspaugh (1974) added one part of spruce essence to 76 parts water, boiling, straining, and allowing to cool; then he added 96 parts warm water, 7 parts molasses, and 1 part yeast. Another recipe for spruce beer (Can. Pharm. J. 13–14. 1878) recites 16.5 oz. double refined powdered sugar, 3 1/2 oz. bicarbonate of soda, 4 oz. citric acid, and 1 oz. concentrated spruce essence. Soda, acid, and sugar must be dried separately, the essence incorporated in the sugar, with small quantities of caramel. This represents an "instant" spruce beer, powdered, which was placed quickly in a dry bottle and corked. To serve, one teaspoonful was stirred into a glass of water. Amerindians also used the "balsam" as a chewing gum. Inner bark in spring and early summer might be eaten. Stripped young shoots can serve as nutritious emergency foods. According to Guenther (1952), commercial oil of spruce is usually not derived from one single well-defined species, but from mixed branches and leaves of spruce species (and hemlock species). The oil is used in pine and cedar blends for scenting deodorants, room sprays, etc. The resin is used for incense (Erichsen-Brown, 1979). In the days of the European invasion of North America, spruce beer was one of the favored remedies for scurvy, which plagued the immigrants after months on a diet of salt meat and dried legumes. A favorite drink of the admirals of those days was calabogus, made of molasses, rum, and spruce beer (Erichsen-Brown, 1979). The Indians were said to use the powder of spruce wood to keep their hair black. Splinters of the roots and/or bark, were used by the Amerindians in sewing their canoes.

Folk Medicine

According to Hartwell (1967–1971), the resin, seeds, and/or shoots are used in folk remedies for cancers, condylomata, excrescences, tumors, and ulcers. Reported to be anodyne, counterirritant, stimulant, and vulnerary, spruces are folk remedies for abrasions, arthritis, boils, burns, catarrh, consumption, cough, diarrhea, dyspepsia, dyspnea, headache, inflammination, nephrosis, ophthalmia, phthisis, renosis, rheumatism, scurvy, sores, sorethroat, stomach, stones, tumors, and wounds (Duke and Wain, 1981; Erichsen-Brown, 1979). Montagnai mixed the root decoction with sourgrass for lung and throat ailments (Duke, 1983c).

Chemistry

In comparison to fir needles (up to 427 mg ascorbic acid per kilogram), spruce was low, but spruce was higher (23 mg/kd) in carotene (Erichsen-Brown, 1979). d-Bornyl acetate, cadinene, d-camphor dipentene, dl-fenchyl alcohol, l-limonene, and β-pinene have been reported from the oil of *Picea*. From *Picea mariana* there was 2.5% santene, 1.0% tricyclene, 16.0% 1-α-pinene, and 6.5% 1-β-pinene, 10.0% 1-camphene, 3.5% myrcene, 5.0% d-delta^3-carene, 6.5% dl- and 1-limonene, 1.0% terpinolene, 1.0% 1-borneol, 37.0% 1-bornyl acetate, 1.0% dl-camphor. Oil from *Picea excelsa* contained 1-bornyl-acetate, cadinene, dipentene, 1-phellandrene, 1-α-pinene, and santene.

Toxicity

Woodworkers and those exposed to the "balsam" may show contact allergies. Of 1247 patients, 5.5% were sensitive to pine and/or spruce, the majority reacting to both. Asthma suffering may be aggravated by the sawdust or the needles (Mitchell and Rook, 1979). Plasters made from spruce balsam may cause redness, itching papules, and/or sensitive skin, even pustules and ulcers.

Description

Large, handsome, evergreen tree. Bark of trunk gray-brown to red-brown, with irregular, close scales; twigs more or less pubescent; buds small, outer scales with long hair-like points. Leaves 4-sided, somewhat curved, 10–15 mm long, spirally and thickly set on the branchlets, falling early on drying and leaving short, peg-like stubs. Male and female cones borne on the ends of previous year's growth; male sporangia opening longitudinally; female cones red-brown, pendent, 2–6 cm long, maturing by Oct. of 1st year, and usually falling soon after shedding seeds (*Picea rubens* from Radford et al., 1968).

Germplasm

Reported from the North American Center of Diversity, some American spruce species or cvs thereof are reported to tolerate bogs, frost, poor soils, and slopes (Duke, 1978). ($2n = 24$)

Distribution

Picea glauca occurs from Alaska to Newfoundland; northeastern and north central United States; also in Black Hills of South Dakota and small scattered areas in western Montana. *Picea mariana* from Alaska to Newfoundland; northeastern and north central United States, and *Picea rubens* from Nova Scotia, southern Quebec, New England, New York, and south in Appalachian Mountains to North Carolina (Ag. Handbook 450, 1974).

Ecology

Estimated to range from Cool Temperate Moist to Wet through Boreal Moist to Wet Forest Life Zones, eastern spruce are estimated to tolerate annual precipitation of 5 to 16 dm, annual temperature of 4 to 12°C, and pH of 4.5 to 7.5.

Cultivation

Seeds may germinate promptly without pretreatment, but cold stratification has been used for some species. When seeds of some species are chilled under moist conditions, light is not required for germination. Conversely, exposure of imbibed seeds to light during germination tests may overcome dormancy without stratification. Presoaking may increase germinative energy without influencing germinative capacity. Seeds may be treated with fumigants, fungicides, insecticides, and rodent repellants prior to sowing, but caution is advised (Ag Handbook 450, 1974). Seedling density targets are ca 300–1000/m^3. Outplantings are more effective with mulches.

Harvesting

Trees apparently should be harvested Jan.–Apr. when essential oils are highest. For seed, fruits should be harvested promptly at ripening to avoid seed shatter. Seeds may lose viability if left in the cone too long.

Yields and Economics

Oil yields mostly run 0.2–0.7%. Branches from isolated sun-exposed trees yielded 20% more oil than trees growing in dense bush. Branches from 25-year old trees gave twice as much as 45-year olds. The first period of maximum yield (Jan.–Apr.) precedes the period of strong cambial activity in the spring, the second follows formation of summer wood. In one Minnesotan study (Perala and Alban, 1982) in an area with annual rainfall ca 6 dm, annual temperature ca 4°C, pH 5–6, the annual litterfall was 5709 kg/ha organic matter on loam soil, (Glossic Eutroboralf), and 5253 on a sandy soil, both soil types located on a gently undulating till plain. On the loam soil, the litter contained 54 kg N/ha, 6.8 kg P, 16 K, 83 kg Ca, and 4.8 kg Mg/ha. On the sandy soil there was 41 kg N, 5.1 kg P, 12 K, 60 kg Ca, and 4.1 kg Mg/ha. It was concluded that harvesting entire above-ground trees would remove up to 3 times more nutrients than harvesting just the bole. On loam, stands of *Picea glauca* ca 39 years old, had 2187 trees/ha with a mean height of 14.4 m, a mean DBH (outside bark) of 15 cm, and a basal area of 41.1 m^2/ha. On the sandy sites, stands 41 years old had 2718 trees per ha, with mean hight of 13.7 m, a mean DBH of 14 cm, and basal area of 44.9 m^2/ha.

Energy

According to the phytomass files (Duke, 1981b), annual productivity of various spruces ranges from 2 to 14 MT/ha, standing biomass from 88–325 MT/ha. The stand of *Picea glauca* on the loam had standing biomass of 17.4 MT/ha in foliage, 35.8 in branches, 11.2 in bole bark, 91 in bole wood, 35 in root and stump, for an above ground total biomass of 155 MT, a total tree biomass of 190 MT/ha. There was a total of 0.2 MT in the understory and herbaceous biomass as well. The stand on the sandy soil had standing biomass of 11.7 MT/ha in foliage, 16.4 in live branches, 13.7 in dead branches, 12.0 in bole bark, 89 in bole wood, and 31 in stump and root for an aboveground total biomass of 143 MT/ha, a total biomass of 175 MT/ha. There was a total of 0.01 MT/ha in the understory and herbaceous layers as well (Perala and Alban, 1982). Ford (1982) reported a net annual aboveground DM of 26.7 MT/ha in Scotland, the total including roots of 35 MT/ha. One of the highest values reported for coniferous forest in the temperate zone. The needle area index was 10–11 at age 16, 7–8 at age 18. Branch area index was 3.6 and the ratio of main stem bark surface area to ground area was 0.4 at age 16. The standing crop of this 17 year old plantation contained 56.3 MT bole, 25 MT branches, 26.6 MT foliage, 4.9 MT fine roots, and 20.1 MT thick roots, for a total of ca 133 MT. The basal area was 26.6 MT/ha (Ford, 1982).

Biotic Factors

For extensive lists of pests and diseases affecting *Picea* spp. see Browne, 1968 and Agriculture Handbook 165. Nematodes include: *Criconema menzeli*, *Crconemella* spp., *Hemicycliophora similis*, *H.* sp., *H. uniformis*, *Hoplolaimus galeatus*, *Pratylenchus penetrans*, *P. pratensis*, *Rotylenchus robustus*, *Tylenchorhynchus maximus*, *T*. sp., and *Xiphinema americana*. (Golden, p.c., 1984)

Pascual-Villalobos, M.J. 2002. Anti-insect activity of bufadienolides from *Urginea maritima*. p. 564–566. In: J. Janick and A. Whipkey (eds.), Trends in new crops and new uses. ASHS Press, Alexandria, VA.

Anti-insect Activity of Bufadienolides from *Urginea maritima*

María Jesús Pascual-Villalobos

Squill [*Urginea maritima* (L.) Baker, Liliaceae] is a native medicinal and ornamental plant from the Mediterranean area. The bulbs were an ancient source of rodenticide products replaced later on by warfarin and modern anticoagulant raticides. Since rats have developed resistance to such products there is now renewed interest in the species.

In the 1950s, attempts were made in the United States to introduce this new crop for arid lands. A collection of bulbs are still maintained at Gentry Experimental Farm, Murrieta, California. Some limitations concerning variability in toxicity were previously discussed (Verbiscar et al. 1986a; Gentry et al. 1987). Scilliroside, a high toxicity bufadienolide glycoside, is the main active principle. Other glycosides and aglycones have also been isolated from the bulb (Verbiscar et al. 1986b).

We tested this plant in our research program to screen botanicals for insecticidal activity at “Centro de Investigación y Desarrollo Agroalimentario” in Murcia, Spain. In Spain squill is a wild plant of coastal areas (Fig. 1). Ethanolic extracts of bulbs have been active against stored product pests (Pascual-Villalobos and Fernández 1999), although such anti-insect effects could not be attributed to specific compounds in that study. The objective of this work was to test pure bufadienolides isolated from *U. maritima*.

Fig. 1. Wild *Urginea maritima* plants in “La Unión,” Murcia, Spain.

METHODOLOGY

Compounds

Five different bufadienolides (proscillaridin A, scillaren A, scillirosid, gammabufotalin, and scillirosidin) were obtained as pure substances (see previous work of Krenn et al. 1994) from *U. maritima* bulbs and they were provided by B. Kopp from the Institute of Pharmacognosy in Vienna (Austria).

Insects

The effects of compounds were studied on the stored product pest *Tribolium castaneum* (Coleoptera: Tenebrionidae). Larvae were obtained from same age cultures kept on an artificial diet of white wheat flour and beer yeast (95:5) at a constant temperature of 30°C in the dark.

Bioassays

Topical Application Bioassay. Substances (dissolved in acetone) were applied topically (using a micropipete) to 25 day old larvae at doses of 10, 20, 30, and 40 µg/insect. Larvae were placed singly inside glass tubes and kept at a constant temperature of 30°C in darkness; 24 replications per treatment. Mortality (%) was recorded after one and seven days. If a response to increasing doses of the products was obtained, probit analyses were performed and LD_{50} calculated when the fit was good.

Insect Growth Inhibition and Fertility Bioassay. Substances were incorporated into the standard insect diet at a dose of 2%. The experimental unit was a 4 ml glass vial with 100 mg of diet and one newly hatched larvae. Twelve replications were set up for each compound. The experiment was kept in the dark at a constant temperature of 30ºC. Length (mm) and mortality (%) of larvae were measured after 14 days. Emerged adults from each treatment were paired during 4 days on the same diet and the number of fertile laid eggs were counted. The comparison between treatments and control was done using the non parametric Mann-Whitney U test.

RESULTS

Proscillaridin A, scilliroside, and scillirosidin were active by topical application (Table 1). The aglycone, scillirosidin was more lethal, causing over 50% mortality in *Tribolium* larvae at 10 µg/insect, than its glycoside scilliroside. Scillaren A and gammabufotalin were less toxic on insects and a response to increasing doses was not obtained. Only data from scilliroside applications fitted to the probit model being LD_{50} of 25.5 and 17.1 µg/insect for mortality after one and seven days respectively.

Table 1. Mortality[z] (%) of *T. castaneum* larvae (25 day old) caused by topical application of bufadienolides (n=24).

Compound	Days after application	Dose (µg/larvae)				Probit fit χ^2(df=2)		LD_{50}
		10	20	30	40			
Proscillaridin A	1	41.7	29.2	41.7	70.8	23.9	poor	--
	7	45.8	50	87.5	91.7	17.3	poor	
Scilliroside	1	20.8	37.5	66.7	75	2.2	good	25.5
	7	29.2	62.5	83.3	83.3	3.0	good	17.1
Scillirosidin	1	54.2	41.7	58.3	95.8	47.1	poor	
	7	52.3	45.8	79.2	100	46.3	poor	
Scillaren A	1	33.3	25	4.2	41.7	--		--
	7	41.7	33.3	33.3	50	--		--
Gammabufotalin	1	20.8	25	41.7	29.2	--		--
	7	20.8	29.2	50	37.5	--		--

[z]Mortality of control (application of the solvent, acetone) was 0% at day 1 and 8.3% at day 7.

Intake of bufadienolides at 2% in the diet caused a statistically significant larvae growth inhibition and adult fertility reduction (Table 2). Ingestion of scillirosidin or proscillaridin A was most deleterious (larvae of 4.36 mm and 4.73 mm respectively in comparison with 6.9 mm of control); in these treatments a delay to reach pupae stage from 21 to 29.2 days was also obtained. The number of eggs laid per female was clearly reduced if the compounds were added to the diet. Again, scillirosidin and proscillaridin A were more active by completely inhibiting the fertility (Table 2). Also, scillirosidin, the aglycone appears to be more active than the glycoside (scilliroside).

Table 2. Insect growth inhibition and influence on fertility of bufadienolide intake (n=12).

Compound[z]	Larvae length[y] after 14 days (mm)	Mortality (%)	Fertility[yx] (no. eggs/pair)

Proscillaridin A	4.73 ***	25.0	0.0 ***
Scilliroside	6.00 ***	16.7	11.0 ***
Scillirosidin	4.36 ***	8.3	0.2 ***
Scillaren A	5.42 ***	8.3	6.3 ***
Gammabufotalin	5.96 *	25.0	5.8 ***
Control	6.9	0.0	26.1 ***

[z]Mixed at 2% in the diet.
[y]Mean values and significance of Mann-Whitney U test for comparison between treatment and control (ns=non significant, * 0.01<p<0.05, *** p<0.001).
[x]During 4 days.

We report for the first time that *Urginea maritima* bufadienolides induce anti-insect effects on *Tribolium castaneum*. This suggests that squill should be investigated for activity against other insects and pests.

St. Augustine grass

Gramineae *Stenotaphrum secundatum* (Walt.) Kuntze

Source: Magness et al. 1971

This grass, native to the West Indies, is now planted along the Southeastern Coastal Plain. It is an extensively creeping perennial with stolons that have rather long internodes. These stolons send up branches at the nodes, which are not over 12 inches high. Leaf blades are 4 to 6 inches long, glabrous and blunt. It will stand salt water spray so can be used along sea coasts. In the area of adaptation it is used for lawns, golf fairways and pastures. It forms dense sods which stand tramping well. As pasture it is grown mainly on muck soils in the Florida Everglades. It is not hardy north of central Georgia and central Alabama. It forms little seed and is propagated by planting the rooted runners. Ample fertilizer must be used to secure good growth.

Uses

Tree produces abundant fodder, palatable to sheep, cattle and goats. It is said that older stands will support 26 sheep per hectare. The wood, though hard and difficult to work, is used for furniture and firewood. Man-made *tamarugo* plantations are being introduced in the Tamarugal Pampa which are transforming the absolute desert ecosystem into an agroecosystem. The result, is a noteworthy increase in overall productivity in one of the most inhospitable regions of the world (Habit et al., 1981). The potential value of the tamarugo was noted as early as 1918 when Maldonado, a forest inspector called for a tamarugo forest preserve, considering it most important for the Chilean desert (Burkart, 1976).

Folk Medicine

No data available.

Chemistry

Per 100 g, the fruit is reported to contain 3.34 g H_2O, 11.14 g protein, 1.62 g fat, 79.63 g total carbohydrate, 31.45 g fiber, 4.27 g ash, 280 mg Ca, and 1,440 mg P. Leaves were analyzed at 94.7% H_2O, 90.53% dry matter, 9.98% total protein, 10.72% crude fiber, 1.9% ether extract, 45.91% N-free extract, 22.02% ash, 2.82% Ca, and 0.91% P (Habit et al, 1981). By contrast Gohl (1981) reports:

		As % of dry matter						
	DM	CP	CT	Ash	EE	NFE	Ca	P
Browse, Chile	89.3	10.7	32.1	5.0	2.7	49.5	3.98	0.12

Green leaf	230	24	13.4	42	0.12	136	1.8

*n.d. = not determined.

Cyanogenetic glucosides and alkaloids, were not detected in any of the samples, saponins were only found in green fruits and seeds, both in low percentages, 0.007 and 0.010% respectively. The seeds appeared to have simultaneous presence of antitryptic factor (2.3 trypsin inhibited units per milligiam of defatted dry sample) and haemagglutinins (6.0 units per milligram protein) (Pak et al., 1977).

Description

Deciduous open-crowned tree up to 18 m tall, the trunk to 80 cm in diameter; with a dense mat of lateral roots and deep taproot (to 6 m deep on tree 15 m tall). Flowers golden yellow, in long axillary cylindrical spikes. Stipules spiny, 5–38 mm long. Leaves unijugate, the pinnae 3–4 cm long or less, with 10–15 pairs of leaflets; leaflets linear obtuse or acutish, 4–8 mm long. Pod arcuate, turgid, brown or stramineous, 2–8 cm long, 2–3.5 cm in diameter with ca 6–8 seeds embedded in a brownish edible pulp, seeds ovate, 3–4.3 mm long, brown (Burkart, 1976). Calyx 1.5 mm long; corolla 4–5 mm long; ovary villous.

Germplasm

Reported from the South American Center of Diversity, tamarugo, or cvs thereof, is reported to tolerate drought, high pH, salt, and sand. ($2n = 28$)

Distribution

Native to that part of the Atacama Desert in northern Chile known as Pampa del Tamarugal, an island salt desert about 40 km wide and 300 km long. Also planted in Argentina and recommended for other saline deserts of the world.

Ecology

Found on salty-sandy or clay loam soils, occasionally with a 40-cm salt incrustation. In its native habitat the tree ranges from 1000–1500 m elevation. Ranging from Warm Temperate Desert to Thorn Steppe through Subtropical Desert toSubtropical Thorn Forest Life Zones, tamarugo, or cvs thereof, is reported to tolerate annual precipitation of (0-)3 to 5 dm, annual temperature of 12 to 20°C, and pH of 6.8 to 8.0. The desert ecosystem of the Tamarugal Pampa is highly specific. The climate is the normal desert climate; the most biologically significant factors are: high day-time temperatures, great day-to-night temperature range, almost total lack of rainfall, occasional mist, relatively low humidity and intense sunlight. The soils are composed of deposits of fluvial origin from the cordillera of the Andes, and have a surface salt crust ranging in thickness from 10–60 cm or more. Under certain conditions of atmospheric humidity, tamarugo absorbs water through its leaves, transporting it to the root system and depositing it in the micro-rhizosphere, whence it is reabsorbed along with the soil nutrients. This explains why measurements of mean annual evaporation show much higher rates outside than inside the forest area, where a mere fraction of the water is lost in evaporation. This is also why tamarugo trees are found in areas where the ground water table lies 40 m deep and has no contact with the roots of trees (Habit et al, 1981). According to Burkart (1976) the leaves absorb water through their stomata when the relative humidity of the air >95%. Variations in salinity of groundwater had little or no effect on growth rate but distance from water table. The greater the depth to groundwater the smaller the height growth of the trees, tending to minimize the importance of absorption of water from atmosphere (Felker, 1982).

Cultivation

For rooting cuttings a 34°C air temperature and vermiculite medium is recommended. N fixation in tamarugo may be limited. Since the leaf N content appears to be sensitive to phosphorus levels, there is hope that pod N levels may also be P-sensitive. Pods are generally 10% crude protein 3% short of the 13% crude protein level required for good animal growth. In N-fixing systems, phosphate has tremendous leverage over dry matter production. N:P levels are generally ca 10:1, and N:DM ratios ca 1.5:100. Thus every kg deficient P that is corrected has the opportunity to provide 600 kg DM. Habit et al. (1981) cite the following planting instructions: Use a 2:1 mixture of earth and guano. Plant in unperforated plastic bags, 12 cm in diameter, 30 cm long, filled with this mixture and placed in a carefully-levelled planting bed. Water to saturation. Sow three to five seeds a depth of 1.5 cm. First treat with sulfuric acid for 7 minutes, then wash and let dry in shade. Keep the surface, where the seeds are planted, wet, but do not accumulate water in the bottom of the bags, as this encourages fungus growth. Treat the soil with fungicide before sowing to avoid fungus attack. Once seeds germinate, give more water but at greater intervals, to ensure moisture for the downward-growing roots. Avoid excessive use of water. Keep seedlings in nursery 3 to 5 months, until they are 8 to 10 cm tall. Be sure the roots do not pierce the plastic. Plantation spacings in the Tamarugal Pampa are at 10 x 10 m and 15 x 15 m, taking into consideration the tree's growth and its function as fodder. A pit is dug in the ground and in it a hole is made 20 cm in diameter and 50 cm deep, abundantly manured with guano. Pit depth depends on terrain, usually 80 cm in diameter by 30–70 cm deep, varying according to depth of salt crust which must be penetrated before making the planting hole.. Before planting, water hole to saturate soil as far down as possible. Split the bottom of the plastic bags at planting so roots can pass through. Remove plastic bags with care to avoid breaking the cylinder of earth. There must be enough water to penetrate to the roots and keep them moist. It is most important to avoid excess watering, which shows up at the first stages of the seedlings as a "fall" due to fungi, and later as a yellowing of the leaves. Plants are established when they send out new shoots. When this occurs, watering can be spaced at intervals of 20 days, though care should be taken to ensure that the water penetrates properly. If there is moisture in the subsoil, it is advisable to determine whether the roots have reached it by suspending watering and observing the reaction of the plants.

Harvesting

Sheep and goats feed on fallen leaves and pods (fresh seed produced from October to January). Harvested for firewood as needed, the tree coppices readily.

Yields and Economics

In their tabulation, Felker and Bandurski (1979) list yields of 12 MT/ha leaves and pods. According to Habit et al. (1981), the average yield of fruit per tree is 2.1 kg/m^2 of crown projection, even higher with adult trees. With insecticides, single tree yield increased from 105 to 210 kg, translating to 10 MT pods/ha. Felker suggests 5 MT. Aerial application of insecticides was suggested. Chileans estimate cost of aerial application at $15–20(US)/ha and the heptachlor at $24 for the 4 liters required, for a total cost of $35/ha compared to $500/ha for ground application. High quality Prosopis wood retails for $6.00 per board foot ($2,540 per cu m) when cut, planed, and cured. Straight growing trees of algarobo occur in Argentina. One could get straight pieces 4 m long and 40 cm in diameter in 20 years. This wood, after being cut, planed, and dried would be worth at least $300 per tree, or $36,000 per ha (Felker, 1982).

Energy

Felker (1982) estimates that prunings from a tree would be 200 kg (not annually) suggesting 20 MT/ha. These could be converted to chips with a heating value of 18,000 BTU/kg. Felker (1982) suggests that trees should be pruned every 6–10 years, removing the lower branches which may preclude animals from eating the fallen pods. The 200 kg/tree prunings could be chipped and blown into a truck at a cost of ca $10/ton. The chips are estimated to produce energy at the rate of $1.47 per million Btu's, about 1/4 the cost of oil energy. Tractor driven chippers are available at $3,000 to $12,000 (US). If there were no market for chips, or charcoal were not available, a small wood-fired turbine could convert the wood to electricity. Felker notes that Aerospace Corporation of Virginia sells 3000 kilowatt wood fired gas generators for ca $2,250,000 (US). They consume ca 3 MT/hr generating 3,000 KWH at $0.15 KWH. At 15 trees per hour and 100 trees/ha, 1,314 ha would need be pruned every year to fuel the generator. Cross yearly electrical sales would be $4,000,000 (US) (Felker, 1982).

Biotic Factors

Habit et al. (1981) present detailed information on the insect pests of tamarugo, listing *Leptotes trigemmatus* (purple moth), *Tephrinopsis memor* (measuring worm), *Hemiberlesia rapax, Heteropysylla texana, Aphis* sp. (tamarugo louse), cecidomids, *Eriophyes tamarugae, Ithome* sp. (flower moth), *Leptotes trigemmatus, Tephrinopsis memor, Frankliniella rodeos* (tamarugo thrips), *Crytophlebia carpophagoides* (fruit moth), and *Scutobruchus gastoi* (tamarugo worm). Despite its anemophilous pollenization, insect participation seems important to fructification. The solitary bee *Centris mixta* is the most important insect pollinator. Imported *Apis mellifera* served as a good pollinator and honey producer (Habit et al., 1981). In addition to enumerating insect pests and control mechanisms, Habit et al. (1981) enumerate associated animals and plants. Marked increases in pod production were evident following insecticide treatment. Untreated tamarugo showed considerable abortion of young pods, much pod stunting, disfiguration, and insect holes (bruchid emergence holes). Rhizobia capable of nodulating tamarugo are being multiplied at INTEC (Felker, 1982). Hectares of dead tamarugo trees were suspected to be fungal infestations, transmitted through root graftings. Felker et al. (1981) review the pest infestations of their *Prosopis* plantings with suggestions for their control.

White clover

Ladino clover

Leguminosae *Trifolium repens* L.

Source: Magness et al. 1971

White clover, like red, is believed native to the eastern Mediterranean region. It was widely grown in Europe before America was colonized and was brought here by the earliest settlers. It is now grown in all areas of the United States except the Great Plains and the extreme South. The plants are perennials with a prostrate growth habit. They develop stolons which root at the nodes, resulting in thickening of the stands. They do not develop upright stems. Leaves grow at the crown and at the nodes of stolons. They are trifoliate and the leaflets vary in shape from broadly elliptical to obovate - generally about half an inch across. Flower beads are aenerally white, sometimes pink-tinted, and contain up to 100 florets.

Among many strains, Ladino white clover is now most widely grown. It differs from the common kinds in that it grows 2 to 4 times as large- otherwise, it is similar. White clovers are used primarily as pastures, often in combination with grasses. They are highly nutritious and palatable.

Prosopis juliflora DC.

Prosopis chilensis (Mol.) Stuntz is often considered synonymous, but see Burkart, 1976.
Mimosaceae
Velvet mesquite

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Mesquite pods are among the earliest known foods of prehistoric man in the new world. Today flour products made from the pods are still popular, although only sporadically prepared, mostly by Amerindians. Pods are made into gruels, sometimes fermented to make a mesquite wine. The leaves can be used for forage. Providing good bee pasturage also, nectar from mesquite yields a superior honey. The wood is used for parquet floors, furniture, and turnery items, fencepost, pilings, as a substrate for producing single-cell protein, but most of all for fuel. Toasted seeds are added to coffee. Bark, rich in tannin, is used for roofing in Colombia. The gum forms an adhesive mucilage, used as an emulsifying agent. Gum is used in confectionary and mending pottery. Roots contain 6–7% tannin, which might discourage Rhizobia.

Folk Medicine

According to Hartwell (1967–1971), the juice is used in folk remedies for that cancerous condition he terms "superfluous flesh." Reported to be cathartic, cyanogenetic, discutient, emetic, POISON, stomachic, and vulnerary, mesquite is a folk remedy for catarrh, colds, diarrhea, dysentery, excrescences, eyes, flu, headcold, hoarseness, inflammation, itch, measles, pinkeye, stomachache, sore throat, and wounds (Duke and Wain, 1981). Pima Indians drank the hot tea for sore throat (Lewis and Elvin-Lewis, 1977). Aqueous and alcoholic extracts are markedly antibacterial.

Chemistry

Per 100 g, the flower is reported to contain (ZMB): 21.0 g protein, 3.2 g fat, 65.8 g total carbohydrate, 15.5 g fiber, 10.0 g ash, 1,310 mg Ca, and 400 mg P. Leaves contain 19.0 g protein, 2.9 g fat, 69.6 g total carbohydrate, total carbohydrate, 21.6 g fiber, 8.5 g ash, 2,080 mg Ca, and 220 g P. Fruits contain 13.9 g protein, 3.0 g fat, 78.3 g total carbohydrate, 27.7 g fiber, and 4.8 g ash. Seeds contain (ZMB) 65.2 g protein, 7.8 g fat, 21.8 g total carbohydrate, 2.8 g fiber, and 5.2 g ash. (FAO, 1981a). Another analysis of the fruit shows 14.35% water (hygroscopic), 1.64% oil, 16.36% starch, 30.25% glucose, 0.85% nitrogenous material, 5.81% tannin-like material, 3.5% mineral salts, and 27.24% cellulose. Mesquite gum readily hydrolyses with dilute sulfuric acid to yield L-arabinose and D-galactose and 4-o-methyl-D-glucuronic acid at 4:2:1. Owing to the high content of arabinose, the gum is an excellent source of sugar. Roots contain 6.7% tannin, bark 3–8.4%, and dry wood 0.9%. The alkaloids 5-hydroxytryptamine and tryptamine are reported from this species (Simpson, 1977).

Toxicity

According to Mitchell and Rook, the thorn from mesquite, on penetrating the eye, causes more inflammation than expected from the physical injury. The irritation may be due to waxes. Injection of cerotic acid is destructive to the eye. (Still Amerindians applied the leaves for conjunctivitis.) Using the wood in a fireplace has caused dermatitis, as has working with seasoned wood. The gum has irritant properties. Reports on cattle toxicity vary. Lewis and Elvin-Lewis (1977) report that ingestion over long periods of time will result in death in cattle. Further, they report that the pollen may cause allergic rhinitis, bronchial asthma, and/or hypersensitivity pneumonitis. Kingsbury (1964) goes into some detail on mesquite poisoning in cattle, including cases where autopsies showed pods and seeds in the rumen 9 months after the cattle could have ingested them. Mesquite poisoning may induce a permanent impairment of the ability to digest cellulose. Felker and Bandurski (1979) also provide interesting detail. If *Prosopis* pods are the sole food source for cattle, ca 1% become sick, and some die with a compacted pod ball in the rumen. Death is attributed to high sugar content repressing the rumen-bacterial cellulose activity. Mesquite feeding to pigs was promising during the first four weeks, deteriorating thereafter, perhaps due to phytohemagglutinins and trypsin inhibition. Feeding trials with sheep show a 15% higher protein digestibility coefficient for mesquite pods than for alfalfa hay. Trypsin inhibition has been demonstrated the TI content 1.4 TIU/mg (Del Valle et al., 1983). Contains isorhamnetin 11

3-glucoside, apigenin 6, 8-diglycoside, and traces of quercitin 3',3diOMe, leutolin 3'-OMe, and apigenin diglycoside (Simpson, 1977).

Description

Perennial deciduous thorny shrub or small tree, to 12 m tall; trunk to 1.2 m in diameter, bark thick, brown or blackish, shallowly fissured; leaves compound, commonly many more than 9 pairs, the leaflets mostly 5–10 mm long, linear-oblong, glabrous, often hairy, commonly rounded at the apex; stipular spines, if any, yellowish, often stout; flowers perfect, greenish-yellow, sweet-scented, spikelike; corolla deeply lobate. Pods several-seeded, strongly compressed when young, thick at maturity, more or less constricted between the seeds, 10–25 cm long, brown or yellowish, 10–30-seeded. Seed compressed and oval or elliptic, 2.5–7 mm long, brown (Reed, 1970).

Germplasm

Reported from the South American Center of Diversity, mesquite, or cvs thereof, is reported to tolerate drought, grazing, heavy soil, sand, as well as saline dry flats and weeds. Some Argentine germplasm tolerated mild frost at 40° S latitude. ($2n$ = 28, 52, 56, 112) (Zevin and Zhukovsky, 1975, Simpson, 1977).

Distribution

Originally Central and/or South American, the mesquite is now pantropically introduced and establishing, often as a weed. It is classified as a principal weed in Mexico, a common weed in the US (but does not naturally occur in the US, this report due to the long prevailing taxonomic confusion), and a weed in Australia, Dominican Republic, India, Iraq, and Venezuela. According to the NAS, the tree ranges from sea level to 1,500 m. According to the taxonomic work of Burkart (1976), neither *P. juliflora* nor *P. chilensis,* as now defined, occur in the US.

Ecology

Probably ranging from Tropical Thorn to Dry through Subtropical Thorn to Dry Forest Life Zones (with little frost), mesquite is reported to tolerate annual precipitation of 1.5 to 16.7 dm (mean of 29 cases = 9.9), annual temperature of 20.3 to 28.5°C (mean of 21 cases = 25.5), and pH around neutral (Ecosystematic Data Base) (NAS, 1980a).

Cultivation

Propagated, if need be (weeds rarely need be), by seed, root suckers, and hardwood cuttings. Hot water or acid treatment will expedite seed germination. In India, seeds collected in May–June may be sown right after collection, but September–October seed are not sown until April. For line fencing, seeds may be sown in two adjacent rows ca 50 cm apart, with a spacing of 30 cm between the sowings. Transplanting one-year olds in the rainy season is preferable to direct sowing. Root and shoot cuttings with minimum diameter 12.5 mm at the collar and 100 mm long are satisfactory (C.S.I.R., 1948–1976). Pot studies have shown water requirements of nearly 5,000 cm^3 per g of dry matter (Felker et al, 1981).

Harvesting

Bearing fruits in 3 to 4 years, the trees are usually harvested by hand, often after the fruits have fallen.

Yields and Economics

Felker and Bandurski (1979) estimate 2,000 kg/ha pods for such species as *Prosopis juliflora* in unmanaged Arizona desert, 4,000–20,000 kg/ha pods in arid Hawaiian savannas. Speaking of wood, the NAS (1980a) states that on a 15-year rotation, expected yields are 75–100 MT/ha, on 10-year rotation, 50–60 MT, suggesting wood yields of 5–7.5 MT/ha/yr over and above the fruit yields. According to TIME (March 12, 1984, p. 70), mesquite wood is selling for nearly $5.00 a kilogram. TIME quotes Joe Messina, founder of Mesquite Treat Enterprises, as saying that in Arizona mesquite costs about $100 a cord, which in dry wood approximates 3,000 lbs. In one instance, Messina cleared the mesquite off the land of a grateful farmer, free for the chopping. He sells the wood to restaurants in 50-lb. bags at $12.50 for logs, $17.50 for chunks, and $20 for chips. All this because "Mesquite grilling imparts a sweet smoky burnishing of flavor...an almost imperceptible flavor to fish, though a more pronounced and interesting one to shrimp." (TIME, Mar. 12, 1984). Galt et al. (1982) showed that a mesquite free pasture (annual precipitation ca 4 dm) produced 1,165 kg/ha forage compared to 818 kg/ha (17% mesquite) on the mesquite pasture. Burkart (1943) cites studies showing yields of 87 hectoliters/ha in the wild. He also cites Indian studies suggesting that bees can harvest nectar more than enough for 1 kg of honey.

Energy

Fast-growing, drought resistant, and with remarkable coppicing power, *Prosopis* is a natural fuelwood candidate. With specific gravity 0.70 or higher, the wood has been termed "wooden anthracite", because of its high heat content, burning slowly and evenly and holding heat well. This species provides >90% of the fuelwood in some Indian villages (Sharma, 1981). Although no direct data on N-fixation of *Prosopis* are available, Felker and Bandurski (1979) suggest that tree legumes (exclusive of Caesalpiniaceae) fix between 155 and 580 kg/ha/yr. Soils under the crowns of legumes in the desert usually have 10 times more N (0.3%) than those under non nitrogen fixers (0–03%).

Biotic Factors

Fungi reported on this or related species include *Agrobacterium tumefaciens, Cerospora prosopidis, Didymosphaeria cryptosphaerioides, Fomes everhartii, F. rimosus, Gloesporium leguminum, Leveilulla taurica, Napicladium prosopodium, Phoma* sp., *Phyllosticta juliflora, Phymatotrichum omnivorum, Physalospora mutila, Polyporus adustus, P. pinsitus, P. texanus, Ravenelia arizonica, R. holwayi, Schizophyllum commune, Scleropycnium aureum, Septoria prosopidis,* and *Sphaeropsis prosopodis.* Among the Coleoptera, *Amblycerus* sp., *Apate monachus, Bruchidius uberatus, Caryedon serratus, Celosterna scabrator, Oncideres putator, Rhipibruchus prosopis;* among Hemiptera, *Icerya formicarum,* and *Oxyrhachis tarandus;* among Isoptera *Anacanthotermes macrocephalus;* among Nematoda *Meloidogyne* sp. Galt et al. (1982) show the botanical composition of mesquite pastures on the Santa Rita Experiment Range. Felker et al. (1981) review the pest infestations of their *Prosopis* plantings with suggestions for their control.

Vetches

Leguminosae *Vicia* sp.

Source: Magness et al. 1971

The vetches are weak-stemmed, semi-vining plants with pinnate leaves terminating in tendrils. Some 150 species are known, about 25 of which are native in the United States. However, the species grown agriculturally here are all introduced, being native to Europe or westem Asia. The vetches are extensively used as green manure for soil improvement, for hay, and in the South for winter pasture. Vetch seed is harvested from more than 100,000 acres annually (112,956 acres in 1959, census figure) in the United States - sufficcient to seed around 1,000,000 acres. Vetches may become troublesome weeds in grain fields but are readily controlled with herbicides. Tares as mentioned in the Bible are believed to have been common vetch.

Last update June 27, 1996 bha

Common vetch

Tares

Leguminosae *Vicia sativa* L.

Source: Magness et al. 1971

This vetch is less winter hardy than hairy. When fall seeded winter injury often occurs at temperatures below 100 F. The plants are sparingly pubescent with procumbent stems up to 3 or more feet. Leaves consist of up to 7 pairs of elliptic or oblong leaflets. Common vetch is sown both as a soil improvement crop and for hay. For hay or seed production it is usually planted with a grain crop, as oats or wheat, to support the vetch plants. Seeding is in the fall in mild climates, in spring in cold areas. Common vetch produces a palatable bay, especially for cattle. Good winter and spring grazing is provided in mild climates. Williamette, Warrior and Doark are important varieties of common vetch.

Vicia villosa Roth

Leguminosae

Hairy vetch

We have information from several sources:

Hairy Vetch: Alternative Field Crops Manual, University of Wisconson Cooperative Extension Service, University of Minnesota Extension Service, Center for Alternative Plant & Animal Products

New Crops: Solutions for Global Problems—Noel Vietmeyer

Magness, J.R., G.M. Markle, C.C. Compton. 1971. Food and feed crops of the United States.

Hungarian vetch

Leguminosae *Vicia pannonica* Crantz

Source: Magness et al. 1971

This vetch is intermediate in winter bardiness between hairy and common. Its special virtue is tolerance to wet soils. It is mainly grown as a hay crop on heavy soils in western Oregon where winter precipitation is heavy. Plants are pubescent. Leaves consist of 4 to 8 pairs of linear to oblong leaflets. in Oregon it is commonly fall seeded with a grain crop for partial support. It produces a palatable and nutritious hay on soils poorly adapted for other vetches.

Last update February 18, 1999 by ch

Minor vetches

Leguminosae *Vicia* sp.

Source: Magness et al. 1971

Additional vetch species are crown to a limited extent in the United States.

Monantha vetch, *V. articulata* Hornem. can be grown under the same conditions as common vetch. Plants are smooth or nearly so. The light lavender colored flowers are borne singly. It is distinguisbable mainly by flat seeds.

Bard vetch, *V. monantha* Retz. is much restricted in adaptation. It is grown only in irrigated areas of southern Califomia and Arizona. It is very similar to monantha vetch in appearance, but seeds are oval to round.

Narrowleaf vetch, *V. augustifolia* L., is adapted to soil and climatic conditions like those of common vetch. It is early maturing, ripening seed from spring plants in the north and is characterized by the narrow leaflets. It is suitable for pasturage throughout the Cotton Belt. It may be a troublesome weed in spring wheat.

Horse bean, *V. faba* L., is grown as a feed crop in the United States only in coastal valleys in California, and now much less than formerly. The upright-growing, near glabrous plants have large leaves with broad, oval leaflets. Weevils infesting the seeds are responsible for reduced usage of horse bean as a feed crop.

Woolypod vetch, *V. dasycarpa* Ten., is quite similar to hairy or smooth vetch, *V. villosa*, but is slightly less winter hardy and grows at slightly lower winter temperatures. It is a valuable winter vetch for the Cotton Belt.

Last update February 18, 1999 by ch

Purple vetch

Leguminosae, Fabaceae *Vicia benghalensis* L.

Source: Magness et al. 1971

In general purple vetch resembles hairy vetch, with pubescent stems and pods. It is, however, the least winter hardy of the commonly grown vetches, and temperatures below 20 F. generally cause injury. It is grown mainly in milder sections of California where it is primarily a hay crop. Stems are up to 30 inches or more in length, prostrate or climbing. Leaves consist of 5 to 8 pairs of linear to oblong-linear leaflets. It is little grown in colder climates where spring seeding would be necessary.

Tall wheatgrass

Gramineae, Poaceae *Agropyron elongatum* (Host) Beauv.

Source: Magness et al. 1971

Tall wheatgrass is a tall-growing, coarse-textured bunchgrass native to the Eastern Mediterranean Region, introduced from Russia in 1932. It is adapted to growing on wet, alkaline soils and has been used extensively for seeding such sites in the Northern Plains and Intermountain Regions. Clumps reach up to 6 feet and yield heavily with sufficient available moisture. It is less drought resistant and less palatable than crested wheatgrass, but is useful for both hay and pasturage on soils not suitable for other wheatgrasses.

Yellowroot

Xanthorhiza simplicissima Marsh

Synonym.—*Zanthorhiza apiifolia* L'Her.

Other common names.—Shrub yellowroot, southern yellowroot.

Habitat and range.—Yellowroot grows in woods from southwestern New York to Kentucky and Florida, chiefly in the mountains

Description.—This slightly shrubby plant, 1 to 2 feet high, has compound slender-stemmed leaves 5 to 6 inches long clustered at the summit of the short stem. The leaves consist usually of five thin leaflets 1 to 3 inches long, with sharp, irregular teeth. The small, purplish-brown flowers are produced in spring, borne either singly or in clusters from terminal scaly buds. A characteristic of this plant is the bright-yellow color and bitter taste of its bark and long roots.

Part used.—The roots.

Figure 126.—Yellowroot (*Xanthorhiza simplicissima*)

Zoysia grasses

Gramineae *Zoysia* sp.

Manilagrass *Z. matrella* (L.) Merr.

Japanese lawngrass *Z. japonica* Steud.

Mascarene grass *Z. tenuifolia* Willd. ex Trin.

Source: Magness et al. 1971

All of these grasses are native to tropical or Eastern Asia. In this country they are used exclusively for lawns, golf courses, and occasionally for erosion control. They form excellent green turf, green in summer but becoming brown during the winter months.

Mascarene grass is the smallest, finest-leaved and least hardy of the three. It grows only 2 inches high, is shallow rooted. It is grown somewhat in southern areas.

Japanese lawngrass has a broad, coarse leaf and makes a dense sod. It is winter hardy as far north as Boston. It is tough, harsh, unpalatable to livestock. Once established, it is very persistent. Propagation is by inserting plugs of sod. Varieties are available, of which Meyer is best known.

Manilagrass has a general limit of hardiness at about 40 N. It appears best adapted to rather heavy soil but will thrive on other types. It is propagated by planting sod pieces and is rather slow to become established; but makes a dense, persistent sod.
