What is NewCROP?

Online since 1995, NewCROP (New Crops Resource Online Program) is an information-rich site related to crop plants. It is a project of the Purdue University Center for New Crops and Plant Products and is associated with the New Crop Diversification project and the Jefferson Institute.

Acknowledgements:

Funding provided by the Indiana **B**usiness **M**odernization and **T**echnology Corporation and the Indiana Center for New Crops and Plant Products, Indiana Value-Added Grant Program, and the Jefferson Institute.

We welcome your comments, constructive suggestions and hope you'll let us know if you are experiencing any problems while using the system. Good luck and welcome again to NewCROP™.

Tidbits of Info

CRFG Publications 1969-1989 Index - A

Up to Main Index page - Forward to B

ABELMOSCHUS ESCULENTUS (Hibiscus esculentus) - Okra
This annual herbaceous shrub originated in Africa where it was cultivated for many generations. The fruit, large green erect pod, is eaten cooked and the seeds are toasted, ground and used as a substitute for coffee. There are many selections.

ABELMOSCHUS MANIHOT (Hibiscus manihot) - Edible Hibiscus
A shrub from the South Pacific that bears edible leaves when cooked; it grows well in warmer areas of the U.S.

ABIU - Pouteria caimito

ABYSSINIAN BANANA - Ensete ventricosum *See Bananas, Ornamental*

ACER SACCHARUM - Sugar Maple

ACEROLA

- Acerola Comes to California Loaded with Vitamin C. By Floyd L. Cooper. 1971 YB, pp 2-8
- Culture of Rare Fruits in the San Francisco Bay Area. By J. Garrin Fullington. 1974, pp 3-6
- For the Beginner: Suggestions for New Gardeners. By Phil Clark. 1985 #2, pp 6-9
- From the Editor's Mailbag. 1980 #4, pp 4-7
- Ground Cover Acerola. By Peggy Winter. 1980 #4, p 7
- Malphighia Suitable for Ground Cover. By John M. Riley. 1976 #3, pp 7-8
- More Acerolas Than You Can Eat. By Raymond F. Vincent. 1978 #4, pp 13-15
- Notes from a Grower/experimenter. By David Silber. 1987 #3, pp 20-21
- Notes on Growing Tropical Fruits in Southeast Florida. By Claude D. Reese. 1977 YB, pp 15-17
- Some Experiments on Cherimoya Pollination. By Raymond F. Vincent. 1983 YB, pp 30-36

ACHIOTE - Bixa orellana

ACHIRA - Canna edulis

ACMENA SMITHII - Acmena

- Myrtaceae: The Family of the Guava. By John F. Donan. 1984 YB, pp 5-17

ACTINIDIA ARGUTA - Siberian Gooseberry, Hardy Kiwi

ACTINIDIA DELICIOSA - Kiwi
A climbing vine from China with feather-veined simple leaves and a brown, hairy fruit about 3" long. The flesh is emerald green with many small seeds and the flavor is pleasant, slightly acid, and juicy. It grows well in California and New Zealand but cannot stand salt exposure and is

susceptible to nematodes. *See Kiwi*

ACTINIDIA KOLOMIKTA *See Kolomikta*

ACTINIDIA POLUGAMA - Silver vine

AEGLE MARMELOS - Bael Fruit, Golden Apple, Bengal Quince
A citrus family member that grows as a small spiny tree much desired in India. Fruit is round to pear-shaped, 2-4" in diameter; covered with a smooth, hard rind. Pulp is orange, sweet and aromatic with many seeds in the 8-16 fruit cells. Used for drinks, jellies and eating out-of-hand. The wood is used for carving; the shells are made into boxes and the flowers are made into perfume.

AFRICA

- Agroforestry in Zaire. By Roy M.Danforth. 1986 YB, pp 37-48
- Cultivation of Granadillas in South Africa. By Frans A. Kuhne. 1975 YB, pp 56-70
- Irrigation in South Africa; Kepel Apple. By Brian Lanton. 1983 #1, pp 3-4
- Letter from Zaire. By Roy Danforth and Paul Noren. 1987 #4, pp 20-24
- Rare Fruit in Zaire. By Roy Danforth. 1987 J, pp 13-15
- Subtropical Fruits and Nuts of Spain, Kenya and South Africa. By Muriel B. Fisch 1975 #1, pp 6-13
- Wild Fruit of South Africa Part I. By Ian Hartland. 1975 #1, pp 13-16

AFRICAN GOOSEBERRY *See Dovyalis*

AFRICAN HORNED CUCUMBER - Cucumis metuliferus. Kiwano

AFRICAN HONEYSUCKLE

- Halleria lucida. By Bernard King. 1986 #2, p 26
- Research Corner Notes. By John Riley. 1984 #2, pp 26-27

AIR LAYERING - MARCOTTING

- Cherimoya Riddle. By Jim Neitzel. 1982 #3, pp 8-12
- Coffee Tree in Folger's Commercial. By Peggy Winter. 1984 #3, pp 5-6
- Jaboticaba. By Peggy Winter. 1980 #4, p 24
- Planting Instructions for Litchis after Marcotting. By David Guggenheim. 1984 #4, pp 27-28
- Preliminary Report of a Successful Mango Air Layer. By Louis G. Lopyan. 1988 #3, pp 9-10
- Sapindaceae Family. By Bill Louscher. 1980 YB, pp 41-45
- Update from Palm Beach. By Tommy Reese. 1982 #2, pp 19-21

ALECTRYON EXCELSUS *See Titoki*

ALEURITES MOLUCCANA - Candlenut, Country Walnut
A large, open and well-formed tree native to tropical Asia. The oily nuts were used by the natives as candles, hence the name of the tree. The shells are black when ripe and, in Hawaii, are polished and used in leis. The kernels are eaten as a relish after baking and act as a laxative on some people. The plant grows in Hawaii and in the warmer protected areas of South Florida. Propagation is by seeds or cuttings.

ALLSPICE

- Bits & Pieces: By Peggy Winter. 1985 #1, pp 25-26
- Myrtaceae: The Family of the Guava. By John F. Donan. 1984 YB, pp 5-17

- News from the Hills. By David Silber. 1988 #4, pp 5-7

ALMOND

- A Naturalist in Western China. By Ernest H. Wilson. 1976 YB, p 94
- Bare Root Time Again. By Jim Neitzel. 1979 #1, pp 18-21

- Horticultural Puzzle. By Burt and Muriel Fisch. 1979 #2, p 22

AMAIIT *See Rukam*

ANACARDIACEAE

- Anacardiaceae: Lacquer Mastic and Poison Ivy. By John F. Donan. 1986 YB, pp 1-9

ANACARDIUM OCCIDENTAL - Cashew
An easily grown evergreen relative of the mango, poison sumac and poison ivy. Very sensitive to cold, especially in warm winters followed by a freeze. Leaves are simple, leathery, light-green with a copper-red blush when young. The nut is not edible or safe when raw. Touching an uncooked nut can cause skin eruptions and the smoke given off by roasting is itself an irritant and poisonous. The cashew apple grows above the nut; it is edible and safe without treatment and makes good jelly or fermented liquor. *See Cashew*

ANANAS COSOSUS *See Pineapple*

ANNATTO - Bixa orellana

ANNONA ASIATIC (Cananga odorata) *See Yang-yang*

ANNONA CHERIMOLA - Cherimoya
This tropical highland is reportedly the best of the annonas. It is a spreading, deciduous, small tree that prefers sun, can't stand wet feet and can survive a light frost but not heavy freezes. A seedling will bear in 4-5 years. The fruit is 3-9" long, generally conical, smooth skin with bumps or dents, green to yellow when ripe. October to May in California. The pulp is white, sweet and aromatic with a custard-like texture. *See Cherimoya*

ANNONA CHERIMOLA X A. SQUAMOSA - Atemoya
A cross between cherimoya and sugar apple which does well in Florida. It resembles the sugar apple in growth but the fruit is much like the cherimoya. Propagation is by budding or grafting to seedling rootstock. *See Atemoya*

ANNONA DIVERSIFOLIA - Illama
Considered an excellent annona of the tropical lowlands, it is not well known outside Mexico and Guatemala. This slender, erect or spreading tree grows to 20-25'. Maroon-colored 1" flowers yield fruit weighing 1½ lbs., with a sweet flavor like sugar apple. *See Illama*

ANNONA GLABRA *See Pond Apple*

ANNONA MONTANA - Mountain soursop
Similar to guanabana but the fruit is less desirable and about the size of a small custard apple. Native to the West Indies, where it is called wild guanabana, the tree is larger than the guanabana and hardier, withstanding temperatures several degrees below 32°F.

ANNONA MURICATA - Soursop, Guanabana
A small, upright evergreen which cannot stand frost. It may be grown only in warmest parts of Florida or in greenhouses. The leaves are dark green and glossy. The fruit is 6-9", yellow green in color, with white flesh. The pulp is excellent for making drinks and sherbets and, though slightly sour-acid, can be eaten out-of-hand. *See Soursop*

ANNONA PURPUREA - Soncoya
From Mexico and Central America, this tropical lowland, moisture-loving tree has a fruit up to 6" in diameter. It is brownish-gray and covered with protuberances ending in hooks curved toward the stem. The flesh is bright orange and soft. *See Soncoya*

ANNONA RETICULATA - Custard apple, Bullock's Heart
A 25' low-branched deciduous tree, scraggly in appearance. The fruit is large, with yellow or brownish skin and a creamy pulp. Like all annonas, it cannot stand wet feet. Generally used as a rootstock for other annonas. *See Annona Species*

ANNONA SQUAMOSA - Sugar Apple, Sweetsop
A deciduous tree, small and open. The fruit is green, heart-shaped, 3" long, broken up by protuberances on the skin. The flesh is sweet and refreshing, considered the best of the tropical annonas. It is eaten raw, in drinks or sherbets. The flavor is best when picked before maturity and ripened in a bag. The tree does well in alkaline soils but freezes at about 27°F. *See Sweetsop*

ANNONA SPECIES

- 7th International Fruit Club Seminar. By David M. Guggenheim. 1989, #4 pp 3-10
- A Journey to Vilcabamba - the Sacred Valley of Ecuador. By Steven Spangler. 1981 #3, pp 14-17

- Chelonocarpus - a New Section of the Genus Annona. By W. E. Safford. 1982 #3, pp 1-3, 28
- Chromosome Numbers in the Annonaceae. By Wray M. Bowden. 1974 YB, pp 73-81
- Two Scholars at the CRFG Meeting. By Clytia M. Chambers. 1980 #3 pp 13-14, 21-22
- Update from Palm Beach. By Tommy Reese. 1982 #2, pp 19-21

ANON *See Rollinia*

ANONILLA - Annona palmeri

ANTIDESMA BUNIUS - Bignai, Bignay
Dioecious. This large evergreen with shiny deep-green leaves is easily grown and bears large amounts of small shiny red fruits which are edible out of hand but generally used for wine or jelly. It freezes at 26°F but will recover from the roots. *See Bignai*

ANTIDESMA DALLACHYANUM - Herbert River Cherry
Small to medium Australian Tree. The best of the Antidesma species. It is dioecious, but a single female plant will bear a small amount of fruit.

Sweeter than the bignay, the fruit are large and black. Grows well in Florida and has been grown in San Diego.

APPLE CACTUS *See Pitaya*

ARATICU *See Rollinia*

ARAUCARIA ARAUCANA - Monkey Puzzle Tree
This Chilean pine tree is a relative of the Norfolk Island Pine, but the tiered branches are weirdly shaped, which accounts for its common name. Grown from North Carolina southward in the U.S., it is both lovely and grotesque. The seeds are boiled and eaten in Chile, where they are well liked.

ARAUCARIA BIDWILLI - Bunya-Bunya, Brunya
This Australian relative of the Monkey Puzzle grows to 150' in its native habitat and will grow well, though not that tall, in Florida and Southern California.

ARBUTUS UNEDO *See Strawberry Tree*

ARIZONA

- Mangoes in the Arizona Desert. By Alois Falkenstein, M.D. 1989 #4, pp 12-13

ARTOCARPUS COMMUNIS - Breadfruit, Breadnut
An exceedingly difficult to grow tree as temperatures below 40°F kill it. Fruit is green, round, to 8" and generally seedless. A seeded form is common in the tropics and called Breadnut. Fruits are cooked as vegetables. Seeds are used like chestnuts. *See Breadfruit*

ARTOCARPUS HYPARGYRAEUS - Kwaimuk
This S.E. Asian tree is extremely ornamental; moderately slow grower and not as cold sensitive as previously thought. The fruit is small, yellow and quite good to eat, with best flavor when picked dead ripe from the tree.

ARTOCARPUS INTEGRIFOLIA - Jackfruit, Jakfruit
A large interesting relative of the breadfruit. Cold sensitive (27°F) but will grow in protected areas. It bears the largest of tree fruits, on the trunk and larger branches. Spiked on the outside and weighing up to 80 lbs., the flesh is edible, soft and quite aromatic; the seeds are chestnut-like when roasted. The tree grows wild in India and S.E. Asia. Will grow in Florida and Southern California but not to its full size. Only care required is watering and fertilization. *See Jackfruit*

ARTOCARPUS ODORATISSIMUS *See Marang*

ASIAN PEAR

- Nostalgic Memories of North China Fruits. By Albert Fei. 1971 #1, pp 5-7

ASIMINA PARVIFLORA - Dwarf Pawpaw

ASIMINA TRILOBA - Pawpaw, Paw Paw
Native to North America and related to the custard apple. Cold hardy and grown as far north as New York and Michigan. This may give it promise as a rootstock for the Annonas. The fruit is edible, brown-black, with soft orange flesh tasting something like banana when ripe. The fruit must be thoroughly ripened or it is unpalatable. *See Pawpaw*

ASPARAGUS BEAN *See Winged Bean*

AUSTRALIAN BRUSH CHERRY - Syzygium paniculatum

AUTUMN OLIVE

- Growing Rare Fruit in Northern Calif. By John M. Riley. 1973 YB, pp 67-90

AVERRHOA BILIMBI - Bilimbi
A medium-sized Asian tree similar to carambola but with fewer branches and longer leaves clustered at the branch tips. The red and white flowers develop on the trunk and lower branches; the fruit is 2-3" long, waxy, green cucumber-like and sour. They can be used to remove stains from clothing, can be pickled or cooked with sugar. *See Camias*

AVERRHOA CARAMBOLA - Carambola, Star Fruit
This dense, evergreen tree common in India and China grows to about 20'. Red and white flowers appear on bare branches or at leaf bases. Fruit has a thin, waxy, green-yellow, yellow or orange skin. Oblong and five-angled it is star-shaped when cut across the middle. It has a sweet, watery, slightly acid, pleasant tasting pulp that is eaten raw or preserved. Seedlings have been known to bear in 3 years. Large trees have been known to survive 26°F without damage but young trees must be protected from frost. *See*

Abelmoschus moschatus (L.) Medic, Malvaceae (Syn. *Hibiscus abelmoschus* L.) is a tropical weedy shrub native to India valued for its scented seed. Ambrette is a close relative to Okra, a popular horticultural crop. The genus *Abelmoschus* has six species distributed in the South and South East Asia and in North Australia. *Abelmoschus moschatus* Medic., *A. manihot* (L.) Medic., and *A. esculentus* (L.) Moench, contain wild and cultivated forms, and *A. ficulneus, A. crinitus,* and *A. angulosus*, are only wild. *Abelmoschus manihot, A. moschatus* and *A. esculentus* are compared in Table 1. In Hindi, it is popularly known as *mushkdana, kasturi bhendi* (kasturi = musk; *bhendi* = lady's finger). In other Indian languages it is known as *gukhia korai* (Assamese), *kasturi bhenda* (Telgu), *kattukasturi* (Malylam), *varttilai kasturi* (Tamil), *lalkasturika* (Sanskrit) (Krishnamurty 1993). The area under ambrette is presently low in India but is increasing rapidly (Oudhia and Tripathi 2000) with seed exports to France, Germany, Japan, Singapore, Spain for its use as an aromatic oil. Indian drug manufacturers are introducing new herbal drugs containing ambrette for medicinal use.

Table 1. Comparison of *A. esculentus, A. manihot* and *A. moschatus*.

Particulars	*A. esculentus* (n=65)	*A. manihot* (n=60)	*A. moschatus* (n=36)
English name	Okra, Gumbo	Manihot-mallow	Musk-mallow
Place of origin	Old world tropics	East Asia	India
Life cycle	Annual	Annual or perennial	Annual or biennial
Leaves	Large often 12 inch or more across; cordate-ovate.	Leaves large ovate to nearly orbicular in outline 6-12 inch or more. Manihot probably suggests the resemblance of leaves to those of cassava or manihot	With variously 3-9 lobed or divided. Margins coarsely toothed

Floral characteristics	Calyx large and spathe-like; bracts of involucre linear; pod 4-5 inch or more long.	Calyx large and spathe-like; bracts ovate to oblong.	Calyx large and spathe-like; Bracts of involucre linear; pod 3 inch or less long.
Flower colour	Yellow with a reddish center	Yellow or whitish with a dark brown center.	Yellow with a crimson center.

Botany

Erect hispid herbs or undershrubs, 0.5-2.5 meters high, with a long slender tap root. Leave extremely variable, lower suborbicular in outline, cordate, lower or palmately 3-7 lobed, upper narrower, hastate or sagittate at the base with linear-oblong or triangular lobes. Flowers regular, bisexual, involucral bracts 8-12, hairy yellow with purple centre. Fruits capsule fulvous hairy, oblong lanceolate, acute. Seeds subreniform and blackish (Verma et al. 1993; Agharkar 1991; Lindley 1985).

Uses

Ambrette oil obtained from seeds possess an odor similar to that of musk and its aromatic constitents have long been used in perfumery industry. Different grades of essential, or aromatic absolute, are marked in Europe as high-grade perfumes (Singh et al. 1996) The seeds are valued for the volatile oil present in the seed coat. Seed analysis report 11.1% moisture, 31.5% crude fiber; 14.5% lipids, 13.4% starch, 2.3% protein, volatile oil (0.2-0.6%) and ca/ 5% resin (Srivastava 1995).

Analysis of volatiles report myricetin-3-glucoside and a glycoside of cyanidin in flowers, an aromatic constituent in seeds, beta-sitosteral and its beta-D-glucoside, myricetin and its glucoside in leaves and petals and beta-sitosterol from dry fruit husk (Rastogi and Mehrotra 1991a,b).

In India, roots, leaves (rarely), and seeds of ambrette are considered valuable traditional medicines. The bitter, sweet, acrid, aromatic seeds are used as a tonic and are considered "cooling, aphrodisiac, opthalmic, cardiotonic, digestive, stomachic, constipating, carminative, pectoral, diuretic, stimulant, antispasmodic, deodorant, and effective against "*kapha*" and "*vata*," intestinal complaints, stomatitis; and diseases of the heart, allays thirst and checks vomiting. According to *Unani* system of medicine seeds allay thirst, cure stomatitis, dyspepsia, urinary discharge, gonorrhea, leucoderma and itch. Roots and leaves are cures for gonorrhea (Agharkar 1991). Even use against venomous reptiles has been reported (Lindley 1985).

Cultivation

Ambrette is cultivated as pre-kharif crop in India. It is usually sown in March–April but as late as the first week of July in Central India (Oudhia 2001a). Seed rates of 41g/kg are optimum (Oudhia 2000b). Application of dried Neem leaves (500Kg/ha) at last ploughing increased oil content and quality. April sown crop start flowering in September; fruits ripen from November to January and are harvested when fully mature. Applications of fertilizers improves growth of plant and seed yields (Krishnamurty 1993) but studies conducted by SOPAM indicate the use of chemical inputs resulted in negative impact on oil content and quality. Harvested capsules are sun dried and seeds dehisce when the capsules burst. The oil for perfumery is extracted by steam distillation of crushed seeds.

Abies balsamea (L.) Mill.

Abietaceae
Balsam Fir, Balm of Gilead Tree, Canada Balsam

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

The balsam or pitch, in extreme emergency, forms a highly concentrated, though disagreeable, food." (Fernald, Kinsey, and Rollins, 1958). Bark of conifers, mostly, was so important in the diet of some tribes that at least one tribe, the Adirondacks, owe their name to the Mohawk term for "tree eaters." Erika Gaertner devotes a four-page article to the making of breadstuff from the bark of balsam fir. In contrast to pine bark, the fir bark is a delight to chew in winter or early spring, slightly mucilaginous and sweetish, better raw than cooked (Gaertner, 1970). Inner bark that does not show any discoloration can be used for breadstuff and it takes about an hour to peel enough for one loaf. Leaves average 0.65% essential oil, ranging to 1.4% or higher. Trunks also yield oil of "Canada balsam" or turpentine, used as a permanent mounting medium in microscopy and as a cement for glassware. Canada turpentine yields 15–25% volatile oil, the resin being used for caulking and incense (Erichsen-Brown, 1979). Often used for Christmas trees. *Abies* species are commercially valuable for timber even though their wood is relatively soft, weak, and perishable. Balsam fir is used in the US for timber and plywood, and is the mainstay of the pulp wood industry in the northeast.

Folk Medicine

According to Hartwell (1967–1971), the buds, resin, and/or sap are used in folk remedies for cancers, corns, and warts. Reported to be anodyne, antiseptic, diaphoretic, diuretic, masticatory, and vulnerary, balsam fir is a folk remedy for bronchitis, burns, cancer, catarrh, cold, consumption, cough, dysentery, earache, gleet, gonorrhea, heart ailments, leucorrhea, paralysis, rheumatism, scurvy, sores, ulcers, urogenital ailments, warts, and wounds (Duke and Wain, 1981; Erichsen-Brown, 1979). Chippewa used the gum as an analgetic, the root decoction as an antirheumatic. Kwakiutl used the gum as a laxative and held the root in the mouth to cure sores there. Menominee used the gum for colds, cuts, lungs, and sores, the inner bark for chest pains, colds, and skin. Montagnai applied the gum for chest or heart pain. Ojibwa use the gum for colds, sores, sore eyes, and venereal diseases; the leaves as stimulant; Penobscot used the gum for cuts and sores; Pillagers used the needles in sweat baths and fumitories. Potawatomi used the gum for colds and sores, the bark infusion for consumption and other ailments. Caughnawaga used the gum as a cataplasm for cancer (Duke, 1983c).

Chemistry

Reducing sugars are said to account for 47% of the DM of balsam fir bark. The leaf oil contains 17.6% bornyl acetate and probably 1-α-pinene, Canada balsam contains ca 20% 1-β-phellandrene and smaller quantities of α- and β-pinene bornyl acetate, and the alcohols androl and bupleurol (Guenther, 1948-1952). Oils are also reported to contain juvabione and dehydrojuvabione (List and Horhammer, 1969–1979). The term Canada Balsam is a misnomer because balsams are supposed to contain benzoic and cinnamic acids, both absent from the Canada oleoresin. "Turpentine" is also a misnomer, implying that the oleoresin is entirely steam volatile. Actually it contains 70–80% resin, only 16-20% voaltile oil (Anderson, 1955). One analysis of the essential oils reports 14.6% bornyl acetate, 36.1% β-pinene, 11.1% 3-carene, 11.1% limonene, 6.8% camphene, and 8.4% α-pinene (Erichsen-Brown, 1979).

Toxicity

Canada balsam is reported to produce dermatitis when applied as perfume. The foliage has also induced contact dermatitis.

Description

Tree to 20 m tall; trunk 3–5 dm in diameter. Bark brown, broken into scaly plates with resin-filled pockets. Twigs pale green and pubescent when young, becoming gray, reddish, or purplish. Leaves dark green, linear, sessile, spiral in origin, but twisted at base to form two ranks; leaves persisting many years; leaf-scars circular. Lower leaves to 3 cm long, those on coniferous branches much shorter. Winter buds globose, 3–6 mm in diameter, with orange-green scales, resinous. Mature cones nearly cylindrical, 3–8.5 cm long by 2–3 cm thick, dark purple when growing. Bracts ovate, the distinct awn protruding beyond the scale below it. Seeds ovoid or oblong, acute at base, with thin wing and resinous vesicles, maturing in one summer. Germination phanerocotylar (Brown and Brown, 1972).

Germplasm

Reported from the North American Center of Diversity, balsam fir, or cvs thereof, is reported to tolerate frost and slope. ($2n = 24$)

Distribution

Labrador and Newfoundland south to New York and Pennsylvania, west to central-Wisconsin and Minnesota, north and west to Alberta; generally south of 55°N latitude, except in Alberta and Saskatchewan (Ag. Handbook 450, 1974).

Ecology

Estimated to range from Cool Temperate Moist to Wet through Boreal Moist to Wet Forest Life Zones, balsam fir is estimated to tolerate annual precipitation of 6 to 15 dm, annual temperature of 5 to 12°C, and pH of 4.5 to 7.5. Female strobili may be wholly or partially aborted up to 6 to 8 weeks after bud burst by late spring frosts. Pollen dispersal can be reduced by adverse weather (Ag. Handbook No. 450)

Cultivation

Flowering in May, fruiting August-September; seeds are dispersed in late September. Extensive data on seed vitality etc. are reported in Agriculture Handbook No. 450. Seeds should be moist stratified 14–28 days at 1–5°C. Seed may be sown in autumn without stratification, with target seedling densities in the nursery ca 450–500/m^2, often mulched with sawdust. Of slow initial growth, the stock is usually outplanted as 2- to 3-year-old seedlings or 3- to 4-year-old transplants (Ag. Handbook 450, 1974).

Harvesting

"Turpentine" is usually collected July-August by breaking the turpentine blisters into small metal cans with sharp-pointed lids. Trees are then allowed to recuperate 1–2 years. For the leaf oil, it would appear that branches should be snipped off younger trees in early spring (January-March).

Yields and Economics

Fifteen year old trees yield 70% more leaf oil than 110-year-old trees; oil yields are highest in January–March and September, lowest from April to August. Around 1800, one author reported averaging nearly a ton of balsam at "6 pence a lb." (Erichsen-Brown, 1979).

Energy

According to the phytomass files (Duke, 1981b), annual productivity ranges from 9 to 13 MT/ha, standing biomass from 77–200 MT/ha. Gaertner cites references dealing with the potential use of bark for fuel, as charcoal or briquets.

Biotic Factors

The following are listed as affecting *Abies balsamea*: Acanthostigma parasiticum, *Adelopus nudus, Aleurodiscus abietis, A. amorphus, Armillaria mellea, Ascocalyx abietis, Bifusella faulii, B. linearis, Cenangium ferruginosum, Cephalosporium* sp., *Coniophora puteana, Corticium galactinum, Coryne sarcoides, Cryptosporium macrospermum, Cyptospora pinastri, Dasyscypha agassizii, D. arida, D. calyciformis, D. calycina, D. resinaria, Dermea balsamea, Dimerosporium balsamicola, Echinodontium tinctorium, Flammula alnicola, Fomes pini, F. pinicola, F. robustus, F. roseus, F. subroseus, Fusicoccum abietinum, Gloeosporium balsameae, Herpotrichia nigra, Hyalopsora aspidiotus, Hydnum balsameum, Hymenochaete tabacina, H. mirabilis, H. nervata, H. punctata, Lenzites saepiaria, Leucostoma kunzei, Limacina alaskensis, Lophodermium autumnale, L. lacerum, L. piceae, Melampsora abieti-capraearum, M. epitea, Melampsorella caryophyllacearum, M. cerastii, Merulius himantoides, Micropera abietis, Milesina fructuosa, M. laeviuscula, M. marginalis, M. polypodophila, M. pycnograndis, M. vogesiaca, Nectria cucurbitula, Nothophacidium abietinellum, Odontia bicolor, Ophionectria scolecospora, Peniophora gigantea, Peridermium balsameum, Phacidium abietinellum, P. abietis, P. balsameae, P. infestans, Phaeocryptopus nudus, Phaeophacidium abietinum, Polyporus abietinus, P. anceps, P. balsameus, P. circinatus, P. fragilis, P. guttulatus, P. hirtus, P. mollis, P. resinosus, P. schweinitzii, P. tomentosus, Poria sericeo-mollis, P. subacida, P. vaporaria, Potebniamyces balsamicola, Pucciniastrum epilobii, P. goeppertianum, P. pustulatum, Rehmiel-lopsis abietis, R. balsamea, Rhizosphaera pini, Rhizothyrium abietis, Sarcotrochila balsamea, Scoleconectria cucurbitula, Sphaeropsis abietis, Stereum chailletii, S. pini, S. sanguinolentum, Thyronectria balsamea, Trametes heteromorpha, Trichoscyphella resinaria, Tympanis pinastri, Uredinopsis ceratophora, U. longimucronata, U. mirabilis, U. osmundae, U. phegopteris, U. struthiopteridis, Valsa abietis, V. pini* (Ag. Handbook 165, 1960; Browne, 1968). Also listed in Browne (1968) are the following: Angiospermae: *Viscum album*; Acarina: *Trisetacus grosmanni*; Coleoptera: *Dryocoetes confusus, Hylobius pales, H. pinicola, H. warreni, Melanophila drummondi, Monochamus scutellatus, Pityokteines sparsus, Pityophthorus cariniceps, P. granulatus, P. puberulus, Polygraphus rufipennis*; Diptera: *Dasyneura balsamicola*; Hemiptera: *Adelges piceae, Aphrophora parallela, Cinara curvipes, Mindarus abietinus, Prociphilus bumeliae*; Hymenoptera: *Camponotus* spp., *Gilpinia hercyniae, Megastigmus specularis, Neodiprion abietis, Pleroneura borealis, Urocerus albicornis, Xeris spectrum*; Lepidoptera: *Acleris variana, Choristoneura* *fumiferana, Cladaria limitaria, Dasychira plagiata, Dioryctria abietivorella, Hemerocampa leucostigma, Lambdina fiscellaria, Lymantria dispar, Melanolophia imitata, Orgyia antiqua, Protoboarmia porcelaria, Semiothisa granitata, Zeiraphera canadensis*; Aves: *Loxia curvirostra, L. leucoptera*; and Mammalia: *Alces alces, Erethizon dorsatum, Euarctos americanus, Odocoileus virginianus, Peromyscus* sp., *Tamiasciurus hudsonicus*. Seed production may be reduced by squirrels and birds. *Abies* cones are preferred source of food for squirrels in some localities. Large quantities of cones are cut and cached; such cutting may also reduce future cone crops. Cone and seed insects may significantly reduce seed yields and occasionally totally destroy seed crops. Seed chalcids (*Megastigmus* spp.) are most common and may be abundant enough to have a major impact. For example, *Megastigmus pinus* typically infest 8-10% of *A. concolor* seed and have destroyed as much as 60% of a crop. Cone moths (e.g., *Barbara colfaxiana siskiyouana* and *Dioryctria abietivorlla*) and cone maggots (*Earomyia* spp.) cause the most conspicuous damage; all seeds are lost in heavily infested cones. Cone and scale midges cause no significant loss, but seed or gall midges may reduce seed yields by fusing seeds to cone scales (Ag. Handbook 450, 1974). Nematodes reported include *Criconemella (Criconemoides) lobata, Paratylenchus* sp., *Rotylenchus* sp., *Tylenchorhynchus maximus* and *Xiphinema americana* (Golden, p.c. 1984).

Acacia species

Mimosaceae or Leguminosae (Fabaceae), subfamily Mimosoideae

Acacia, Catclaw acacia, Egyptian thorn, Mimosa, Prairie acacia, Wattle

The genus *Acacia* includes about 800 species, which are mostly tropical shrubs and trees. The genus is very similar to the genus *Mimosa*, with many species having been reassigned from one genus to the other, creating synonomous epithets.

NewCROP has Acacia information at:

Acacia in Australia: Ethnobotany and Potential Food Crop. Lister, P.R., P. Holford, T. Haigh, and D.A. Morrison. 1996. p. 228-236. In: J. Janick (ed.), Progress in New Crops. ASHS Press, Alexandria, VA.

Acacia albida Del.

Mimosaceae
Apple-Ring Acacia, Ana Tree, Winter Thorn

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Acacia albida is a widely used tree well documented for increasing the yields of crops grown under it. According to VITA (1977) "*A. albida* is highly valued in conservation efforts. It is the only species which loses its leaves during the rainy season; therefore, farming under these trees is not only possible but profitable." It is held sacred by the Africans of the Transvaal. In Nigeria, the pod is used as camel food. The gum that exudes spontaneously from the trunk is sometimes collected like gum arabic. The timber, though straight grained, close, and weighty, is soft, fibrous, and unsuitable for agricultural implements (Watt & Breyer-Brandwijk, 1962). One writer even questions its value for fuel wood. Masai use it as the soft flat wood upon which the firestick is twirled to make fire. Wood is used for canoes, mortars, and pestles. The bark is pounded in Nigeria and used as a packing material on pack animals. Ashes of the wood are used in making soap and as a depilatory and tanning agent for hides. VITA (1977) says the wood is used for carving; the thorny branches useful for a natural barbed fence. Pods and foliage are highly regarded as livestock fodder. Some 90% of Senegalese farmers interviewed by Felker (1981) collected, stored, and rationed *Acacia alba* pods to livestock. Rhodesians use the pods to stupefy fish. Humans eat the boiled seeds in times of scarcity in Rhodesia. Apparently it is erroneously taken as an indicator of a shallow well site.

Folk Medicine

Reported to serve as an emetic in fevers (Masai), taken for diarrhea in Tanganyika. Also used for colds, diarrhea, hemorrhage, and ophthalmia in West Africa. The bark of the Ana tree is a folk remedy for diarrhea among several tribes. On the Ivory Coast it is used for leprosy. The bark decoction curtails nausea. A liniment, made by steeping the bark, is used for bathing and massage in pneumonia. The bark infusion is used for difficult delivery, and is used as a febrifuge for cough (Irvine, 1961). Pods worn as charm by African women and children to avert smallpox.

Chemistry

The following table is reproduced, with permission from FAO's Tropical Feeds (1981):

Nutritive Table (Gohl, 1981)

		As % of dry matter						
	DM	CP	CF	Ash	EE	NFE	Ca	P

Bark contains 2–28% tannin, the fruit 5–13%.

Description

A large thorny tree up to 20 m high and >2 m in diameter; bole forming up to 1/3 of height of tree; bark dull grey, fissured when old, crown dense; tree puts out leaves during dry season and sheds them during rains; branchlets light grey, spiny only at nodes, spines straight, up to 1 in. long; leaves pale and glaucous, bluish grey, glabrous or pubescent, 2-pinnate, 9 to numerous pairs of pinnae, cup-like glands on rachis, each pinna with 12 or more pairs of leaflets, leaflets oblong, up to 1 cm long, hairy, unequal at base; flowers (Jan., Apr., Nov.) in yellow spikes 10–12.5 cm long; fruits (Jan., May, Nov.) bright yellowish green when dry, up to 12–15 x 4 cm, slightly curved, ends rounded (Irvine, 1961).

Germplasm

Reported from the African Center of Diversity, the Ana Tree, or cvs thereof, is reported to tolerate poor soil, drought, savanna, and some waterlogging (VITA, 1977). Back in 1978, when Senegalese farmers wanted seedlings, none were available. There is great variability in the morphology and pod yields. Selection of wild plants for pod yield and/or fast growth would be a worthwhile contribution to arid developing countries. ($2n = 26$)

Distribution

Native to the Transvaal and Southwest Africa, through West and North Africa to Egypt, East Africa.

Ecology

Probably ranging from Tropical Thorn to Subtropical Moist Forest Life Zones, the Ana Tree is reported to tolerate annual precipitation of 3 to 6dm. Irvine (1961) describes it as the largest thorn tree in Savanna Forest, especially in inhabited areas; often left untouched, sometimes gregarious. In more mesic Sahelian regions (400–600 mm/yr), yields of millet, peanuts, and sorghum are increased from ca 500 to ca 900 kg/ha/yr by growing under the canopy of *Acacia albida* (Felker, 1978). Does best in sandy soils, growing well where millet grows. Though faring best on sandy soils, it will tolerate heavier soils with some waterlogging.

Cultivation

As late as 1978, techniques for establishing new seedlings had not been worked out, according to Felker (1978). Seeds devoid of bruchid holes should be scarified and started in deep containers to accomodate development of the tap root. Good-sized plants develop in 10–14 weeks, but frequent root pruning is advised. Transplants from the wild are usually unsuccessful because of the long tap root. VITA (1977) has a novel approach, feeding the seed to livestock, which then graze the desired areas, eliminating seeds with their manure. Nursery plantings, spaced at 10 x 10 m may require watering at first, and protection from grazing animals for 5–8 years.

Harvesting

Peasants gather pods to feed to their cattle, or lop the foliage in the dry season, when most other trees are leafless.

Yields and Economics

According to FAO (1980) a full grown tree can produce more than 100 kg pod/yr. Felker (1978) notes that pod yields range from 6–135 kg/tree. Some scientists believe that yields could be managed to a much higher level than those of the grasses and annual crops grown under the tree. Trees have reached 2 to 4 m after only 3 or 4 years growth.

Energy

Related species such as *Acacia tortilis* have been reported to yield giraffe forage to the tune of 5 MT/ha/yr. Yield increases under *Acacia albida* correlate with a several fold increase in soil N and organic matter, coupled with improved soil water-holding capacity. *Acacia albida* has been shown to nodulate and reduce acetylene. While Acacias cannot be recommended for cold and/or humid or everwet climates, they are suggested by the NAS (1980a) as firewood sources in developing countries. Among the species they consider are *Acacia arabica, auriculiformis, brachystachya, cambagei, cyanophylla, cyclops, dealbata, decurrens, ehrenbergiana, fistula, heteracantha, holosericea, lysiophloia, mangium, mearnsii, mollissima, nilotica, nubica, raddiana, saligna, senegal, seyal, spirocarpa, tortilis*, and *verek*. The Ana Tree was not recommended for firewood.

Biotic Factors

Caterpillars, locusts, and grazing animals may destroy the seedlings.

Acacia auriculiformis A. Cunn.

Mimosaceae
Darwin Black Wattle

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Used for fuelwood plantations as an ornamental and shade tree, quite tolerant of heat, the Australian species is widely planted in Oceana and southeast Asia. The wood is also employed for making farm tools and furniture (NAS, 1983a). Recent Australian tests suggest that 10-year old trees can be pulped readily by the sulfate process, giving high pulp yields, with good strength properties. Also produces high quality pulp by the neutral sulfite semichemical process. The tannin produces a good quality leather, inclined to redden upon exposure to sunlight (NAS, 1980a). The plant is amazing in its ability to recolonize wastes, papermill sludge, pH ca 9.5; even uranium spoils, pH ca 3.0; the only tree found on 20-year old uranium spoil. Used for the cultivation of the lac insect in India.

Folk Medicine

No data available.

Chemistry

The gum contains 5.3% ash, 0.92% N, and 1.68% methoxyl, and ca 27.7% uronic acid. The sugar from the gum after hydrolysis, contained 10.1% 4-0-methylglucuronic acid, 17.6% glucuronic acid, 59% galactose, 8% arabinose, and 5% rhamnose (Anderson, 1978). Bark contains ca 13% water.

Description

Resilient, vigorously growing, crooked or gnarled deciduous or evergreen tree, possibly attaining 30 m height, 60 cm DBH. Leaves alternate, simple flattened phyllodes, lanceolate or oblong, arcuate, long-attenuate at both ends, 10–16 cm long, ca 1.5–2.5 cm broad, thick coriaceous, glabrous with several long parallel veins from the base. Spikes 5–8 cm long, paired at the leaf bases. Flowers sessile, ca 3 mm long, the calyx glabrous, 5-toothed, the 5 petals ca 2 mm long. Stamens numerous, filiform, ca 3 mm long. Ovary pubescent, the style filiform. Pods 6–8 cm long, 1–1.5 cm broad, flattened but coiled. Seeds several, flattened-ellipsoid, ca 5 mm long, with a reddish or orangish aril (Little, 1983). Seeds 53,000–62,000/kg.

Germplasm

Reported from the Australian Center of Diversity, *Acacia auriculiformis*, or cvs thereof, is reported to tolerate alkalinity, desiccation, drought, fire, high pH, laterite, poor soil, sand dunes, and savanna. It is intolerant of hurricane, shade, and weeds, at least in early stages. Once established, the tree is quite competitive with weeds. Though somewhat tolerant of fire, it is not so resistant as Eucalyptus. ($2n$ = 26)

Distribution

Native to the savannas of New Guinea, islands of the Torres Strait, and northern Australia, it has been widely introduced, e.g. in Fiji, India, Indonesia, Java, Malaysia, Niger, Nigeria, Philippines, Tanzania, Thailand, the Soloman Islands, Uganda, and Zanzibar.

Ecology

Estimated to range from Subtropical Moist to Wet through Tropical Dry to Wet Forest Life Zones, *Acacia auriculiformis* is reported to tolerate annual precipitation of 7.5 to 27 dm, annual temperature of 26 to 30°C, and pH of 3.0 to 9.5. With practically no maintenance it will grow on a wide range of deep and shallow soils, compacted clays, coral soils, laterites, limestone, mica schist, mine spoil, podzols, even sand dunes and unstable slopes.

Cultivation

It has been suggested as an interplant with long-term timber Dalbergias, itself serving as a short-term but renewable firewood source. Seeds, storable for 18 months in airtight containers, should be soaked in hot water for 24 hours. Sow in full light, allowing 6 days for germination (ca 80% germination after 2–4 weeks). To reforest grassland, burn and plant in holes ca 36 x 30 x 30 cm, spaced at 1–2.5 or 1–3 m if intercropped with *Cassia siamea*. Recent spacings have been 2.5 x 2.5 m.

Harvesting

In Indomalaysia, stands are operated on 10–12 year rotations. Trees coppice poorly. Indonesians have gotten some coppice when trees are cut at least 50 cm above the ground. When trees are felled, there is usually a swarm of seedlings, so cutover stands regenerate readily.

Yields and Economics

With rainfall at 2700 mm, at 3 years, average height of a stand with 1010 trees/ha was 12.4 m, average diameter 12.2 cm, standing wood volume 73.2 m^3/ha; at age 4, 13.1 m, 13.6 cm, and 96.1 m^3/ha. Stemwood volume is ca 60% of total above ground biomass. Leaf biomass is important, the LAI being 7–8, good for shading out weeds. Average amount of dead litter is 4800 kg/ha. In Java, there may be 3 MT/ha leaves and 2 MT/ha twigs and branches beneath the trees (NAS, 1982a). On infertile abandoned sites in Papua, trees grew 6 m in 2 years, 17 m in 8 years. On shallow arid soils in West Bengal, yields were only 5m^3/ha/yr at the 15th year. Under moister conditions 10 m^3 is reported, 17–20 in Indonesia and Malaysia.

Energy

Wiersum and Ramlan report that yields can run higher than 20 m^3/ha/yr on a 10–20 year rotation. On poor soils yields drop to 8–12 m^3. On the Island of Madura, with annual rainfall 1700–1900 mm, 7–12 year old rotations run 7.6–9 m^3/ha/yr, but on West Bengalese laterites with annual precipitation 1,000–14,000 mm, yields are only 2–6 m^3/ha/yr in 10–20 year rotations. With its capacity to produce good fuelwood on poor soils, even where there are extended dry seasons, the species "merits large scale testing as a fuelwood species" (NAS, 1980). Wood has specific gravity of 0.6–0.75 and calorific value of 4,800–4,900 kcal/kg. Wood yields excellent charcoal that glows well and burns without smoke or sparks. Litter beneath the trees, both branches and dried leaves, annually adds up to 4.5–6 MT/ha, all used for fuel in China. Hawaiian grown material possesses N-fixing nodules.

Biotic Factors

While no pest or disease problems are reported in Indonesia, insects and nematodes have been reported to attack seedlings in Zanzibar. The rust *Uromyces digitatus* has been a problem in Java, where it is also occasionally infested with a rather inocuous black mildew, *Meliola adenanphererae*. In India, the root rots are *Ganoderma lucidum* and *Ganoderma applanatum*. *Hypothenemus dimorphus* has caused shoot fatality in Malaysia. The weevil *Hypomeces squamosus* can be a pest in India and Malaysia. Used to cultivate *Kerria lacca* in India. On Java, the ant *Iridomyrmex rufoniger* may protect the plant from some phytophagous insects.

Acacia cyclops A. Cunn. ex G. Don

Mimosaceae
Rooikrans

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Producing a dense high quality firewood, this species has been recommended for stabilization of coastal dunes. Goats and antelope browse the phyllodes. The seeds and their oily funicles are eaten by birds, primates, and rodents, and if crushed, might be suitable for cattle.

Folk Medicine

With its high tannin content, the species could serve as an astringent.

Chemistry

Bark has yielded 6.5% tannin, or in Natal, up to 12.1%. Seed contains 10% of fixed oil, the aril or funicle 40%.

Description

Dense, evergreen bushy shrub, often multistemmed, or small tree 3 to 8 m tall, with a rounded crown . In windy coastal sites it forms a hedge less than 0.5 m high. The foliage comprises light green phyllodes, varnished when young, and growing in a downward vertical position. Pods, maturing in summer, are not shed, but remain on the tree, exposing the seeds to predators and dispersers.

Germplasm

Reported from the Australian Center of Diversity, *Acacia cyclops* is reported to tolerate drought, salt, sand, weed, and wind.

Distribution

Native to southwestern Australia, where it grows mostly on coastal sand dunes. Used for stabilization in South Africa, it is spreading on sand and sandstone into coastal bush and heathland. This is an extremely weedy species spread by birds into indigenous vegetation. Once established, it is difficult to remove or replace. There is little vegetation cover beneath an *Acacia cyclops* thicket. The seeds remain viable in the soil for many years. It is relatively slow growing.

Ecology

Acacia cyclops can grow in dry areas with annual precipitation less than 300 mm. Tolerating salt spray, wind, sand-blast, or salinity, it is useful for dune stabilization. This species has a high light demand; it will not survive in deep shade. Monthly temperature means within the distribution range of this species vary from 5°C in winter to 31°C in summer. It is slightly resistant to frost. The species is generally found below 300 m altitude where annual rainfall is 200 to 800 mm. It grows on quartzitic or calcareous sand or limestone. It also is found in drier sites such as dune crests (NAS, 1980a).

Cultivation

Direct sowing of pretreated seed is recommended (NAS, 1980a). Seed are treated with abrasion, acid, and hot water treatment.

Harvesting

Trees may be harvested as needed. This species rarely coppices, and mature trees do not survive felling. The pods are nondeciduous and are therefore not easily gathered. Unlike many *Acacia* species, it is not considered a valuable tannin or gum producer (NAS, 1980a).

Yields and Economics

Standing biomass of *Acacia cyclops* in the southwestern cape of Africa, where it is replacing indigenous Fynbos vegetation and coastal shrub communities, was 131 MT/ha. Of this, the litterfall was said to represent 7.4% of the total biomass, 21.2% of the canopy mass.

Energy

Recommended by the NAS (1980a) as a firewood source. The wood is dense, the logs rarely exceeding 20 cm in diameter. It is a very popular firewood in South Africa, sold regularly in Cape Town. The annual litterfall of four Acacia species naturalized in the South African Cape, comprising 60% foliage and 30% reproductive structures, averages 7 MT/ha, double the value expected in evergreen scrub communities in winter rainfall regions. Standing biomass in the *Acacia* thickets is ca 10 times greater than that of mature Fynbos (11–26 MT/ha) and shrublands in other Mediterranean climates (15–30 MT/ha). *Acacias* lose ca 10% of their standing crop annually as litter, at a rate 3–4 times that of the Mediterranean heath and shrub communities. The litter accumulates on the ground. In a mature thicket, the dry mass of the ground litter per unit area exceeds that of the living canopy. The ground litter layer runs 14–28 MT/ha, which is fairly average by world standards. "The annual nitrogen and phosphorus input by Acacia litter should be about nine times as great per unit area as that of Fynbos." Assuming an N content of 1.5% and a P content of 1.13%, *Acacia* litter would contribute 105 kg N/ha and 92 kg P. In an area where the annual precipitation averages between 500 and 750 mm/yr and the annual temperature average ranges between 16 and 18°C, with radiation averaging 450–500 Langleys/day (Capetown has an average annual precipitation of ca 600 mm, average temperature approaching 18°C), the total annual litterfall is 9,680 kg/ha, with 1.4% as flowers, 35.5% as pods, 5.3% as seed, 11.3% as twigs, 39.0% as phyllodes, and 7.7% unidentified fragments. The total standing biomass was 131 MT/ha DM, ˜±4% (Milton, 1981).

Biotic Factors

Most African Acacias are thought to be cross pollinated. Pests and diseases are not an important factor in South Africa; in fact, the lack of seed destroyers is partly responsible for the weediness of the species. Grazers may damage seedlings.

Acacia mearnsii de Wild.

Syn.: *Acacia mollissima* auct., not Willd.
Acacia decurrens var. *mollis* Lindl.
Mimosaceae
Black Wattle, Acacia Negra, Acacia Noir, Schwarze Akazie, Gomboom

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Tree of economic importance in South and East Africa, Rhodesia, India, and Rio Grande do Sul area of South America etc. for tanning of soft-leather. Ranging from 30–54 percent tannin in dried bark. Wood furnishes badly needed fuel and building material in some areas. Trees not only provide tannin and fuel, but also add nitrogen and organic material to improve the soil. Bark is used for wood adhesives and flotation agents (Duke, 1981a). The pulp is suitable for wrapping paper and hardboard. Some regard it as an attractive ornamental. Sometimes used for erosion control on poor sloping soils unsuitable for agriculture. Densely packed plantations are effective in preventing further erosion on 50° slopes. Some farmers claim that tobacco and vegetable yields are doubled in rotating with the black wattle. In places it is regarded as a "green cancer", spreading vigorously as a weed (NAS, 1980; Little, 1983).

Folk Medicine

Products are often used in folk medicine as styptics or astringents (Duke, 1981).

Chemistry

Black wattle bark contains (-)-robinetinidol and (+)-catechin; the biflavonoids (-)-fisetinidol-(+)-catechin (2 diastereoisomers), (-)-robinetinidol-(+)-catechin and (-)-robinetinidol-(+)-gallocatechin; triflavonoids and condensed tannins. The heartwood is rich in (+)-leucofisetinidin (mollisacacidin) together with (-)-fisetinidol, (+)-fustin, butin, fisetin, butein, and biflavonoid condensates (tannins) (Duke, 1981).

Description

Tree 6 to 20 m tall, 10 to 60 cm in diameter; crown conical or rounded; all parts except flowers usually pubescent or puberulous; stems without spines or prickles; leaves bipinnate, on petioles 1.5–2.5 cm long, with a gland above; rachis 4–12 cm long with numerous raised glands all along its upper side; pinnae in 8–30 pairs, pinnules in 16–70 pairs, linear-oblong, 1.5–4 mm long, 0.5–0.75 min wide; flowers in globose heads 5–8 mm in diameter, borne in panicles or racemes, on peduncles 2–6 mm long; pale yellow and fragrant; pods gray-puberulous, or sometimes glabrous, almost moniliform, dehiscing, usually 3–10 cm long, 0.5–0.8 cm wide, with 3–14 joints; seeds black, smooth, elliptic or compressed ovoid, 3–5 mm long, 2–3.5 mm wide; caruncle conspicuous; areole 3.5 mm long, 2 mm wide. Seeds 66,000 to 110,000/kg (Duke, 1981a).

Germplasm

Can be crossed with *Acacia decurrens*, hybrids show more sterility than parents. Meiosis is regular, with no gross cytological abnormalities, and sterility may be due to gene differentiation between species. There is little geographic overlap in the native Australian ranges of the species, and there are differences in phenology (flowering; seedset). Most of the characters that vary among the species are quantitative. The development of black wattle strains or of hybrids with enhanced vigor, better quality bark, outstanding stem form, or resistance to insect pests and disease would benefit the wattle industry. Assigned to the Australian Center of Diversity, black wattle or cvs thereof is reported to exhibit tolerance to drought, laterite, and poor soil (Duke, 1981). For an Acacia, it is relatively tolerant to frost, and its growth is slowed by high temperatures. ($2n = 26$.)

Distribution

Native to Southeast Australia (Victoria to New South Wales and southern Queensland) and Tasmania. Introduced and cultivated widely for afforestations. See Sherry (1971) for details.

Ecology

In Kenya grows on or near Equator at altitudes of 2,000–2,800 m, is well adjusted to the climate of East Africa. Grows well at 30°S Lat. in South America on rolling terrain at altitudes of 50–70 m. Thrives on poor, dry soils but favors deeper, moister, more fertile soils. In Australia, black wattle may occur on soils derived from shales, mudstones, sandstones, conglomerates, and alluvial deposits. In Kenya on podsols, krasnozems, sandy hills, lava flows or on mixtures of lava and contemporaneous volcanic tuffs and breccias. In South America, grown on red clay or sandy soils that have suffered from severe erosion and soil depletion (ferruginous clay loams with little or no free silica). In East Africa grows where annual rainfall is 1,041–1,321 mm, (about 75% between April and September). On the equator where black wattle is grown in South America, the rain pattern is nearly opposite, mean annual temperature range is 17–23°C; there is little seasonal variation, but considerable diurnal variation. At higher altitudes in South America, frost is a risk and heavy snows may break tree limbs. Tannin content varies inversely with precipitaton. Ranging from Warm Temperate Dry through Tropical Thorn to Tropical Moist Forest Life Zones, black wattle is reported to tolerate annual precipitation of 6.6–22.8 dm (mean of 6 cases=12.6), annual mean temperature of 14.7–27.8°C (mean of 6 cases=2.6°C), and pH of 5.0–7.2 (mean of 5 cases = 0.5).

Cultivation

Propagation by seed is easy. Seeds retain their viability for several years. For germination seed are covered with boiling water and allowed to stand until cool. This cracks the hard outer coat and facilitates germination. Seeds may be broadcast or sown in rows on any barren site. Usually they are sown about 5 cm apart in seedbeds, and are transplanted after 3–6 months. In South America, fields are usually plowed and harrowed in April or May. Seedlings are set out May–November, but usually in winter, June–August, after a rain. Plants are spaced 2 m each way, at rate of 2,500/ha. Propagation by cuttings is almost impossible without mist. Air layering is more promising. Two types of farmers grow acacia: the tanner or business man plants 200 ha or so entirely to black wattle, usually one section at a time so that he can plant and harvest within the same year and continue year after year; the farmer plants half or less of his land to black wattle and the rest to crops such as corn, beans, maniac, sugarcane, other vegetables, or pasture. He plants 2–6 hectares of acacian each year and thus evenly distributes work and production. Oxen may be useful for plowing, but most work is by hand. Usually only plows and hoes are used in Cultivation. Intercrops may be grown the first year during which trees grow about 4–5 m in height, and about 2.5 cm in diameter (Duke, 1981).

Harvesting

Trees provide bark 5–10 years after seeding (avg 7). Bark is stripped from lower part of tree, then tree is felled, the remaining bark removed, and tree and bark are cut into 1 m lengths. Thoroughly dried bark is arranged in bales of 75 to 80 kg when ready for transportation. Tanning power improves by 10–15% in bark carefully stored for a season. Percent tannin does not differ between barks harvested in dry and wet seasons. However, the amount of bark on trees may be less on poor than on rich soils. Tannin runs about 25–35% per kilo of dried bark, on either poor or rich soil. Acacia bark may be sold as baled bark, or bark powder. Dried bark may go first to commercial bark processors where it is ground or shredded in a hammermill, then sold in 40-kg sacks. Bark powder is sold in 60-kg sacks. Liquid extract is sold in 300-kg wooden barrels. In Rio Grande do Sul an estimated 5,000 MT of liquid extract is produced annually (Duke, 1981a).

Yields and Economics

Except for some mangrove species, black wattle in pure stand produces more tannin per hectare than most tanniniferous plants. In South Africa well-managed have produced the equivalent of 3 MT/ha tannin, about twice the average, when grown in rotations in excess of 12 years. One 7-yr-old tree produces 3–5 kg of dried bark. Twelve trees produce 1 cu m of firewood. The wood of debarked trees is dried and used for mine timbers, pulpwood, and fuel. Moisture loss is rapid in first 4 weeks after felling, then much slower. Wood weighs 708.7 kg/cu m. One tree can produce up to 10 cwt of bark or about 5 cwt stripped. One ton of black wattle bark is sufficient to tan 2,530 hides, best adapted for sole leather and other heavy goods; the leather is fully as durable as that tanned with oak bark. One ton of bark yields 4 cwt of extract tar. Destructive distillation of the wood yields 33.2% charcoal, 9.5% lime acetate, and 0.81 methyl alcohol. As a source of vegetable tannin, black wattle shares with quebracho and chestnut a large portion of the world market for vegetable tannins. According to Sherry (1971), plantation grown wattle in South Africa, Rhodesia, Tanzania, Kenya, and Brazil supplied about 38% of world demand for tannin. South Africa was the largest producer, with annual output of 72,000 MT of ca 120,000 MT on the world market. *Eucalyptus grandis* produces more wood than wattle, but it is inferior for fuel and charcoal. At one time in South Africa, 56% of the proceeds from wattle was from bark, the balance from timber (Duke, 1981a).

Energy

An efficient N-fixer, it is reported to annually yield 21–28 MT/ha wet leaves containing 245–285 kg N. If we put the information in our cultivation paragraph and our yields paragraph, we find the improbable 2,500 plants per hectare, with 12 producing 1 m^3 firewood, suggesting a potential of more than 200 m^3/ha for 7 year old trees, suggesting annual yields of ca 30 m^3/ha. NAS (1980a) reports annual thickwood production of 10–25 m°3/ha and bark production of 0.8–4.0 MT. The dense wood (sp. grav. = 0.7–0.85) 3,500–4,000 kcal/kg (oven-dry Indonesian specimens 4,650 kcal/kg), its ash content ca 1.5%. The charcoal (sp. grav. = 0.3–0.5) has a calorific value of 6,600 kcal/kg, with an ash content of 0.4%.

Biotic Factors

The most serious disease is disback, caused by *Phoma herbarum*. Other fungi attacking black wattle include: *Chaetomium cochliodes*, *Daldinia* sp., and *Trichoderma viride*. In Rio Grande do Sul, disease and insects cause about 20% loss of trees. Principal insects attacking Brazilian wattle are *Molippa sabina, Achryson surinamum, Placosternus cyclene, Eburodacrys dubitata, Neoclytus* *pusillus, Oncideres impluviata, Oncideres saga,* and *Trachyderes thoracica.* Ants, termites, and borers are the most damaging. The sauva ant which attacks the leaves is fought constantly with arsenicals and carbon disulfide. Nematodes reported on this species include *Meloidogyne arenaria, M. incognita acrita,* and *M. javanica* (Golden, pers. commun. 1984).

Acacia farnesiana (L.) Willd.

Syn.: *Mimosa farnesiana* L.
Mimosaceae
Cassie, Huisache

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Cassie perfume is distilled from the flowers. Cassie absolute is employed in preparation of violet bouquets, extensively used in European perfumery. Cassie pomades are manufactured In Uttar Pradesh and the Punjab. Pods contain 23 percent tannin, a glucoside of ellagic acid, and are used for tanning leather. Bark also used for tanning and dying leather in combination with iron ores and salts. In Bengal and West Indies, pods are used for a black leather dye. Gummy substance obtained from pods used in Java as cement for broken crockery. Gum exuding from trunk considered superior to gum arabic in arts. Trees used as ingredient in Ivory Coast for arrow poison; elsewhere they are used as fences and to check erosion. Wood is hard and durable underground, used for wooden plows and for pegs. Trees often planted as an ornamental (Duke, 1981). Morton (1981) says that the seeds, containing an unnamed alkaloid, are used to kill rabid dogs in Brazil.

Folk Medicine

Bark is astringent and demulcent, and along with leaves and roots is used for medicinal purposes. Woody branches used in India as tooth brushes. The gummy roots also chewed for sore throat. Said to be used for alterative, antispasmodic, aphrodisiac, astringent, demulcent, diarrhea, febrifuge, rheumatism, and stimulant (Duke, 1981a). Morton (1981) notes that Guatemalans value the flower infusion as a stomachic. It is also used for dyspepsia and neuroses. Mexicans sprinkle powdered dried leaves onto wounds. The flowers are added to ointment, rubbed on the forehead for headache. Green pods are decocted for dysentery and inflammations of the skin and raucous membranes. Colombians bathe in the bark decoction for typhoid. Costa Ricans decoct rhe gum from the trunk for diarrhea, using the pod infusion for diarrhea, leucorrhea, and uterorrhagia. Panamanians and Cubans used the pod to treat conjunctivitis. Cubans use the pod decoction for sore throat. For rheumatic pains, West Indians bind bark strips to the afflicted joint. The root decoction has been suggested as a folk remedy for tubersulosis. According to Hartwell (1967–1971), the decoction of the root, used in hot baths, is said to help stomach cancer. A plaster, made from the pulp, is said to alleviate tumors.

Chemistry

Dried seeds of one *Acacia* sp. are reported to contain per 100 g: 377 calories, 7.0% moisture, 12.6 g protein, 4.6 g fat, 72.4 g carbohydrate, 9.5 g flber, and 3.4 g ash. Raw leaves of *Acacia* contain per 100 g: 57 calories, 81.4% moisture, 8.0 g protein, 0.6 g fat, 9.0 g carbohydrate, 5.7 g fiber, 1.0 g ash, 93 mg Ca, 84 mg P, 3.7 mg Fe, 12,255 μg β-carotene equivalent, 0.20 mg thiamine, 0.17 mg riboflavin, 8.5 mg niacin, and 49 mg ascorbic acid. Reporting 55% protein on a dryweight basis, Van Etten et al (1963) break down the amino acids as follows: lysine, 4.7 (g/16 g N); methionine, 0.9; arginine, 9.2; glycine, 3.4;. histidine, 2.3; isoleucine, 3.5; leucine, 7.5; phenylalanine, 3.5; tyrosine, 2.8; threonine, 2.5; valine, 3.9; alanine, 4.3; aspartic acid, 8.8; glutamic acid, 12.6; hydroxyproline, 0.0; proline, 5.1; serine, 4.1; with 76% of the total nitrogen as amino acids. Cassie has been reported to contain anisaldehyde, benzoic acid, benzyl alcohol, butyric acid, coumarin, cresol, cuminaidehyde, decyl aldehyde, eicosane, eugenol, farnesol, geraniol, hydroxyacetophenone, methyleugenol, methyl salicylate, nerolidol, palmitic acid, salicylic acid, and terpineol (Duke, 1981). The leaves contain lipids, carotenoids, alkaloids, and reducing and non-reducing sugars (Morton, 1981). El Sissi et al (1973) isolated and identified from pods, seven polyphenols (gallic acid, ellagic acid, m-digallic acid, methyl gallate, kaempferol, atomadendrin, and narigenin). Also they found narigenin-7-glucoside and naringenin-7-rhamnoglucoside (naringin), as well as naringenin, glucose, and gallic acid.

Description

Thorny bush or small tree, 8 m tall; bark light brown, rough; branches glabrous or nearly, purplish to gray, with very small glands; stipules spinescent, usually short, up to 1.8 cm long, rarely longer, never inflated; leaves twice pinnate, with a small gland on petiole and sometimes one on the rachis near top of pinnae; pinnae 2–8 pairs, leaflets 10–12 pairs, minute, 2–7 mm long, 0.75–1.75 mm wide, glabrous, leathery; flowers in axillary pedunculate heads, calyx and corolla glabrous, scented; pod indehiscent, straight or curved, 4–7.5 cm long, about 1.5 cm wide, subterete and turgid, dark brown to blackish, glabrous, finely longitudinally striate, pointed at both ends; seeds chestnut-brown, in 2 rows, embedded in a dry spongy tissue, 7–8 mm long, ca 5.5 mm broad, smooth, elliptic, thick, only slightly compressed; areole 6.5–7 mm long, 4 mm wide (Duke, 1981a).

Germplasm

Both *A. farnesiana* and its var *cavenia* are extensively cultivated in and around Cannes, southern France, which is the center for production of the perfume. The variety seems to be more resistant to drought and frost. Assigned to the South American Center of Diversity, cassie or cvs thereof is reported to exhibit tolerance to drought, high pH, heat, low pH, salt, sand, slope, and Savanna. ($2n = 52, 104$). (Duke, 1981a).

Distribution

Probably native to tropical America, but naturalized and cultivated all over the world, e.g. Africa (Rhodesia, Mozambique) and Australia. Planted in coastal areas of Ghana and elsewhere in tropical Africa. Grown throughout India, and often planted in gardens (Duke, 1981a).

Ecology

Thrives in dry localities and on loamy or sandy soils where it may serve as a sand binder. Will grow on loose sandy soil of river beds, on pure sand in plains of Punjab. Requires a dry tropical climate. Ranging from Warm Temperate Dry through Tropical Desert to Moist Forest Life Zones, cassie is reported to tolerate annual precipitation of 6.4–40.3 dm (mean of 20 cases 14.0 dm), annual mean temperature of 14.7–27.8°C (mean of 20 cases = 24.1°C), and pH of 5.0–8.0 (mean of 15 cases = 6.8) (Duke, 1981).

Cultivation

Propagated mainly from seed and cuttings. Seeds germinate readily and plants grow rapidly. Plants do not require much cultivation, watering or care (Duke, 1981a).

Harvesting

Trees begin to flower from the third year, mainly from November to March. Perfume is extracted from the flowers in form of concrete or pomade. Macerated flowers are placed in melted purified natural fat and allowed to stand for several hours. They are then replaced by fresh flowers and the process repeated until the fat is saturated with perfume. Fat is then melted, strained and cooled. This constitutes the pomade. Odor is that of violets but more intense. Absolute is prepared by mixing pomade with alcohol (2–3 kg to about 4 laters) and allowed to stand for 3–4 weeks at about

-5°C. The alcohol is then separated and distilled over. The extract obtained is an olive-green liquid with strong odor of cassie flowers (Duke, 1981a).

Yields and Economics

Mature trees yield up to 1 kg of flowers per season. Southern France (Cannes and Grasse) is main production center for cassie flower perfume. India and other Eastern countries produce much for local use (Duke, 1981a).

Energy

Though omitted by the recent fuelwood books (NAS, 1980; Little, 1983), this species should be considered along with other Acacias for its energy potential. Other species yield fuelwood at rates of 5–20 m^3/ha/yr, but lower yields may prevail in very humid environments. Of course the straggly bushy forms would not make very good fuel sources. Morton (1981) notes that the wood is used for fuel. Allen and Allen (1981) note that it fixes nitrogen.

Biotic Factors

Fungi reported on this plant include: *Camptomeris albizziae, Clitocybe tabescens, Hypocrea borneensis, Lenzites palisoti, L. repanda, Phyllachora acaciae, Phymatotrichum omnivorum, Polystictus flavus, Ravenelia austris, R. hieronymi, R. siliquae, R. spegazziniana, Schizophyllum commune, Systingophora hieronymi, Tryblidiella rufula*, and *Uromycladium notabile*. It may also be parasitized by the flowering plants *Dendrophthoe falcata* and *Santalum album* (Duke, 1981a).

Acacia tortilis (Forsk.) Hayne

Syn.: *Acacia raddiana* Savi,
Acacia spirocarpa Hochst. ex A. Rich
Acacia heteracantha Burch.
Mimosaceae
Umbrella Thorn, Israeli Babool

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Since this is one of the few timber species of the Arabian deserts, it is suspected as being the wood from which the Biblical Ark of the Tabernacle was made. Kaplan (1979) says rather emphatically it is the Shittim of the Bible, which provided the Israelites with the large-size timbers for the Ark. The timber is also used for fenceposts, firewood, furniture, and wagonwheels. The prolific pods made good fodder for desert grazers and the foliage is also palatable, being one of the major dry season fodder trees for the Sahara-Sahelian belt. Bark, used for string in Tanganyika. Gum used as a poor man's gum arabic, said to be edible. It is the tree most recommended for reclaiming dunes in India and Africa (Roy et al, 1973). The thorny branches are used to erect temporary cages and pens. Bark said to be a good source of tannin (Roy et al, 1973). Africans once strung the pods into necklaces. Senegalese use the roots for spear shafts, Lake Chad natives use the stems for fish spears. African nomads often use the flexible roots for frameworks of their temporary shelters.

Folk Medicine

While I find few data specific to this species, I suspect that the gum is used like that of gum arabics in folk remedies. In French Guinea, the bark is used as a vermifuge and dusted onto skin ailments (Dalziel, 1937).

Chemistry

Pods contain close to 19% protein (Palmer and Pitman, 1972). NAS (1979) reports unconfirmed allegations that the foliage can be toxic to livestock. Certainly HCN has been reported in several Acacias. The following tables are reproduced, with permission, from FAO's Tropical Feeds (1981):

Nutritive tables (Gohl, 1981)

		As % of dry matter

Acacia tortilis (Forsk.) Hayne subsp. *spirocarpa* (Hochst. ex A. Rich) Brenan

Description

Medium umbrella-shaped tree 4–15 m tall, often with several trunks, reduced to a small wiry shrub less than 1 m tall under extremely arid conditions. Two types of thorns abound (1) long, straight, and white, and (2) small, hooked, and brownish. Leaves up to 2.5 cm long with 4–10 pairs of pinnae, each with ca 15 pairs of minute leaflets. Flowers white, aromatic, in small clusters. Pods flat, glabrose, coiled into a spring-like array.

Germplasm

Reported from North African and Middle Eastern Centers of Diversity, Umbrella Thorn, or cvs thereof, is reported to tolerate alkalinity, drought, heat, sand, slope, and stony soils. It seems to be more frost tolerant than *Prosopis juliflora*, still plants less than 2 years old are easily damaged by frost. Four subspecies are known in different ecological zones: subspecies *tortilis*—Sahel, Middle East; subspecies *raddiana*—Sudan, Middle East, Sahel(2n=104); subspecies *spirocarpa*—Eastern Africa, Sudan; and subspecies *heteracantha*—Southern Africa (2*n*= 52). The different subspecies seem to have different ecological tolerances, which is important to consider when choosing a subspecies for plantations. (2*n*= 52, 104)

Distribution

Native to much of Africa and the Middle East, this species has been introduced in many arid parts of the world. Ironically, it grows faster in the Rajastan Desert of India, where used for charcoal, firewood, and fodder, than in its native Israel (Kaplan, 1979). In Malawi, this species is already scorned by the rural public because it is thorny and difficult to work with. It is being tried for fencings (Nkaonja, 1980).

Ecology

Deemed the most promising of 56 Acacia species tried at Jodhpur, India. Probably ranging from Subtropical Desert to Dry through Tropical Desert Scrub to Very Dry Forest Life Zones, umbrella tree is reported to tolerate annual precipitation of 1 to 10 dm, estimated annual temperature of 18 to 28°C, and pH of 6.5 to 8.5. This species tolerates hot, arid climates with temperatures as high as 50°C subspecies *raddiana* grows where minimum temperatures are close to 0°C. It is best adapted to the lowlands. It thrives where rainfall is up to 1,000 mm. However, it is also extremely drought resistant and can survive in climates with less than 100 mm annual rainfall with long, erratic dry seasons. The tree favors alkaline soils. It grows fairly well in shallow soil, less than 0.25 m deep, though it develops long lateral roots that can become a nuisance in nearby fields, paths, and roadways. In shallow soil, the plants remain shrubby and must be widely spaced to allow for their lateral root growth.

Cultivation

For good seed germination, seeds should be treated with concentrated sulphuric acid for 30 minutes (Roy et al, 1973). Artificial regeneration aiming at large-scale nursery production requires full use of the germination capacity of the available seeds. This may be achieved by sulfuric acid pretreatment, which brings about the germination of all viable seeds. Treatment with boiling water is selective and mainly breaks the dormancy of bruchid-infested seeds, some of which are no longer able to germinate. Sowing of unripe seeds without pretreatment may be called for as an emergency measure in case of very severe infestation, to achieve at least partial success. Prior to storage, seeds should be fumigated to arrest progressing deterioration of seed viability by bruchids (Karschon, 1975). NAS (1980a) recommends dipping the seed in hot water to soak overnight. Seedlings require initial weeding to facilitate faster growth. Plantations can be spaced at 3 x 3 m.

Harvesting

Firewood harvested as needed, but 10-year rotations are suggested. In Jodhupr, flower initiation is ca May-June in 3-year old trees, fruits forming in July but ripening from November through February. Since the tree coppices well, there is no need to replant after every harvest.

Yields and Economics

Eleven-year old trees in deep sandy soils at Jodhpur averaged 6.4 m tall and 14 cm DBH. In shallow sandy loams over hardpan at Pali, India, 7-year old trees (98% survival) averaged 4.8 m tall, and 10 cm DBH. In sanddunes at Barmer, India, 5-year old trees averaged 3 m tall, 7 cm DBH. An average tree yields 6 kg pods of which 2.6 kg is clean seed. One tree is said to yield 14–18 kg pods and leaves per year in India (Muthana and Arora, 1980). *Acacia tortilis* has been reported to yield giraffe forage at 5 MT/ha/yr.

Energy

A 12-year-old plantation in India yielded 54 MT fuel , suggest, annual returns of 4.5 MT, not a bad return for the desert (NAS, 1980a). The heartwood has calorific value of 4,400 kcals/kg, making superior firewood and charcoal. It is one of the main firewood and charcoal sources in parts of Africa, e.g. around Khartoum. Nitrogen-fixing nodules are reported in South Africa and Zimbabwe.

Biotic Factors

Bruchids often damage or destroy the seeds, on the tree or after collecting. Herbivores, tame and wild alike, are liable to graze seedlings and innovations. Trees attacked by beetles, mimosoid blights, and caterpillars. The wood is susceptible to termites. In Tanzania, elephants which eat the bark are wiping out some park populations. In Israel, the native Acacias host several species (>40) of mostly monophagous insects, whereas on one exotic, Australian *Acacia saligna*, only a few polyphagous species occur (Halperin, 1980). Only *Microcerotermes diversus* and *Kalotermes flavicollis*, which feed on woody parts of both Acacias and *Apate monachus* (a beetle which tunnels the stems and branches, causing them to collapse in windblow), may seriously damage the tree. In nature, regeneration and spread of Acacias are probably limited by bruchids destroying much of the seed crop. Seedlings from natural regeneration may come from damaged seeds with a still intact embryo axis, since seedcoat dormancy is removed by the effect of exit holes permitting rapid water absorption and germination. Intact seeds with hard impermeable seedcoats may require a long time to germinate, and probably function as a reserve to ensure the survival of the species (Karschon, 1975).

Acacia mangium Willd.

Mimosaceae

Mangium, Forest mangrove

We have information from several sources:

Handbook of Energy Crops—James A. Duke. 1983. unpublished.

New Crops: Solutions for Global Problems—Noel Vietmeyer

last update October 23, 1997

Acacia nilotica (L.) Del.

Syn.: *Mimosa nilotica* L.
Mimosaceae
"Motse", Egyptian Mimosa, or Thorn

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Some feel that the thorn bush of Exodus 3 was *Acacia nilotica*, the fire, the parasite *Loranthus acaciae*. Inner bark contains 18–23% tannin, used for tanning and dyeing leather black. Young pods produce a very pale tint in leather, notably goat hides (Kano leather). Pods were used by the ancient Egyptians. Young bark used as fiber, twigs esteemed for tooth brushes (chewsticks). Trees tapped for gum arabic. The gum arabic is still used in making candles, inks, matches, and paints (NAS, 1980). Tender pods and shoots used as vegetable, and used as forage for camels, sheep and goats, especially in Sudan, where it is said to improve milk from these animals. Seeds are a valuable cattle food. Roasted seed kernels, sometimes used for flavoring and when crushed provide the dye for black strings worn by Nankani women. Trees used in Sudan for afforestation of inundated areas. Sapwood is yellowish-white, heartwood reddish-brown, hard, heavy, durable, difficult to work, though taking a high polish. Because of its resins, it resists insects and water, and trees are harvested for the timber for boat-making, posts, buildings, water-pipes, well-planking, plows, cabinet-work, wheels, mallets and other implements. Wood yields excellent firewood and charcoal (Duke, 1981a). The aqueous extract of the fruit, rich in tannin (18–23%) has shown algicidal activity against *Chroccoccus*, *Closteruim*, *Coelastrum*, *Cosmarium*, *Cyclotella*, *Euglena*, *Microcystis*, *Oscillatoria*, *Pediastrum*, *Rivularia*, *Spirogyra*, and *Spirulina* (Ayoub, 1983).

Folk Medicine

Zulu take bark for cough, Chipi use root for tuberculosis. Masai are intoxicated by the bark and root decoction, said to impart courage, even aphrodisia, and the root is said to cure impotence. Astringent bark used for diarrhea, dysentery, and leprosy. Bruised leaves poulticed onto ulcers. According to Hartwell, the gum or bark is used for cancers and/or tumors (of ear, eye, or testicles) and indurations of liver and spleen, condylomas, and excess flesh. Said also to be used for cancer, colds, congestion, coughs, diarrhea, dysentery, fever, gallbladder, hemorrhage, hemorrhoids, leucorrhea, ophthalmia, sclerosis, smallpox, and tuberculosis. Bark, gum, leaves, and pods used medicinally in West Africa. Sap or bark, leaves, and young pods are strongly astringent due to tannin, and are chewed In Senegal as antiscorbutic; in Ethiopia as lactogogue. Bark decoction drunk for intestinal pains and diarrhea. Other preparations used for coughs, gargle, toothache, ophthalmia, and syphilitic ulcers. In Tonga, the root is used to treat tuberculosis. In Lebanon, the resin is mixed with orange-flower infusion for typhoid convalescence. Masai use the bark decoction as a nerve stimulant. In Italian Africa, the wood is used to treat smallpox. Egyptian Nubians believe that diabetics may eat unlimited carbohydrates as long as they also consume powdered pods (Duke, 1983a). Extracts are inhibitory to at least four species of pathogenic fungi (Umalkar et al, 1976).

Chemistry

Babul has been reported to contain l-arabinose, catechol, galactan, galactoaraban, galactose, N-acetyldjenkolic acid, N-acetyldjenkolic acid, sulphoxides pentosan, saponin, tannin. Seeds contain crude protein 18.6%, ether extract 4.4%, fiber 10.1%, nitrogen-free extract 61.2%, ash 5.7%, and silica 0.44%. Phosphorus 0.29% and calcium 0.90% of DM. When bullocks were given the seeds and bran (2:1) with dry pasture grass daily DM intakes were 1.82, 0.91, and 5.35 kg respectively. Total DM intake/100 kg bodyweight was 1.40 kg. The animals retained 20.8 g N and 7.4 g Ca daily but the P balance was slightly negative (Pande et al, 1981). Walker (1980) puts the CP content of the browse at 12.9%, the crude fiber at 15.2%

Description

Small tree, 2.5–14 m tall, quite variable in many aspects; bark of twigs not flaking off, gray to brown; branches spreading, with flat or rounded crown; bark thin, rough, fissured, deep red-brown; branchlets purple-brown, shortly or densely gray-pubescent, with lenticels; spines gray-pubescent, slightly recurved, up to 3 cm long; leaves often with 1–2 petiolar glands and other glands between all or only the uppermost pinnae; plnnae 2–11 (-17) pairs; leaflets 7–25 (-30) pairs, 1.5–7 mm long, 0.5–1.5 mm wide, glabrous or pubescent, apex obtuse; peduncles clustered at nodes of leafy and leafless branchlets; flowers bright yellow, in axillary heads 6–15 mm in diam.; involucel from near the base to about half-way up the peduncle, rarely somewhat higher; calyx 1–2 mm long, subglabrous to pubescent; corolla 2.5–3.5 mm long, glabrous or pubescent outside; pods especially variable, linear, indehiscent, 8–17 (-24) cm long, 1.3–2.2 cm broad, straight or curved, glabrous or gray-velvety, turgid, blackish, about 12-seeded; seeds deep blackish-brown, smooth, subcircular, compressed, areole 6–7 mm long, 4.5–5 mm wide. Fl. Oct.–Dec.; fr. Mar.–June (Duke, 1981a).

Germplasm

Acacia nilotica var. *kraussiana* (Benth.) Brenan is the most common form in east tropical Africa. Young branches more or less densely pubescent; pods not necklace-like, 1–1.8 cm wide, oblong, more or less pubescent all over at first with raised parts over seeds becoming glabrescent, shining and black when dry, margins shallowly crenate. Exhibits wide range of altitudinal and habitat requirements. Found in Botswana, Zambia, Rhodesia, Malawi, Tanzania, Angola, Mozambique, Transvaal, and Natal. *A. nilotica* var. *tomentosa* A. F. Hill *(A. arabica* var. *tomentosa* Benth.), has pods straight, constricted between seeds and densely tomentose; found in Senegal and northern Nigeria, to Sudan, Arabia and India. *A. nilotica* var. *adansonii* (Guill. et Perr.) Kuntze is a tree up to 17 m with dark reddish-brown bark deeply fissured, tomentose, reddish-brown twigs and gray fruits; commonest variety in West Africa, from Senegal to Nigeria and widespread in northern parts of Tropical Africa. Assigned to the African Center of Diversity, babul or cvs thereof is reported to exhibit tolerance to clay, drought, heat, heavy soil, high pH, poor soils, salt, savanna, and waterlogging. (2n=52.)

Distribution

Native from Egypt south to Mozambique and Natal; apparently introduced to Zanzibar, Pemba, and India; Arabia. Considered a serious weed in South Africa.

Ecology

Woodlands of various sorts, wooded grasslands, scrub and thickets. Thrives in dry areas, but endures floods. Grows 10–1,340 m altitude, in a wide range of conditions. Grows on a wide variety of soils, seemingly thriving on alluvial soils, black cotton soils, heavy clay soils, as well as even poorer soils (NAS, 1980). Ranging from Subtropical Desert to Subtropical Dry through Tropical Desert to Tropical Dry Forest Life Zones, babul is reported to tolerate annual precipitation of 3.8–22.8 dm (mean of 12 cases = 12.0 dm), annual mean temperature of 18.7–27.8°C (mean of 12 cases = 24.1°C), and pH of 5.0–8.0 (mean of 10 cases = 6.9) (Duke, 1981a).

Cultivation

Trees propagated in forest by seeds. Direct seeding is the common practice. Stored seed may require scarification. Young seedlings are said to "require full sun and frequent weeding" (NAS, 1980a).

Harvesting

Although there are other sources of gum arabic, trees are still tapped for the gum by removing a bit of bark 5–7.5 cm wide and bruising the surrounding bark with mallet or hammer. The resulting reddish gum, almost completely soluble and tasteless, is formed into balls. Though used in commerce to some extent, it is inferior to other forms of gum arabic, with which it is sometimes mixed.

Yields and Economics

Various products of the tree are used locally in tropical Africa, but none enter international markets. Trees usually add 2–3 cm in diameter each year (NAS, 1980a).

Energy

Extensively used, e.g. in India, for firewood and charcoal, this species has been used in locomotives and steamships as well as industry balers. It is cultivated for industrial fuel in the Sudan. The calorific value of the sapwood is 4,800 kcal/kg of the heartwood 4,950. The species does nodulate and fix nitrogen.

Biotic Factors

Wood borers may afflict the stems and bruchids may afflict the seeds. Following fungi have been reported on this plant: *Ctyospora acaciae*, *Diatryphe acaciae, Diplodia acaciae*, *Fomes badius*, *F. endotheius, F. fastuosus*, *F. rimosus, Fusicoccum indicum, Phyllactinia acaciae, Ravenelia acaciae-arabicae, Septogloeum acaciae, Septoria mortolensis*, *Sphaerostilbe acaciae*. Trees are also parasitized by *Dendrophthoe falcata* and *Loranthus globiferus* var. *verrucosus* (Duke, 1981). In a survey for phytophagous insects on *Acacia nilotica*, 43 species were recorded in Pakistan, of these, 16 appeared stenophagous. The more promising for biological control of the tree were: *Anarsia* sp. cf. *acaciae, Pseudosterrha paulula*, *Azanus ubaldus*, and *Ceutholopha isidis* feeding on flowers; *Bruchidius sahlbergi* and *Sulcobruchus* sp. damaging seeds; *Ascalenia callynella*, *Gisilia stereodoxa* and an unidentified gracillariid boring shoots; and *Cydia* sp. making stem galls (Mohyuddin, 1981).

Yields and Economics

Various products of the tree are used locally in tropical Africa, blit none enter international markets. Trees usually add 2–3 cm in diameter each year (NAS, 1980).

Rademacher, J.H. 1999. New arid land ornamentals: recent introductions for desert landscapes. p. 436–440. In: J. Janick (ed.), Perspectives on new crops and new uses. ASHS Press, Alexandria, VA.

New Arid Land Ornamentals: Recent Introductions for Desert Landscapes

Janet H. Rademacher

Over the past decade, water conservation has become an increasingly important issue across the southwestern United States. This concern has led local horticulturists and landscape architects to explore the use of water-thrifty ornamentals from dry climates throughout the world. The Chihuahuan and Sonoran deserts in particular have yielded a vast array of successful landscape plants. Universities, growers, and plant enthusiasts have all participated in the collection, propagation, evaluation, and promotion of new plant introductions. A group of recent proven introductions, including trees, shrubs, ground covers, and perennials are included below with information on their origins, growth habits, cultural requirements, and potential uses in the landscape.

Acacia redolens

Maslin, Desert Carpet™

Native to inland areas of Western Australia, *Acacia redolens* Maslin has been used extensively in southern California and Arizona to cover large areas inexpensively. Seedlings of *Acacia redolens* vary widely in their growth habits, often reaching heights in excess of 1.8 m (6 feet). The Desert Carpet™ clone was selected from the first Phoenix freeway plantings for its prostrate growth habit, and was released by Mountain States Wholesale Nursery in 1984. Since that time, this groundcover has performed consistently on many projects, and years after installation has maintained a height of only 0.6 m (24 inches). One plant can spread to a width of 3.6 m (12 feet), although we have observed that the cutting-grown Desert Carpet™ plants are slower to establish and reach their mature size than seedlings. The slower growth rate and prostrate nature of this clone should reduce maintenance costs, since pruning is not necessary to control vertical growth. Instead of true leaves, *Acacia redolens* has thick, leathery, gray-green phyllodes. This plant blooms in the spring with small yellow flowers. Freeway acacia will tolerate low temperatures of –11.1° to –9.4°C (12°–15°F), alkaline and slightly saline soils, and does not seem to be choosy about soil types. In coastal areas it requires little or no supplemental irrigation, but does require regular irrigation in hot desert regions. Desert Carpet™ seems to be disease and pest free.

Baccharis

hybrid 'Starn' (P.P.A.F.) Thompson™

When Dr. Tommy Thompson and Dr. Chi Won Lee of the University of Arizona released *Baccharis* hybrid 'Centennial', it filled a great void in our plant palette. Their research has been carried on, and now the improved Thompson™ clone is available. Since *Baccharis* 'Centennial' is a female plant, it has two undesirable characteristics. First, it produces pappus, or white "fluff," which litters the landscape and reduces the esthetic appearance of the plants for a short period of time. Also, since 'Centennial' is a female plant, it can be pollinated by nearby male *Baccharis sarothroides* Gray (Desert broom), and seedlings often result. This is why you sometimes see stands of 'Centennial' with taller *Baccharis* plants growing up through them. The Thompson™ clone is a male plant, eliminating these two negative characteristics. Also, Thompson™ was selected from the next generation after 'Centennial', and has 25% more *Baccharis sarothroides* for heat and disease resistance. The growth habits and uses of these two clones are essentially the same: both grow to about 0.9 m (3 feet) tall by 1.2–1.5 m (4-5) feet wide, are evergreen with bright green foliage and inconspicuous flowers, and provide a low-maintenance, long-lived alternative for difficult locations.

Cercidium

species 'Desert Museum'

This hybrid palo verde is a three-way cross between *Parkinsonia aculeata* L., *Cercidium microphyllum* (Torr.) Rose & I.M. Johnst., and *Cercidium floridum* Benth. ex Gray, and seems to combine the best qualities of all three plants. 'Desert Museum' grows very rapidly to 6.1 m (20 feet) tall and wide in 3 to 5 years, after which it needs little or no irrigation. It is completely thornless, and produces very little litter, with few seed pods. It has a sturdy, upright growth habit which requires very little pruning or staking. It blooms over a long period of time, with the heaviest bloom from about mid-March to May 1. It also tends to bloom again in June and August. The yellow flowers are larger than any of its three "parents." It does not reseed like the messy *Parkinsonia aculeata*!

Chilopsis linearis

(Cav.) Sweet, Lucretia Hamilton™

Desert willow trees occur along washes throughout the southwestern US and northern Mexico. This small deciduous tree has narrow, light green leaves that give it a weeping appearance. In the summer, the tree is covered with fragrant, trumpet-shaped flowers. In the wild, the flower colors range from white to purple, although a pale pink to lavender flower color is the most common. The Lucretia Hamilton™ clone was selected for its intense, deep pink to purple flower color, as well as its small stature. While many desert willow trees can grow to 7.6 m (25 feet) tall and wide, this clone seems to stay below 5.4–6.1 m (18-20 feet) tall and wide. After flowering, long narrow seed pods are produced. Plant *Chilopsis linearis* in full sun and well-drained soil, and in regions where temperatures do not drop below –17.8°C (0°F).

Chrysactinia mexicana

Gray (Damianita)

This small, compact shrub grows to 0.6 m (2 feet) tall and wide, and bears a very strong resemblance to turpentine bush, with needle-like green leaves and yellow daisy-like flowers. However, damianita blooms from March to September, while turpentine bush blooms from September to November. Combining the two plants would be a great way to prolong the color display! Damianita has wonderful-smelling foliage, and would be a great selection for sensory gardens. Damianita is a very tough, durable plant, tolerating extreme heat and cold, down to –17.8°C (0°F). Plant in full sun, and almost any soil. If this plant starts to look woody, prune it back severely in the early spring. Damianita ranges from New Mexico to west Texas and northeastern Mexico, at elevations of 609–2134 m (2000–7000 feet).

Dalea capitata

Sierra Gold™

This well-behaved ground cover grows to about 20 cm (8 inches) tall by 0.9 m (3 feet) wide. Because of its compact size, Sierra Gold™ is a good selection for tight planting areas, such as small planters or medians. Its fine-textured, light green foliage has a fresh, lemony scent. Rabbits seem to avoid it! Yellow flowers carpet Sierra Gold™ in the spring and the fall. This plant is hardy to at least –15°C (5°F), but it will be deciduous at –3.9°C (25°F). The one drawback to this plant is that the whiteflies seem to like it, so some insecticide applications will be necessary in heavily infested areas around Phoenix. Plant in full sun for best results. No soil amendments should be necessary. In hot desert regions this plant requires some supplemental irrigation from spring to fall. Although most dales native to Arizona and Mexico tend to rot out if overwatered, we have observed this plant thriving right next to turfgrass, where it receives heavy irrigation. More testing is needed to determine if it will tolerate coastal areas, or regions with high rainfall.

Dasylirion longissimum

This user-friendly accent plant is a great selection for high-traffic areas such as walkways and near entries. This grasslike plant does well in containers, and its symmetrical form provides a striking focal point. Its thin, stiff green leaves are completely unarmed, and have smooth edges. Eventually, its single trunk can grow to 1.8 m (6 feet), topped by a 1.5 m- (5-foot-) wide rounded head of leaves. The older, bottom leaves can be trimmed off to expose the trunk. *Dasylirion longissimum* is native to Mexico, and is hardy to about –8.3°C (17°F).

Euphorbia biglandulosa

Desf. (Gopher Plant)

This evergreen perennial or subshrub has a very unusual form and appearance. Its arching stems angle out and up, and can reach a length of 0.6 m (2 feet). The plant grows to 0.9 m (3 feet) tall by 1.2 m (4 feet) across; with narrow, fleshy grey-green leaves. Broad clusters of chartreuse flowers occur at the tips of the arching stems, usually in the late winter and early spring. Flowers are followed by small brown seed pods that explode upon ripening. The stems usually die back after fruiting, leaving a small clump of grey-green foliage near the ground. Plant *Euphorbia biglandulosa* in full sun or light shade, in a well-draining soil. It is cold hardy to –15°C (5°F).

Hesperaloe parviflora

(Torr.) J. Coult., 'Yellow' (Yellow yucca)

A clumping perennial with long, gray-green leaves, *Hesperaloe parviflora* grows slowly to form a grasslike clump 1.0–1.2 m (3–4 feet) tall and wide. From spring through fall, it produces 1.5 m- (5-foot-) tall flower spikes. Red-flowering plants have been a staple in southwestern landscapes for many years. This is simply a yellow-flowering selection. Use this tough accent plant in full sun. Since it also tolerates reflected heat, yellow yucca is a reliable plant to use along sidewalks, in parking lots, etc. Tolerant of temperature extremes, yellow yucca is cold-hardy to at least –17.8°C (0°F). Once established, it requires little or no irrigation. All in all, yellow yucca is one of the toughest and most maintenance-free plants.

Hymenoxys acaulis

(Pursh) K. Parker (Angelita Daisy)

This perennial is native to the southwestern US, where it occurs most often at elevations from 1219–2134 m (4000–7000 feet), on dry rocky slopes and mesas. Angelita daisy bears a strong resemblance to *Baileya multiradiata* Harv. & A. Gray ex Torr. (desert marigold). However, the foliage is green rather than gray, and the flower is a deeper gold color. Forming rounded clumps to fifteen inches tall and wide, *Hymenoxys acaulis* is a wonderful plant to use as a border in front of larger shrubs. I f water is available, it will naturalize in the landscape. In Phoenix, this plant blooms all year, with especially heavy bloom in the spring and fall months. This prolonged bloom period results in many dried flower stalks, which can make the plants look scruffy. We recommend cutting off the old flower spikes occasionally to rejuvenate the plant and initiate new flower production. Angelita daisy seems to prefer well-drained soils and full sun. It is very cold hardy, heat tolerant, and drought tolerant.

Leucophyllum candidum

I.M. Johnst. Thunder Cloud™

As with all of the other *Leucophyllum* species, this clone blooms when the humidity is high. The silver, pubescent foliage is a perfect foil for the masses of indigo flowers that appear in the summer and fall months. Thunder Cloud™ was selected and trademarked by Benny Simpson of Texas A&M University. His clone is highly valued because of its small, dense growth habit. Unlike most of the larger *Leucophyllum* species, Thunder Cloud™ remains reliably small, to three feet tall and wide. This plant is cold hardy to at least –12.2°C (10°F). Plant all of the *Leucophyllum* species in full sun and well-drained soil. Avoid overwatering.

Leucophyllum langmaniae

Rio Bravo™

Trademarked by Mountain States Nursery, this clone has a nice, compact growth habit very similar to *L. frutescens* 'Compacta'. Rio Bravo™ has become very popular because of its bright green foliage and rounded, dense form. It has lavender flowers and will eventually grow to 1.5 m (5 feet) tall and wide. Like the *L. candidum* species, it requires well-drained soils and full sun. It is hardy to –12.2°C (10°F).

Muhlenbergia capillaris

(Lam.) Trin. Regal Mist™

We feel that this ornamental grass shows great promise for many different regions of the country. Native to humid southeastern Texas, this grass has adapted extremely well to the hot, dry conditions of deserts in Arizona and Nevada. In fact, it has performed incredibly well in Las Vegas, which is cursed with poor soils, high winds, high summer temperatures, and cold winters. Regal Mist^{TM} is also happy in heavy soils, with ample irrigation. In short, it has worked everywhere it has been tried, so far! It is hardy to at least –17.8°C (0°F). Regal Mist^{TM} has narrow, dark green, glossy leaves. It grows quickly to form a rounded clump to 0.9 m (3 feet) tall and wide. The flower spikes on this grass have attracted a lot of attention... they form misty masses of pink to purple flowers in October and November. We recommend cutting this plant back in early spring to cut off the dead flower spikes and any dormant foliage.

Penstemon

species

There are so many wonderful *Penstemon* species to try in the garden, that is difficult to select just a few. Most of the penstemons are perennials with a basal rosette of foliage, which send up spikes of tubular flowers in the spring and early summer. They add incredible color to the landscape, and attract hummingbirds as well! Penstemons come in a wide range of colors, including blue, purple, pink, and red. After they finish blooming, allow the flower spikes to dry on the plant. Then cut off the spikes and sprinkle the seed in the garden to increase next year's mass of color. There are two new species to try: *Penstemon triflorus* Heller, which has short, 46 cm (18 inch) spikes of dark pink-purple flowers which occur along the stem in clusters of three; and *Penstemon clevelandii* Gray, native to southern and Baja California, with spikes of clear, bright pink flowers to 0.6–0.8 m (2–2.5 feet) tall.

Acacia saligna (Labill.) H.Wendl.

Mimosaceae
Orange Wattle

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Orange wattle is an extremely rugged tree, adaptable to barren slopes, derelict land, and exceptionally arid conditions in Australia and North Africa. It grows rapidly and is used for reclaiming eroded hillsides and wastelands and for stabilizing drift sands as well as for fuel. This is one of the best woody species for binding moving sand. It is useful for windbreaks, amenity plantings, beautification projects, and roadside stabilization in semiarid regions. The leaves, or phyllodes, are palatable to livestock when fresh or dried into hay, especially used as supplementary feed for sheep and goats. Crushed seeds have been fed to sheep without ill effects. Regrowth of established bushes is so good that *Acacia saligna* can be completely grazed off without harming the plants. The damaged bark exudes copious amounts of a very acidic gum that seems to show promise for use in pickles and other acidic foodstuffs (NAS, 1980).

Folk Medicine

No data observed.

Chemistry

Natal-grown bark contains up to 30.3% tannin compared to 19.1–23.0 at the Cape. The plant has given negative test for HCN.

Description

Dense, bushy shrub, usually 2–5 m tall; may grow treelike to 8 m tall with a single main stem (diameter to 30 cm). In spring its usually drooping branches are clad in beautiful and abundant yellow flowers (NAS, 1980a).

Germplasm

Reported from the Australian Center of Diversity, orange wattle, or cvs thereof, is reported to tolerate alkalinity, drought, heavy soil, poor soil, salinity, salt spray, sand, shade, slope, waterlogging, and weeds. ($2n$ = 26)

Distribution

Acacia saligna is native to the southwestern corner of western Australia. It was introduced to South Africa in the 1840s in an attempt to stabilize the shifting sand dunes. It has also been planted in Uruguay, Mexico Israel, Iran, Iraq, Jordan, Syria, Greece, Cyprus, and North African countries (NAS, 1980a).

Ecology

Acacia saligna can grow throughout the tropical and the warm temperate regions of the world (NAS, 1980a). In its native habitat, the summer temperature ranges from about 23°–36°C, winter temperatures from 4°–9°C. The plant does not withstand frost and grows best where the winter and summer means are between 13° and 30°C respectively. Grows from near sea level to about 300 m, with isolated occurrences at higher elevations. Particularly drought hardy, it grows where annual rainfall is as low as 250 mm, though it probably does better with 350–600 mm. It grows well where annual rainfall is as high as 1,000 mm. Grows mainly on sandy, coastal plains, but is found from swampy sites and riverbanks to small, rocky hills (often granitic) and coastal slopes. It occurs on poor acid or calcareous sands, under the most dry and adverse soil conditions, in moderately heavy clays and a range of podzols (NAS, 1980a).

Cultivation

Seeds germinate readily; young plants can often be found under mature trees in the hundreds. Seedlings are easily raised in a nursery and established in the field. This species develops root suckers and coppices freely. Seeds are normally treated with boiling water, but nicking the seed coat, soaking in sulfuric acid, and exposing the seeds to dry heat are also effective (NAS, 1980a).

Harvesting

In Mediterranean countries, the fuelwood from this species is harvested on a coppice rotation system of 5–10 years (NAS, 1980).

Yields and Economics

Acacia saligna grows quickly, often reaching up to 8 m tall with a spread as great as its height in just 4 or 5 years. In very dry situations, growth rate is slower. Annual yields vary from 1.5 to 10 m^3 per ha, depending on site. Because of its hardiness and profuse reproductive abilities, *Acacia saligna* has become a serious menace in parts of South Africa by invading and displacing indigenous vegetation. It infests water courses (sometimes decreasing the water available for irrigation), and has proved difficult to eradicate (NAS, 1980a).

Energy

Plantations for fuel have been established in some Mediterranean countries. But, according to one report from South Africa, the wood is "sappy, light, and not a popular fuelwood." The plant can withstand some shade and can be grown as an understory beneath pines or eucalypts in energy plantations or village fuel and fodder areas (NAS, 1980a). The annual litterfall of four *Acacia* species naturalized in the South African Cape, comprising 60% foliage and 30% reproductive structures, averages 7 MT/ha, double the value expected in evergreen scrub communities in winter rainfall regions.

Biotic Factors

Acacia saligna supports a diverse and abundant range of herbivores that cause damage to the plant. Among pests cited are *Icerya purchasi* (Hemiptera) and *Euproctis fasciata* (Lepidoptera) (NAS, 1980a) and *Meloidgogyne* sp. (Nematoda)

Acacia senegal (L.) Willd.

Syn.: *Acacia verek* Guill. et Perr.
Mimosaceae
Gum Arabic, Senegal Gum, Sudan Gum Arabic, Kher, Kumta

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Tree yields commercial gum arabic, used extensively in pharmaceutical preparations, inks, pottery pigments, water-colors, wax polishes, and liquid gum; for dressing fabrics, giving lustre to silk and crepe; for thickening colors and mordants in calico-printing; in confections and sweetmeats. Causing partial destruction of many alkaloids including atropine, hyoscyamine, scopolamine, homatropine, morphine, apomorphine, cocaine, and physostigmine, gum arabic might be viewed as a possible antidote. Pharmaceutically used mainly in the manufacture of emulsions and in making pills and troches (as an excipient); as demulcent for inflammations of the throat or stomach and as masking agent for acrid tasting substances such as capsicum; also as a film-forming agent in peel-off masks. Its major use is in foods, for example, as suspending or emulsifying agent, stabilizer, adhesive, flavor fixative, and to prevent crystallization of sugar, etc. Used in practically all categories of processed foods (candy, snack foods, alcoholic and nonalcoholic beverages, baked goods, frozen dairy desserts, gelatins, and puddings, imitation dairy products, breakfast cereals, and fats and oils). Use levels range from less than 0.004% (40 ppm) in soups and milk products, 0.7 to 2.9% in nonalcoholic beverages, imitation dairy, and snack foods, to as high as 45% in candy products (Leung, 1980). Strong rope made from bark fibers. White wood used for tool handles, black heartwood for weaver's shuttles. The long flexible strands of surface roots provide one of the strongest of local fibers, used for cordage, well-ropes, fishing nets, horsegirdles, footropes, etc. Seeds are dried and preserved for human consumption (NAS, 1980). Young foliage makes good forage. Plants useful for afforestation of arid tracts, soil reclamation, and windbreaks (Duke, 1981a). In modern pharmacy, it is commonly employed as a demulcent in preparations designed to treat diarrhea, dysentery, coughs, throat irritation, and fevers. It serves as an emulsifying agent and gives viscosity to powdered drug materials; is used as a binding agent in making pills and tablets and particularly cough drops and lozenges. Because of its enzyme, the gum is not suitable for use in products having readily oxidizable ingredients. For example, it reduces the vitamin A content of cod liver oil by 54% within three weeks. It is incompatible with aminopyrine, morphine, vanillin, phenol, thymol, α- and β-naphthol, guiacol, cresols, creosol, eugenol, apomorphine, eserine, epinephrine, isobarbaloin, gallic acid, and tannin; also with strongly alcoholic liquids, solutions of ferric chloride and lead subacetate and strong solutions of sodium borate. It was formerly given intravenously to counteract low blood pressure after hemorrhages and surgery and to treat edema associated with nephrosis, but such practices caused kidney and liver damage and allergic reactions and have been abandoned (Morton, 1977).

Folk Medicine

The demulcent, emollient gum is used internally in inflammation of intestinal mucosa, and externally to cover inflamed surfaces, as burns, sore nipples and nodular leprosy. Also said to be used for antitussive, astringent, catarrh, colds, coughs, diarrhea, dysentery, expectorant, gonorrhea, hemorrhage, sore throat, typhoid, urinary tract (Duke and Wain, 1981).

Chemistry

Gum acacia contains neutral sugars (rhamnose, arabinose, and galactose), acids (glucuronic acid and 4-methoxyglucuronic acid), calcium, magnesium, potassium, and sodium. Its complex structure is still not completely known. Its backbone chain consists of D-galactose units, and its side chains are composed of D-glucuronic acid units with l-rhamnose or l-arabinose as end units. The molecular weight has been reported to be between 200,000 to 300,000 and as high as 600,000 (Leung, 1980).

Toxicity

Ingested orally, acacia is nontoxic. However, some people are allergic to its dust and develop skin lesions and severe asthmatic attacks when in contact with it. Acacia can be digested by rats to an extent of 71%; guinea pigs and rabbits also seem to utilize it for energy, as does man to a certain extent. Gum arabic may actually elevate serum or tissue cholesterol levels in rats (Leung, 1980).

Description

Savanna shrub or tree, up to 20 m tall, over 1.3 m in girth, spiny; bark gray to brown or blackish, scaly, rough; young branchlets densely to sparsely pubescent, soon glabrescent, crown dense; stipules not spinescent; prickles just below the nodes, either in threes up to 7 mm long, with the middle one hooked downwards and the lateral ones curved upwards, or solitary with the laterals absent; leaves bioinnate, up to 2.5 cm long; leaf-axis finely downy with 2 glands; pinnae 6–20 pairs; leaflets small, 7–25 pairs, rigid, leathery, glabrous, linear to elliptic-oblong, ciliate on margins, pale glaucous-green, apex obtuse to subacute; flowers in spikes 5–10 cm long, not very dense, on peduncles 0.7–2 cm long, normally produced with the leaves; calyx bell-shaped, glabrous, deeply toothed; corolla white to yellowish, fragrant, sessile; pod straight or slightly curved, retrap-shaped, 7.5–18 cm long, 2.5 cm wide, thin, light brown or gray, papery or woody, firm, indehiscent, glabrous, 5–6-(-15) seeded; seeds greenish-brown. Fl. Jan.–Mar.; fr. Jan.–Apr., July, Aug. or Oct. (Duke, 1981a).

Germplasm

Tree with a single central stem and a dense flat-topped crown, bark without any papery peel, rough, gray or brown, with pubescent, rarely glabrous inflorescence, and pods variable in size, rounded to somewhat pointed but not rostrate or acuminate at apex. Variety *rostrata* Brenan is a shrub, branching at or close to base, or a small tree, with a single stem, 1–6 m tall, with dense flattened crown, bark normally with a flaking papery peel, creamy-yellow to yellow-green or gray-brown, inflorescence axis always pubescent and pods 2–3.5 times as long as wide, rostrate or acuminate at apex. Variety *leiorhachis* Brenan, is always a tree with central stem, and rounded or irregular with straggling branches; bark with conspicuous yellow papery peel, and inflorescence axis always glabrous. Variety *pseudoglaucophylla* occurs on fixed sand duned in Africa. Assigned to the African Center of Diversity, gum arabic is reported to exhibit tolerance to alkali, drought, fire, high pH, poor soil, sand, slope, and wind. (2n=26) (Duke, 1981a)

Distribution

Widespread in tropical Africa from Mozambique, Zambia to Somalia, Sudan, Ethiopia, Kenya, and Tanzania. Cultivated in India, Nigeria, and Pakistan.

Ecology

Thrives on dry rocky hills, in low-lying dry savannas, and areas where annual rainfall is 25–36 cm. This hardy species survives many adverse conditions, and seems to be favored by low rainfall and absence of frost. Ranging from Warm Temperate Thorn through Tropical Thorn to Tropical Dry Forest Life Zones, gum arabic is reported to tolerate annual precipitation of 3.8–22.8 dm (mean of 9 cases = 12.4 dm), annual mean temperature of 16.2–27.8°C (mean of 9 cases 23.8°C), and pH of 5.0–7.7 (mean of 7 cases = 6.4), but Cheema and Qadir (1973) report 7.4–8.2.

Cultivation

In Sudan, trees are cultivated over a very large area. Best propagated from seeds which are produced once every few years, grown in Sudan, in special "gum gardens." Elsewhere, it is collected from wild trees. In Pakistan, the best period for afforestation is the early monsoon season (Apr.–Jun.). Surface sowing is recommended in mildly alkaline sandy soils. Plants can also be reproduced by shoot cuttings. Trees coppice well (NAS, 1980).

Harvesting

Gum exudes froin cracks in bark of wild trees, mostly in the dry season, with little or none in the rainy season when flowers are out. In some areas, a long strip of bark is torn off and the gum allowed to exude. In Africa, it is regularly tapped from trees which are about 6 years old by making narrow transverse incisions in bark in February and March. In about a month, tears of gum form on surface and are gathered. Trees begin to bear between 4–18 years of age and are said to yield only when they are in unhealthy state due to poor soil, lack of moisture or damaged. Attempts to improve conditions tend to reduce yield. Gum from wild trees is variable and somewhat darker colored than that from cultivated plants. Collected gum is carefully freed of extraneous matter, sorted and sometimes ripened in sun before export. Gum arabic is oderless with a bland taste, yellowish and some tears are vermiform in shape. Ripened or bleached gum occurs in rounded or ovoid tears over 2.5 cm in diameter, and in broken fragments. Tears are nearly white or pale yellow and break readily with a glassy fracture. Gum is almost completely soluble in an equal volume of water and gives a translucent, viscous, slightly acid solution, but is insoluble in 90% alcohol. Kordofan (Sudan) Gum is yellow or pinkish, has fewer cracks and is more transparent (Duke, 1981a).

Yields and Economics

Annual yields from young trees may range from 188 to 2856 g (avg. 900 g), from older trees, 379 to 6754 g (avg. 2,000 g). Gum arabic is important export product for some areas in tropical Africa and Mauritania. From Africa some genuine gum is shipped to India then to Europe and America. Between 1940 and 1950, United States imports range from 3,179–8,989 MT (Duke, 1981a) Morton (1977) reports >11,000 MT more recently.

Energy

Considered the best firewood in Mauritius and Senegal, this is not a big yielder, annual running 0.5–5 m^3/ha wood, with an energy value of ca 3,500 kcal/kg. A nitrogen,fixing species, it can be used to reestablish vegetation cover in degraded areas, as well as for sand-dune fixation and wind erosion control (NAS, 1980a).

Biotic Factors

Fungi reported on this crop are *Cladosporium herbarum*, *Fusarum* sp., *Ravenelia acaciae-senegalae* and *R. acaciocola*. Many insect visitors mimic the plant, the buffalo treehopper, *Stictocephala bisonia*, being a good example. Spiders (Cyclops sp.) may completely cover the young growing apex. Seedlings are often grazed by gazelles, goats, and pigs (Morton, 1977).

Acacia seyal Del.

Mimosaceae
Shittim Wood, White Whistling wood

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

According to some Biblical scholars, the Shittah tree is mentioned in the Bible only once (*I will plant in the wilderness... the Shittah tree.* Isaiah 41), but its wood is referred to many times as shittium, which is the plural of shittah in Hebrew. Some even speculate that it was only natural that Moses should turn to shittium when he came to build the Ark of the Covenant and the Tabernacle and needed beams and timber. No one can really be sure which species of Acacia was meant. Wood is white to yellow-brown, finely-striated with dark lines, coarse-grained, soft, easy to work, polishes well, but discolors eastly with mold and is susceptible to insect attack. Ancient Egyptians made coffins, some still intact, from the wood. Nigerians used sapling stems, or also the roots for spear shafts. Tree also yields a gum of good quality, inferior to that of *A. senegal*. Systematic tapping has produced a product of better color and taste. Bark contains tannin and yields a red liquid extract. The gum is said to be edible. The leaves are important for forage and the wood for fuel where the trees are abundant. In parts of Africa the tree is important for livestock, natives driving their animals to where it is common and lopping off branches for them, both leaves and young pods being eaten. The pods are sold, especially for fattening sheep. The tree is believed to provide the best firewood in Chad, and the best fodder in Sahelian savannas (NAS, 1980a; Duke, 1983a).

Folk Medicine

The gum is believed to be aphrodisiac. The bark decoction Is used for dysentery and leprosy. Tanganyikans use the bark as a stimulant in tropical Africa. The gum is used as emollient and astringent for colds, diarrhea, hemorrhage and ophhthalmia. Mixed with *Acacia sieberana* DC, it is used for intestinal ailments on the Ivory Coast. Wood used as a fumigant for rheumatic pains, and to protect puerperal mothers from colds and fevers. Eating the gum is supposed to afford some protection against bronchitis and rheumatism (Duke, 1983a).

Chemistry

This species has been reported to contain 18–20% tannin.

Description

Tree 3–12 m tall, crown flat-topped; bark powdery, white to greenish-yellow or orange-red; sparsely branched, the branches horizontal or ascending; young branchlets with sparse hairs or almost glabrous, with numerous reddish sessile glands; epidermis of twigs becoming reddish and shed annually; leaves often with a large gland on petiole and between the top 1–2 pairs of pinnae; stipules spinescent, up to 8 cm long, ant-galls present or absent; pinnae usually 3–7 pairs, the leaflets in 11–20 pairs, 3–8 cm long, 0.75–1 mm wide, sparingly ciliolate or glabrous; lateral veins invisible beneath; flowers bright yellow, in axillary, pedunculate heads 10–13 mm across, borne on terminal or short lateral shoots of current season; involucel in lower half of peduncle 2–4 mm long; apex of bracteoles rounded to elliptic, sometimes pointed; calyx 2–2.5 mm long, puberulous in upper part; corolla 3.5–4 mm long, glabrous outside; pods 7–20 cm long, 0.5–0.9 cm in diameter, dehiscent, falcate, constricted between seeds, glabrous except for sessile glands, 6–9-seeded; seeds elliptic, 7–9 mm long, 4.5–5 mm wide, compressed, minutely wrinkled, olive-brown to olive; areole 5–6 mm long, 2.5–3.5 mm wide.

Germplasm

Species has several botanical varieties. The two main ones are: *A. seyal* var. fistula (Schweinf.) Oliv. (*A. fistula* Schweinf.), is white-barked with some pairs of spines fused at base into 'ant-galls', 0.8–3 cm in diameter, grayish or whitish, often marked with sienna-red and with longitudinal furrows down center, more or less 2-lobed. Found in Zambia, Malawi, and Mozambique. *A. seyal* var. *multijuga* Schweinf. ex Baker f. (*A. stenocarpa* Oliv., pro partem), a shrub or tree, usually less than 5 m tall, sometimes up to 13 m, flattened crown; bark on main stem greenish-brown, peeling in papery rolls; bark on branchlets red-brown, thorns straight, weak, usually less than 2.5 cm long, sometimes absent; pinnae 4–12 pairs, leaflets 10–20 pairs; flowers golden-yellow; pod narrow-linear, strongly curved, up to 10 cm long, 0.6 cm wide, dehiscing on tree. Common in overgrazed pastures and widely distributed in East Africa. Hybrids, *A. seyal* var. *fistula* X *A. xanthophloea* Benth., are known from woodlands on black clay loams on flood plains in Malawi. Pods are conspicuously irregular, 4–11 cm long, 6–10 mm wide, ill-formed and curved. Assigned to the Africa Center of Diversity, shittim wood or cultivars thereof is reported to exhibit tolerance to high pH, heavy soil, insects, mycobacteria, poor soil, salt, savanna, slope, and waterlogging. (2*n*= 26.)

Distribution

Native to the Sahelian Zone from Senegal to Sudan, it also occurs in Egypt and eastern and southern Africa, from Somalia to Mozambique and Namibia (NAS, 1980a).

Ecology

Trees thrive in *Sclerocarya caffra* woodlands, wooded grasslands and especially on seasonally flooded black-cotton soils along water courses. Requires a heavy clay-alluvium, but will grow on stony ground at base of hills. Grows at 20–2,100 m altitude. A gregarious savanna tree, ranging from Subtropical Desert to Dry through Tropical Desert to Very Dry Forest Life Zones, shittim wood is reported to tolerate annual precipitation of 8.7–22.8 dm (mean of 7 cases = 15.0 dm), annual mean temperature of 18.7–27.8°C (mean of 7 cases = 24.0°C) and pH of 5.0–8.0 (mean of 5 cases = 6.9).

Cultivation

Propagated from scarified seed. large cuttings are said to strike root readity in moist soils.

Harvesting

Pods, bark or wood are harvested in season from trees or shrubs in native habitats. Gum also obtained from native plantings, in manner similar to that for other gum arabic plants.

Energy

The dense wood is highly prized for firewood, in areas where few other plants survive. Considered one of the best firewoods in Chad, it is used in the Sudan to make fragrant fires over which women perfume themselves.

Biotic Factors

Following fungi reported on this plant: *Fomes rimosus*, *Ganoderma lucidum*, *Leveillula taurica*, *Ravenelia volkensii*, *Trametes meyenii*, and *Uromyces schweinfurthii*. Although the plant is reportedly resistant to insect attacks, felled logs may be severely damaged by wood borers.

Sarafis, V. 1999. Cucurbit resources in Namibia. p. 400–402. In: J. Janick (ed.), Perspectives on new crops and new uses. ASHS Press, Alexandria, VA.

Cucurbit Resources in Namibia*

Vassilios Sarafis

Namibia has several cucurbits with potential for development into commercial crops either through selection or through the introduction of genes into known crops. *Acanthosicyos horrida* Welw. ex J.D. Hook., wild *Citrullus ecirrhosus* Cogn., and *C. lanatus* (Thunb.) Matsum. & Nakai in the Cucurbitaceae are examples of gene sources. The areas from which these plants come are arid and the plants derive their water needs from dew precipitation in the mornings, very occasional rains every few years, and deep ground water (Seely l987; Lovegrove 1993).

ACANTHOSICYOS HORRIDA

Acanthosicyos horrida forms clumps of vegetation in the dunes of the Sossuvlei region near Walvis Bay (Fig. 1) (Craven and Marais 1986; Lovegrove 1993; Klopatek and Stock 1994). *Acanthosicyos horrida* is a dioecious perennial cucurbit attaining a height of about 1.5 m (Fig. 2). It forms plants of one sex in single clumps which may touch plants of the same or other sex nearby (Fig. l). It bears deep water table seeking roots (G. Wardell–Johnson, pers. commun. 1998). The plants are totally leafless (Fig. 2) and have a fruiting habit of oblong spherical fruits reaching up to 25 cm average diameter. The plants are able to build up sand deposits around themselves and continuously grow to be above these sand deposits. New plants establish only when rain falls and quickly form deeply growing roots that seek the water table (G. Wardell–Johnson, pers. commun. 1998).

Fig. 1. View of *Acanthosicyos horrida* in sand dunes at the Sossuvlei region near Walvis Bay Namibia.

Fig. 2. A close up of *Acanthosicyos horrida* plants. Note the leaflessness.

The fruit may not be spaced apart and may occur in clusters of several touching each other. The fruits are spiny (Fig. 3). Maturation of the fruits occurs between February and April. The fruits do not change color and remain green on the outside but the flesh surrounding the seeds dissociates from the skin, turns orange in color (Fig. 4), extremely sweet in taste and strongly aromatic. Maturational changes are easily detected by the bushmen living in the area without breaking the fruit in any way. The fruits are used by the bushmen for two main purposes. The first is for the extraction of the seed which are consumed as pips by splitting in the mouth and the second is for pulp processing where the flesh is boiled and poured to form a fruit leather. This fruit leather is eaten throughout the year and is considerably less flavorful than the pulp. The plant thus forms an important food resource because of the easy storage of both the seeds and the dried pulp (leather). The fruits are eaten also when immature by animals including jackals and rodents who do not seem to be bothered by the bitter taste of the fruits caused by cucurbitacins (Hylands and Magd 1986).

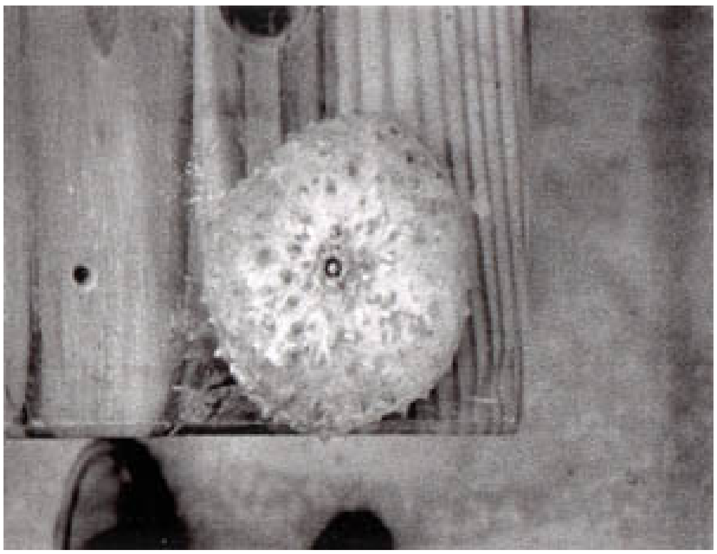

Fig. 3. Back of a mature fruit of *Acanthosicyos horrida* showing the large spines on the surface of the fruit. The distances separating the spines are small in young fruits.

Fig. 4. Cross section through three fruits of *Acanthosicyos horrida*. The one on the extreme right is a bitter immature fruit of full size. The one on the top an almost mature fruit with only a little bitterness. The bottom left hand fruit a fully mature fruit with a flesh having an orange color, no bitterness and very aromatic in flavor.

The mature pulp has a flavor which is aromatic and maybe due in part to sulphur components as in some types of *Cucumis melo* L. No trace can be tasted of cucurbitacins in the mature pulp. The pulp could be commercialized and used to make ice-cream, and could be freeze dried and chocolate coated. The seeds which are already sold to an European population in Walvis Bay can have their market expanded by selling the seeds either whole or dehusked in packaging developed for nuts. Their rarity should provide a premium price and help the economic existence of the bushmen in this area. Ice-cream manufacture and freeze drying facilities are only within 30 km of the bushmen. Partnerships with firms interested in commericalizing the unique, aromatic pulp of *Acanthosicyos horrida* could be fostered to further improve the economic existence of the native people in the area.

CITRULLUS ECIRRHOSUS

Citrullus ecirrhosus is a desert perennial (Fig. 5, 6) which is monoecious. Fruits mature (Fig. 7, 8) February to March. The leaves form an annual stems which die back each year. The leaves have a special feature where the lamina is curved over the mid-rib and the lateral veins so that when viewed from above the top surface is only visible in the vein regions and the leaves have a greenish white appearance due to the lower epidermis being reflected up as the upper surface of the leaf. This lower epidermis is covered with warts and hairs which account for the whitening effect. Both lower and upper epidermis contain similar amounts of stomata. The water relations of this plant are reliant on a deep water layer in the ground which the roots reach and possibly some water availability from morning fogs and the very occasional rainfall. The fruit and seeds contain cucurbitacins but the seeds are harvested in times of need and processed by crushing and decantation to remove the bitter substances. *Citrulls ecirrhosus* plants may be a source of drought tolerance genes for *Citrulls lanatus.* Successful crossability of *Citrulls ecirrhosus* and *C. lanatus* is discussed in Navot and Zamir (1986) and Navot et al. (1990). They have shown the way for breeding *Citrullus lanatus* containing genes from *C. ecirrhosus.*

Fig. 5. *Citrullus ecirrhosus* perennial plant growing approximately 20 km inland from Walvis Bay, showing a mature fruit on current years growth and brown dead stems from last years growth.

Fig. 6. *Citrullus ecirrhosus* perennial plant showing young developing fruit in the foreground and the bending of the leaves over the mid-rib and lateral veins.

Fig. 7. Mature *Citrullus ecirrhosus* showing folded nature of the leaves of the mid-rib and lateral veins.

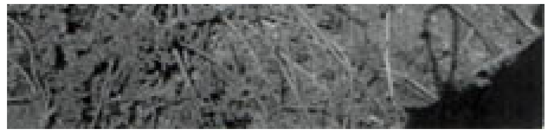

Fig. 8. Fruit of *Citrullus ecirrhosus* cut showing white creamy flesh which is non juicy and brown seeds.

CITRULLUS LANATUS

Citrullus lanatus wild plants seen near Walvis Bay have green fleshed fruit unknown from domesticated watermelons (Fig. 9). The genetics of fruit color in the watermelon, *Citrullus colocynthis* and *ecirrhosus* are discussed by Navot et al. (1990). White, yellow, orange, pink, red, and crimson flesh types are known. The green flesh color of this wild *Citrullus lanatus* (Fig. 9) is a unique feature which can be transferred to domestic watermelon due to the crossability of wild and domestic watermelons. This would offer a new fruit type for consumers to enjoy. A red flesh cultivated watermelon from the north of Namibia has some green zone within the fruit suggesting that the green flesh character can be easily introduced. However, the wild watermelon has cucurbitacins which would render them unfit for human consumption. Drought tolerance and green flesh color from *C. ecirrhosus* and wild *Citrullus lanatus*, could be valiable traits for watermelon improvement.

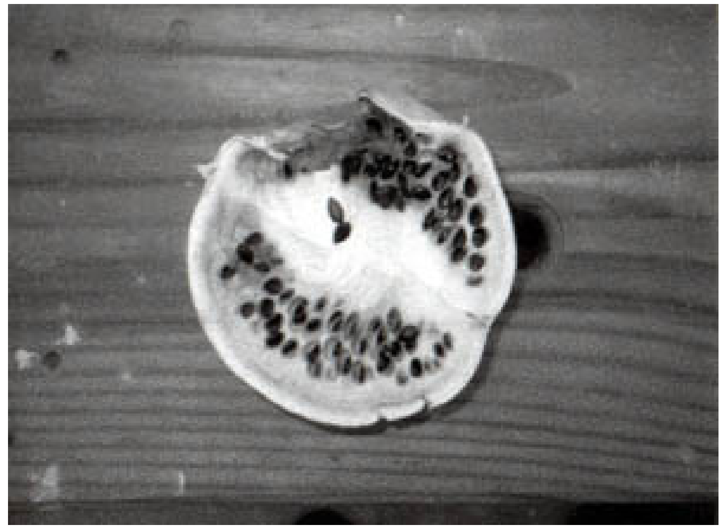

Fig. 9. *Citrullus lanatus* mature fruit from a plant growing on a dry river bed approximately 20 km inland from Walvis Bay, cut to show chlorophyll in the flesh and browny-black seeds. The more deeply colored regions of the flesh are green. The flesh is more juicy than in Citrullus ecirrhosus.

Black sugar maple

Hard maple

***A. nigrum* Michx. f.**

Source: Magness et al. 1971

Maple sugar and syrup are obtained from the sap of these two species and are solely products of the United States and Canada. The Indians were making crude syrups and sugar from maple sap before the coming of white men. The preparation of maple sugar and syrup is strictly a farm industry, occurring from Kentucky northwest to Iowa, northeast to Maine and north into Canada. Native stands of these maple species are tapped to obtain the dilute juice or sap. The trees are not a cultivated crop, although competing useless trees may be removed and maple stands may be thinned to promote better growth and sugar yield. Only a small proportion of the available trees of these species are actually tapped. It is estimated that more than 200 million such trees are growing in the United States, and less than 6 million are tapped.

The tapping is done by boring a small hole (under 0.5-inch diameter) horizontally into the tree so as to penetrate through the outer or sap wood. On large trees up to four such taps may be made at one time. Tapered spouts (hollow tubes) are driven into the holes to fit tightly, and the sap flows through this tube and is collected in sap buckets. it is important to protect the buckets and contents from rain water. Tapping is done in late winter, before bud break. During periods when temperatures are above freezing at this season sap flow is quite abundant, A tap hole usuallv produces 5 to 15 gallons of sap, though much more than that is sometimes obtained. Sugar content of the sap also varies widelv, from l0 to 30°Brix or higher.

Portable tanks of various types are used to collect the sap, which is poured into the tank through strainers. An alternative method is to use pipc lines to carry the sap to the evaporation equipment.

Originally a single open kettle over a fire was used to evaporate the excess water in the sap to produce syrup. Now multiple evaporators are mainly used, the syrup being transferred as it becomes more dense. Usually 2 or 3 transfers are made. Modem evaporating pans have flues in them through which the heat from the fuel passes to speed the process and codserve fuel. For standard-density syrup, concentration is to 65.5°Brix, which is about 86 percent solids by weight. If the sap tests 2.4°Brix, 34 gallons would be required to produce one gallon of syrup.

Slow evaporation--or longer heating time--in the final stages of concentration result in a darker colored syrup. More rapid evaporation at this stage gives a lighter colored, higher grade syrup. Sensitive thermometers are used to determine when the syrup is concentrated to the standard of 65.5 Brix. The completed syrup contains solid granules, mainly calcium malate, termed sugar sand. For toable syrup these must be removed. On the farm they may be allowed to settle out or are removed by filtering. Centrifuging is efficient if available.

To produce various types of maple sugar, the syrup is further heated and additional water driven off. If heated to a boiling point of 230°F. and cooled rapidly without stirring a solid cake is formed. Stirring during cooling results in crystal formation. For fine crystals the highly supersaturated solution is seeded with fine crystals and stirred rapidly, which results in rapid formation of great numbers of fine crystals.

Numerous products, as maple cream, or butters, soft-sugar candies, maple spread, and candies utilize maple syrup or sugar. Total maple syrup production in the United States averaged approximately 1,400,000 gallons, 1961-66, inclusive. This includes that made into sugar. In addition about 800,000 gallons of syrup and 5,145,000 pounds of sugar were imported annually from Canada during those years.

Halevy, A.H. 1999. New flower crops. p. 407–409. In: J. Janick (ed.), Perspectives on new crops and new uses. ASHS Press, Alexandria, VA.

New Flower Crops

Abraham H. Halevy

Most edible crops have been introduced into cultivation thousands of years ago. There are only a few new edible plants in the contemporary western horticulture, such as pecan, blueberry, and kiwifruit, but even these plants have been cultivated since ancient days by local farmers in their native region. This is not the case with ornamental crops. Many of the commercial cut flowers and pot-plants grown today have not been cultivated commercially until several years ago.

The ornamental plant industry is characterized by its great diversity. There are more ornamental species cultivated today than all other agricultural and horticultural crops combined. In some ways the introduction of new ornamental crops is easier that of edible crops. Neither their nutritional value nor their general toxicity to human has to be considered, as evident in plants such as *Aconitum*, *Diffenbachia*, *Oleander*, and many others. Our main considerations in the introduction of new ornamental crops are the esthetic value, production costs, postproduction longevity, quality, and marketability.

The introduction of new crops includes many research stages, that start with the initial search and screening and concludes when the product is introduced commercially, as detailed in my other presentation in this proceedings (Halevy 1999).

Ten years ago the traditional major crops constituted over 60% of the cut flowers grown in and exported from Israel. This year over 60% of the exportable flowers are "new crops," most of them have not been grown commercially 10 years ago as shown in Table 1. Many of these new commercial flower crops are not even mentioned in a recently published textbook on floriculture (Dole and Wilkins 1999). There are several sources that serve for the introduction of new plant material as potential plant crops.

Table 1. Quantities of various exportable cut flowers from Israel in the 1996/7 export season.

Flowers	Exportable flowers (millions of stems)
Roses	453
Carnation	144
Gypsophila	116

Gerbera	45
Limonium	41
Aster	35
Helianthus	32

Asclepias	27
Anemone	27
Safari sunset	20
Anigozanthos	17
Phlox	9
Others	210

MINOR OUTDOOR GROWN CROPS

Many of the new greenhouse floral crops, grown and exported during the winter, are the so called "Summer Flowers." They are field grown plants that were used in Europe during their natural flowering season in the summer. Their introduction as a year round crop requires developing physiological and horticultural techniques for out of season production. *Gypsophila* and peony described above (Halevy 1999) are typical examples of such crops. Other examples are listed below.

Aconitum napellus

L., Ranunculaceae (Monk's hood)

This is a tuberous plant native to Europe. For winter flowering, tubers are cold stored during the summer and pretreated with gibberellic acid before planting.

Asclepias tuberosa L., Asclepiadaceae (Butterfly weed) and *A. incarnata* L. (Swamp milkweed)

Both plants are native to the US and considered as weeds there. They are absolute long day (LD) plants that require warm temperature during their growth and flowering. For winter production they are grown in heated greenhouses and provided with supplementary light at night.

Achillea filipendulina Lam., Asteraceae (Yarrow)

Native to East Asia it is used mainly for summer harvest as dry flowers. Year round production is obtained by digging the crowns and cold storing them for a few weeks before replanting.

Liatris spicata Willd., Asteraceae

Native to Eastern US, for winter production, tubers are cold-stored during the summer and plants are lighted in the field.

Phlox paniculata L., Polemoniaceae

Native to Eastern US, this herbaceous summer perennial is now grown for year round production in greenhouses. It is a LD plant, requiring supplementary night lighting.

Solidago sp. L., Asteraceae (Goldenrod)

Species of goldenrod native to North America are considered as weeds there. New interspecific hybrids turned this plant into an important cut flowers. For winter production plants first receive LD to extend their stems and then are exposed to the natural winter short days (SD) for flower initiation and development.

Trachelium caeruleum L., Campanulaceae

Native to South Europe, it is an absolute LD plant and grown in the warmer parts of Israel for winter production.

NEW CULTIVARS OF ORNAMENTAL FIELD PLANTS

Plants of this group have been grown as minor cut flowers, but recent introduction of new cultivars, with modified and improved horticultural traits, turned them into important floral crops. Examples are:

Anigozanthos hyb., Haemodoraceae (Kangaroo Paw)

This Australian plant was grown mainly outdoors until a few years ago. Recently introduced highly yielding interspecific hybrids are now grown indoors for year round production. These new hybrids are propagated by in vitro tissue culture.

Aster hyb., Asteraceae

New interspecific hybrids of *A. novi-belgii* and other species native to Eastern North America turned these herbaceous perennial, late summer garden plant, into an important greenhouse crop. This is a LD-SD plant, requiring at first LD, until the stems reach a certain desired height and then it is exposed to natural winter SD.

Campanula medium L., Campanulaceae

This plant, native to south Europe, was used only as garden and pot-plant until recently. The original species required a long cold period followed by LD for flowering (Wellensiek 1985). However, new varieties, introduced recently, have long flowering stems and require only LD for flower induction. This enables growing the plant as a commercial cut flower crop.

Clarkia amoena Nels. & Macbr., Onagraceae (Godetia, Satin flower)

This Western North American plant was mainly a garden plant until the recent introduction of improved cultivars for use as cut flowers. The plant requires mild temperature and moderate watering and feeding. It is a facultative LD plant.

Eustoma grandiflorum Shinn (Syn. *Lisianthus russellienus*), Gentianaceae

Native to Southern US, it was used sparsely as garden and cut flower plant. Newly introduced F_1 hybrids turned the plant into an important greenhouse cut flower crop for year round production. Seed propagated, it requires mild-low temperatures in the first growing stage, followed by warmer temperatures.

Leucadendron Hyb., Proteaceae

This South African shrub became an important outdoor crop for cut flowering shoots with the introduction of new hybrid cultivars. The 'Safari Sunset' cultivar is now grown on over 200 hectares in Israel.

Limonium hyb., Plumfaginaceae

Interspecific hybrid cultivars of several perennial limoniums became important greenhouse cut flower crop, used as "filler."

GARDEN AND LANDSCAPING PLANTS

These are mainly woody or herbaceous perennials, used for many years in gardens and introduced recently into the floral trade. Examples are:

Cotinus coggygria Scop., Anacardiaceae (Smoke Tree)

A deciduous shrub, native to South Europe, used for many years as a garden plant. The cultivar 'Royal Purple' is now grown for cut foliage. LD is applied to prevent plants from entering dormancy.

Hypericum sp. (Hypericaceae)

Several species and hybrids of these shrubby plants, native to the Mediterranean and the Canary Islands, have recently became important floral crop grown both outdoors and in greenhouses for cut shoots with fruits of various colors. This is an absolute LD plant that requires night lighting for winter production.

Ruscus hypoglossum L. (Liliaceae)

This herbaceous perennial has been grown in Israel as a garden plants for many years. It is now the main cut foliage crop in Israel, grown exclusively in shaded houses.

ORNAMENTAL CULTIVARS OF FIELD CROPS

In some plants, grown mainly as field crops, new ornamental cultivars have been introduced and used as cut flowers. Examples are: sunflower (*Helianthus annuus* L., Asteraceae), cotton (*Gossypium hirsutum* L., Malvaceae), and safflower (*Carthamus tinctorius* L., Asteraceae).

PLANTS GROWN IN BOTANICAL GARDENS

Botanical gardens and specialized plant collections are rich sources for plant material, some of which can be used for introduction as potential floral crops. Some examples are the bulbous plants of the Liliaceae: *Eremurus* sp. of Central Asia, the South African *Bulbinella kookerri* of yellow, orange, and white flowers, and *Ornithogalum dubium* of yellow and orange flowers, and the South Asian *Curcuma alismatifolia* (Zingiberaceae).

WILD PLANTS IN THEIR NATIVE HABITAT

The introduction and development of Geraldton wax-flower described above (Halevy 1999) is an example of such introduction. Some such plants are currently under intensive developmental stages. They include plants originated from remote areas, but also plants native to Israel and California.

New Herbaceous Ornamental Crops Research

Allan M. Armitage

INTRODUCTION

A great deal of interest in new floricultural crop research has occurred in recent years. The conferences in Davis, California, 1986 (Criley 1987) and Aarslev, Denmark. 1988 provided new and exciting avenues of study In general, three basic areas of research are presently being conducted in herbaceous ornamental crops around the world (Armitage 1987a). The first area consists of cultivar research in well-established ornamental species (type I species). For example, research evaluating new inflorescence shapes of *Dendranthema grandiflora* Tzvelev., new flower colors of *Petunia* x*hybrida* Vilm. or leaf varigation patterns of impatiens fall into this category. The second area deals with new uses for well known minor crop species (type II species). Examples include investigations into species of *Aquilegia* L., *Armeria maritima* Willd., *Calendula officinalis* L., and *Capsicum annuum* L., well known garden species, as potted plants. The third area of research involves development and evaluation of species about which little or no information concerning flowering physiology or performance under production conditions exists (type III species). The use of *Melampodium paludosum* L., *Trachelium caeruleum* L. or *Cedrela sinensis* Juss. as pot plants falls under this type of research as do investigations into *Achillea* x `Coronation Gold', *Caryopteris incana* Miq. or *Oxypetalum caeruleum* Decne. as field grown cut flower crops. The greatest amount of prior selection occurs with type I species, followed by type II while little, if any, selection has taken place in type III species. The grouping of species is dynamic and in a constant state of change. As type III species become accepted in the floriculture trade, they are relegated to type II or type I species. Examples of new crop species are listed in Table 1.

The potential for basic research is rich for type II and III species. Little is known concerning the control of flowering in these species and fruitful areas of investigation might include gas exchange, photoperiod manipulation, carbon partitioning, and factors affecting the onset of flowering. Information pertinent to commercial use, however, such as height control, irradiance levels, optimum temperatures and propagation techniques must also be understood before industry accepts a new species. In the case of cut flowers, the influence of spacing, shading, fertility and planting time on yield and shelf life may be exciting directions for research.

Little funding is available in the United States for new crop research in floriculture and scientists must balance fundamental studies on flowering physiology with applied applications to industry.

UNIVERSITY OF GEORGIA SYSTEMS APPROACH TO NEW CROP EVALUATION

The University of Georgia New Crops Program involves research on type II and type III species in two facets of floriculture: new pot plant crops for the greenhouse and new cut flower crops for the field. An enormous number of species exist with potential as new crops in one or both of these areas. The dilemma of the scientist is to not overlook potential successful species while at the same time ignoring or discarding those with little chance for acceptance. Therefore, a new crop program must have a system to choose species for research and to evaluate and develop information on those selected (Armitage, 1986). The most fundamental aspect of any system is that it be capable of quickly discarding species from the program. The systems approach used at Georgia has a number of places where the decision to terminate research on a species may be made (Fig. 1). The primary objective of our program is to develop information on crops with the following characteristics:

Potted plants must have at least 1 week shelf life without addition of extending sprays; cut flowers, 5 days without silver thiosulfate (STS). Floral preservatives are used in the case of cut flowers. If the shelf life is less than this standard, the decision may be made to terminate the species or to determine methods to extend shelf life.

The time from propagule (cutting or seed) to flower for pot plants must be less than 20 weeks. Many species occur for which rapidly flowering cultivars may one day be developed, however, there is little chance of commercial acceptance if greenhouse production time results in excessive cost of production. The program in Georgia is not in the position to spend the time necessary to breed and select new cultivars. The additional time required for slow flowering species detracts from other species to be investigated. If flowering time is felt to be too long, work on the species is terminated.

Exceptions may be made with species of outstanding potential such as *Eustoma grandiflorum* (Raf.) Shinn. In these cases, production partitioning within the industry will evolve. That is, propagation and growing occurs at one site while forcing into flower occurs at another. In this instance, it behooves the scientist to similarly partition his research on the species.

Species must be relatively tolerant of "normal" pests and diseases. Introducing species particularly attractive to whiteflies or highly susceptible to *Botrytis* should be avoided. If species being tested show weakness to diseases and pests, work may be terminated.

The new species should not have a deleterious effect on established commercial species. For example, our work with unproved cultivars of *Primula obconica* looked promising; however, the species contains primin and results in dermatitis in a small percentage of people. The adverse effects of primin could adversely affect sales of all primula species, particularly *P. acaulis*. Thus, the work was terminated.

Although the system provides objectivity, decisions to terminate are at the discretion of the scientist. Thus, the scientist in charge needs to work closely with industry.

SPECIFIC RESEARCH TOPICS

Flowering Physiology

Salvia leucantha. Plants are SD with a critical photoperiod of 12 hours for macrobud development and 10 hours for subsequent flower development. Approximately 14 cycles are necessary for initiation but 42 cycles are needed for normal anthesis and raceme elongation (Armitage and Laushman 1989).

Trachelium caeruleum. Plants are LD with a minimum of 14 hours for flower initiation but day neutral for subsequent flower development (Armitage 1988b).

Pentas lanceolata. Plants are quantitative LD, flowering 7-10 days earlier than SD (Armitage 1988a).

Oxypetalum caeruleum is day neutral for flowering but significant internode elongation occurs with LD (Armitage et al. 1990).

Gas Exchange

Trachelium caeruleum. Light compensation and light saturation are approximately 15 and 600 µmoles s^{-1} m^{-2} respectively at 25°C. At saturation, net photosynthesis is 10-12 mg CO_2 dm^{-2} h^{-1} (Armitage, 1988b).

Oxypetalum caeruleum. Light compensation occurs at 25 µmoles s^{-1} m^{-2} and saturation at 700

(Armitage et al. 1990).

Growth Regulators

Height control—Height regulation studies with *Melampodium paludosum*, *Pentas lanceolata* (Armitage 1988a), *Calendula officinalis* (Armitage et al. 1987), and *Trachelium caeruleum* (Armitage 1988b) have indicated that these crops may be useful for commercial pot plant production.

Fruit ripening—Use of 150-300 ppm of 2-(chlorethyl) phosphonic acid resulted in accelerated ripening of fruit of *Capsicum annuum* under greenhouse conditions (Armitage 1989a). Concentrations of 75 ppm was less effective and 600 ppm resulted in phytotoxicity.

Spacing

Studies on spacing were conducted with *Achillea* x 'Coronation Gold', *Physostegia virginiana* Benth. and *Salvia leucantha* as field grown cut flowers. Yield per plant increased as spacing increased but yield per area decreased (Armitage 1987b).

Shading (Field Flowers)

Anemone coronaria L. Stem length increased significantly under 55% light reduction compared with ambient (Armitage and Laushman, 1990).

Echinops ritro L., *Eryngium planum* L. Reduction of ambient light resulted in increased stem lengths for both species. Yield of *Eryngium* decreased with 55% light reduction, however, yield of *Echinops*, increased significantly. Additional shade reduced yield of both species.

Postharvest

Species with increased shelf life from dips with sodium silver thiosulfate (STS) include *Anemone coronaria*, *Physostegia virginiana* and *Salvia leucantha.*

Optimum time of bulb planting was determined for *Acidanthera bicolor* Hochst., *Anemone coronaria*, *Brodiaea laxa* Engler, *Allium sphaerocephalum* L., *Polianthes tuberosa* L. and *Liatris spicata* Willd. Perenniality and yield response was determined over a 3-year-period (Armitage and Laushman, 1990).

CONCLUSIONS

New crops are the lifeblood of the floriculture industry. New cultivars of established crops have historically kept the industry strong but entirely new crops must be introduced continually to maintain consumer interest. Research on new crops is necessary to provide information to control flowering time, manipulate plant size, and provide repeatable schedules. However, far more potential species exist than can be evaluated and developed. A systems approach to new crop research is essential in order that limited resources are used efficiently.

Table 1. Potential species for pot and cut flower culture for new crop research.

Type I. (Species well established as ornamental plants)

- Greenhouse pot plants
    - Bedding plants (in general)
    - *Begonia* x *hiemalis*
    - *Denthanthema grandiflora* Tzvelev.
    - *Dianthus caryophyllus* L
    - *Euphorbia pulcherrima* Willd.
    - *Exacum affine* Balf.
    - *Kalanchoe blossfeldiana* Poellnitz
    - *Lilium longiflorum* Thunb.

  - *Pelargonium* x *hortorum* Bailey
  - *Sinningia speciosa* Benth & Hook.
- Greenhouse Cut Flowers
  - *Antirrhinum majus* L.
  - *Dendranthema grandiflora* Tzvelev.
  - *Dianthus caryophyllus* L.
  - *Gerbera jamesonii* Bolus.
  - *Rosa* x *hybrida*
- Field Cut Flowers
  - *Achilles filipendulina* Lam.
  - *Delphinium* sp.
  - *Gypsophila paniculata* L.
  - *Iris* sp.
  - *Iris xiphium* L.
  - *Limonium sinuatum* Mill.

Type II Species (New uses for well known minor crops)

- Greenhouse Pot Plants
  - *Alstroemeria aurantiaca* D. Don.
  - *Aquilegia* x *hybrids*
  - *Armeria maritima* Willd.
  - *Astilbe* x *arendsii*
  - *Bouvardia longiflora* HBK.
  - *Calendula officinalis* L.
  - *Campanula carpatica* Jazq.
  - *Capsicum annuum* L.
  - *Eustoma grandiflora* (Raf.) Shinn.
  - *Fressia* x *hybrids*
  - *Lilium* x *hybridum*
  - *Zantedeschia aethiopica* Spreng.

Type III Species (little information available)

- Pot Plants
  - *Allium neapolitanum* Cyr.
  - *Alonsoa warscewiczii* Regel.
  - *Cedrela sinensis* Juss.
  - *Coprosma* x *kirkii* Cheesem.
  - *Hebe speciosa* Cockayne & Allan
  - *Ixora coccinea* L.

- *Melampodium paludosum* L.
- *Nerine sarniensis* (L.) Herb.
- *Pentas lanceolata* Schum.
- *Reinwardtia indica* Dumort
- *Rhodohypoxis baurei* (Bak.) Nel
- *Tibouchina semidecandra* Aubl.
- *Trachelium caeruleum* L.
- *Veronica longiflora* L.

- Cut Flowers Field or Greenhouse
    - *Achillea* x 'Galaxy Series'
    - *Achillea* x 'Coronation Gold'
    - *Acidanthera bicolor* Hochst.
    - *Allium giganteum* L.
    - *Anemone coronaria* L.
    - *Anigozanthos mangleslii* D. Don
    - *Brodiaea* (*Triteleia*) *laxa* Benth.
    - *Caryopteris incana* Miq.
    - *Centaurea americana* Nutt.
    - *Centaurea macrocephala* Puschk.
    - *Centaurea moschata* L.
    - *Chamelaucium uncinatum* Schauer.
    - *Consolida ambigua* (L) P. W BallaHeyw.
    - *Craspedia globosa* G. Forst.
    - *Crocosmia crocosmiiflora* N.E. Br.
    - *Echinops ritro* L.
    - *Emilia javonica* Cass.
    - *Eryngiun alpinum* L.
    - *Eryngium planum* L.
    - *Euphorbia fulgens* Karw.
    - *Euphorbia marginata* Pursh.
    - *Gomphrena globosa* L.
    - Herbs (e.g. *Foeniculum*)
    - *Hypericum androsaemum* L. (fruit)
    - *Limonium* spp. (many)
    - *Nerine sarniensis* (L.) Herb.
    - *Nigella damescena* L. (fruit)
    - *Ornithogalum* spp.

- *Physalis alkekengi* L. (fruit)
- *Physostegia virginiana* Benth.
- *Polianthes tuberosa* L.
- *Salvia leucantha* Cav.

Acorus calamus L.

Araceae

Sweetflag, calamus, calamus root, flag root, myrtle flag

We have information from several sources:

The Herb Hunters Guide—Sievers, A.F. 1930.

Food and feed crops of the United States—Magness, J.R., G.M. Markle, C.C. Compton. 1971.

Acroceras macrum Stapf

Poaceae
Nile Grass

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

A very palatable grass and rather extensively cultivated as pasture and hay, especially in the highyield areas of South Africa. Forms dense cover used for grazing and haymaking. Unsuitable for leys, as it is difficult to eradicate. Very useful as fodder source during dry season. The grass has been described, perhaps hyperbolically, as "the king of fodder grasses—a truly revolutionary grass" (Rhind and Goodenough, 1979).

Folk Medicine

No data available.

Chemistry

Per 100 g, the forage is reported to contain 8.7 g protein, nearly 6 g fat, 75.4 g total carbohydrate, 30.7 g fiber, 450 mg Ca, and 110 mg P (Bogdan, 1977). Other reports put the crude protein as high as 22%; one report gives 21.3% for leaves, and 7.9% for the stems; crude fiber was given as 30.0% for leaves, 38.5% for stems. On a zero moisture basis, South African hay was 8.5% CP, 31.8% CF, 6.1% ash, 1.8% EE and 51.8% NFE (Gohl, 1981). Many more nutritional details are tabulated in the excellent review by Rhind and Goodenough (1979).

Description

Perennial grass, spreading by creeping slender rhizomes and stolons; culms up to 70 cm or more, sometimes prostrate at base; leaves expanded, to 20 cm long and 12 mm broad, glabrous or minutely hairy, rounded or almost cordate at base, tapering to sharp point, bright green; panicle up to 20 cm long, spikelike, of 2–5 racemes up to 8 cm long, the lower 5–9 cm apart; spikelets light green, acuminate or obtuse, 4–5 mm long, awnless, glabrous, with conspicuous indurate rounded appendages at laterally compressed apex of glumes and lemmas; lower glume more than half as long as spikelet, 3-nerved; upper glume 5-nerved; ligule a membrane fringed with short hairs, sometimes greatly reduced. 4x = 36.

Germplasm

Reported from the Africa Center of Diversity, Nile grass or cvs thereof is reported to tolerate low pH, photoperiod, sand, savanna, virus, and waterlogging. It does not tolerate drought very well. Susceptibility to diseases and an apparent lack of seed-setting ability were partially overcomeby breeding programs initiated at Cedara. Tetraploid ($2n$= 36), pentaploid ($2n$= 45), and hexaploid ($2n$= 54) chromosome races occur. The species is self sterile, but certain combinations of strains of similar chromosome number and flowering data highly cross fertile (Rhind and Goodenough, 1976). ($2n$= 36)

Distribution

Widely distributed in Africa from Ethiopia to South Africa, also in Angola and South West Africa; introduced elsewhere e.g., Australia, Surinam, and Trinidad.

Ecology

Grows naturally in seasonally flooded valley bottoms in areas with 92–150 cm rainfall annually. It is indifferent to day length and will flower equally readily in long or short photoperiods. Flourishes on poorly drained or seasonally flooded land, and does not grow well under dry conditions. It has been successful on loams, sandy loams, and clay loams. Ranging from Warm Temperate Dry through Tropical Moist Forest Life Zones, Nile grass is reported to tolerate annual precipitation of 8 to 27 dm (mean of 4 cases = 13), annual temperature of 16° to 26°C (mean of 4 cases = 17), and pH of 4.3 to 7.3 (mean of 4 cases = 5.5). Rhind and Goodenough (1979) say it favors areas at elevation ca 600 to 2000 m, annual precipitation of 7.5–15 dm where the dry season is not too long.

Cultivation

Propagated by splits or cuttings of rhizomes or stolons. In some areas under humid conditions, grass is cut at hay stage and scattered over surface of land and then covered by a disc-harrow, as in Trinidad. Planted in holes 45 x 45 cm apart. Grass should be alllowed a full year to become established. Although its growth habit, having both rhizomes and stolons, serves for vegetative propagation and for exploring new ground, it also allows for carbohydrate storage in the rhizomes and brings some of the growing points below ground level where they are more effectively protected from frost, drought and burning. Has been used for improving natural moist pastures by planting splits or rhizome cuttings into existing natural grassland or plowed grassland following an arable crop. It was persistent although not very productive in Kenya and South Africa, and was reasonably successful in Rhodesia, Surinam and Swaziland (Bogdan, 1977). Seeds have a dormancy characteristic, germination improving after 9 months storage.

Harvesting

Grazed or cut for hay. Grass should be mown towards end of rainy season (summer) for hay or silage. Good aftermath is available for grazing during dry autumn and winter months when it is most valuable. A further flush can be grazed in spring during the early season.

Yields and Economics

Cut for hay, it yields 5–8 MT/ha (Bogdan, 1977). In one Rhodesian trial, it was one of the lowest yielders, at 7 MT/ha. Yields may attain 12.5 T/ha per season. In Natal, it averaged 9.8 MT/ha/a for three seasons (Theron and Arnott, 1979). A valuable pasture and fodder grass in areas of adaptation especially in humid tropical areas, as South Africa.

Energy

According to the phytomass files (Duke, 1981), annual productivity ranges from 4 to 12 MT/ha. Rhind and Goodenough (1979) report 2 to 18 MT DM (the latter is Swaziland). Such DM (dry matter) can be converted to energy by burning or conversion to alcohol or methane. According to Gohl (1981), ME (metabolizable energy) is 2.35 megacalories per kilogram of dry matter in hay.

Biotic Factors

The fungi, *Phyllosticta* sp. (leaf spot) and *Ustilago syntherismae* (smut) have been reported on this grass.

New Crops from Brazil

David Arkcoll

INTRODUCTION

Brazil and especially the unexplored regions of the Amazon, are extremely rich sources of plant germplasm with potential as new crops. Establishing the correct selection criteria is important to evaluate the true potential of the many promising species by calling attention to their assets and to the missing information and problems facing each species. This must be accomplished efficiently to justify the considerable investment in relevant research needed to develop the most promising plants into commercially viable crops.

Much of the current interest in new crops arises from the over production of traditional cereals and soybeans by major producer and exporting countries. This has led to the expensive practice of paying farmers to leave land idle in the USA, clearly an undesirable situation. Furthermore, traditional markets like Europe and the developing world are increasing their own production to relieve their shortages and reduce their imports. In some cases, these countries are even compelling in export markets with their surpluses. Examples are the explosion of rape seed in Europe and the large amount of soybeans now being produced by Brazil and Argentina. The tendency is to replace imports, hence the interest in the USA in finding alternatives to rubber (e.g. guayule), lauric oils (e.g. *Cuphea*) and cellulose (e.g. kenaf). This in turn will force traditional producers of these products to search for alternative crops as well.

There are many other good reasons for looking to new crops. These include the need to diversify from vulnerable dependence on the few major grain crops, the increasing interest in novelty foods, the industrial requirement for new compounds (e.g. new colorants, polyvinyl plastics), and new nutritional recommendations (e.g. gamma linolenic acid and new low calorie sweeteners). There is also a need for new crops to expand agriculture into marginal lands, especially in the tropics where few viable alternatives are found. New systems like agroforestry and biomass production also may require new crops.

SELECTING NEW CROPS

Ideally, having decided on a precise need, one would then look for a plant that has the desired characteristics. In practice what has tended to happen is that a botanist studies an interesting species and then tries to find a market for it. However, there are a series of characteristics that a wild plant must have if it is to ever make the large jump from botanical curiosity into viable crop. These include agricultural industrial and marketing characteristics (Arkcoll and Clement 1989). It should be easy to propagate, precocious, rustic, productive, be easy to harvest, and fit into current farm practice. The product must be easy to transport, store, and process. It should also be able to enter an established market at a competitive price or should be so attractive that a new market can be easily created.

We have been evaluating some of the most interesting species in this light in an effort to reduce the number to a few with the greatest potential. These and other species being developed in Brazil, are examined below to draw attention to the current stage of development, the missing data and the major problems that each one faces.

Bactris gasipaes (Peach palm, Pejebaye)

The Peach palm has attracted much attention in the last decade because of the texture and composition of the fruit mesocarp which is usually similar to that of a starchy cereal or root crop. It is consequently an important backyard tree in much of tropical Latin America and is used as a dietary staple by some Amerindian tribes (FAO 1986, Clement and Arkcoll 1989). The small crown and very high yield of some trees have suggested that it could be a useful plantation crop capable of producing large amounts of basic food in the wet tropics. We have been studying this potential as an important part of attempts to create ecologically attractive "food forests" to produce food from a permanent perennial system (Arkcoll 1978, 1979, 1984). Some introductions are very rich in oil (62% of mesocarp dry matter) suggesting that selecting for this character would be an interesting alternative because of the local and world markets for oil and protein rich meals (Arkcoll and Aguiar 1984). Most fruit have a bland taste that is not exotic enough to export, however some with a sweetish flavor may have more potential as a table fruit and at least expand local markets. The crop has only been grown on a large commercial scale for palmhearts in Costa Rica where over 2000 ha have been planted. The viability of this venture has been dependent on Government subsidy as it is difficult for plantations to compete with raw material coming from wild *Euterpe edulis* in Brazil. It is especially interesting as a source of palmhearts because it tillers and grows extremely fast (Gomes and Arkcoll 1987). Unfortunately, this vegetative vigor is proving to be a problem in fruit production as the fruit are produced too high above the ground to harvest after a few years. Precocity has been observed and there are signs of different growth rates suggesting that researchers might locate dwarf phenotypes. Managing tillers as in banana plantations, is also being considered. While individual stem yields of over 80 kg/yr. have been recorded, plantation yields have been frustrated by uneven bearing and tremendous fruit drop caused by poor pollination, drought, nutrient deficiencies, and principally pests and diseases. It is hoped that these problems can be controlled the crop is better understood. The successful selection and combination of desired characteristics could make this crop as important as the coconut in the wet tropics.

Astrocaryum aculeatum (Tucuma)

Tucuma, a heavily spined palm, is of interest because of the oily mesocarp and large kernel. A very brief examination of a few dozen introductions from the Manaus market, identified one with over 30% oil in the fresh fruit (Arkcoll et al. 1986, Arkcoll 1988). However, the species is only used locally for the direct consumption of the very thin pulp. This is bitter, nutty, and oily and rarely appreciated by the newcomer. However, it is so appreciated by locals that it costs as much as a dollar a dozen. Despite the premium price, tucuma is not grown commercially because there are enough native trees to satisfy demand. The species often becomes dominant in secondary forests because of resistance to fire and perhaps this characteristic can be used to recover worn out and abandoned pasture (FAO 1986). Difficulty in breaking seed dormancy and slow initial growth, have dampened the enthusiasm of research workers, but the large variation found in *A. vulgare* (Lima et al. 1986), a similar species with several stems, suggests that both species deserve more attention.

Acrocomia aculeata (Macauba)

Macauba palm is somewhat similar to the last palm in that its fruit have a large amount of both pulp and kernel oil and together with several very similar species, is widespread throughout central and Latin America often on poor soils. Its apparent tolerance to drought, makes it an attractive species for producing oil in regions that are too dry for the African oil palm and coconuts. The very high yield predictions of 6 t/ha (Wandeck and Justo 1982) have not been confirmed yet because of difficulties in breaking dormancy and slow early growth. Rapid hydrolysis of the mesocarp oil and difficulty in separating oil from the moist, fibrous and mucilaginous pulp, are among the other problems that still have to be faced (FAO 1986, Arkcoll 1988).

Cuphea spp.

The several hundred widely spread species in this genus have been of interest for about a decade, because of the unique composition of their seed oils. This varies with species, with the most interesting having over 80% lauric acid (Graham et al. 1981, Graham and Kleiman 1985). As most species are small herbaceous plants and many are adapted to the colder regions of highland Mexico, it is hoped that a mechanized crop suitable for temperate climates might be developed and reduce the dependency of lauric oil importing countries on wildly fluctuating supplies from coconut producers. Satisfactory yields have not been achieved in the USA because of shattering (Hirsinger and Knowles 1984, Hirsinger 1985). Attention has been drawn to several other problems such as seed dormancy, slow growth and the variable chromosome numbers and fatty acid composition observed in different species (Arkcoll 1988). Many wild species have not yet been studied and an effort is being made to collect this germplasm in order to locate desirable characteristics. Research is also in progress to obtain indehiscence through mutations and also to splice the appropriate *Cuphea* genes into a conventional crop such as rape (Thompson 1984, Tokay 1985). Sudden success in either of these efforts could lead rapidly to the development of an important new crop to supply the enormous market for lauric oils. It would also help to expand markets for medium chain (mixtures of C8 and C10) triglycerides that have considerable commercial potential, especially as lubricants and nutritionally desirable and medically useful oils (Bach and Babayan 1982). There is considerable interest in the pharmacological properties of extracts from the whole plant of some species used as a cure-all in local folk medicine in Brazil. There is now scientific confirmation of several potentially useful separate effects including depression of the central nervous system and the ability to reduce blood pressure in experimental animals (Ericeira et al. 1984).

Annona muricata (Soursop)

The large fruit of the soursop is much appreciated in several Latin American countries mainly as a sweetened juice but also as an ice cream and yoghurt flavoring. Several small commercial plantations are now in operation with about 2000 ha planted in Brazil and more planned. Yields have been disappointingly low, rarely reaching 7 t/ha in plantations sown from seed. Yields from individual trees very significantly suggesting that considerable improvement could be achieved via clonal selection. Production problems include low fruit set due to poor pollination and adverse climatic conditions and the attack of several devastating pests and diseases (FAO 1986). The flavor is somewhat volatile so pasteurized products are less attractive than fresh ones, and the off white color can become an unpleasant grey unless oxidation is prevented. The premature sale of several poor bottled products is thought to have limited market penetration. Frozen and chilled products seem more successful elsewhere (Arkcoll 1987), especially in regions where the fresh fruit is well known and appreciated.

Eugenia stipitata (Araçá-boi)

Araçá-boi, a little known fruit from the Western Amazon is very attractive in appearance and has an exquisite fragrance. Although extremely sour to the taste, the sweetened juice has performed well in acceptance trials. In early performance trials two-year old bushes produced high yields

(FAO 1986). The main production drawbacks are susceptibility to anthracnose, soft fruit texture and volatility of aroma. Consequently, resistance is being sought, firm fruit are harvested a little green with small loss in quality and the market will probably be restricted to fresh and frozen products. Studies on the aroma are planned as this may have a market in its own right.

Psidium angulatum (Araçá-Pera)

This is one of the most interesting of the many wild acidic guavas known collectively in Brazil as Araçá. Its sour juice is so concentrated that it must be diluted 10 times and well sweetened to produce a very acceptable drink. Once again, the delicate flavor is affected by heating so that fresh and frozen products are superior to pasteurized juices. The fruit comes from the eastern Amazon and there are only a few experimental plantations at the moment. Initial impressions are that the plant is rustic and productive although the yields are low compared to guavas. Interspecific breeding may be promising. The leathery skin should avoid damage during transport and together with the high acidity, give some resistance to insect attack. Fruit are quite variable and clonal selection is needed to obtain superior introductions (FAO 1986). Another wild acidic guava receiving attention *is Feijoa sellowiana* from the extreme south of the country (Mattos 1986).

Spondias lutea (Taperebá, Cajá)

Taperebá or Cajá is one of the most popular fruit in the North and Northeast of Brazil. The fruit itself is rarely eaten directly as the pulp is thin and usually quite sour, however it makes a superb sweetened juice and ice cream or ice lollipop of excellent flavor. The flavor is volatile and pasteurized products are not attractive. No plantations are known which is surprising as the demand is in excess of the current supply from the many large trees found scattered at low density over a wide area of forest. Trees grow fast from seed but take over 5 years to fruit. Like most *Spondias,* they can be propagated easily from large cuttings to fruit quickly and reduce the size of the trees. This is important as the very soft fruit are often bruised when harvested from the ground beneath large trees. Most fruit are small and have a large seed and thin layer of pulp so a search is on for fruit said to be as large as *S. dulcis*. The tree appears to be rather rustic and productive although no data on yields is available (FAO 1986).

Theobroma grandiflorum (Cupuassu)

A highly perfumed pulp surrounding the seeds of Cupuassu, a large relative of Cacao, is much appreciated in the Amazon region for making sweetened juice, ice cream or charlotte desserts. It fetches the highest price of all fruits in the local markets and there are now several hundred hectares planted to supply the Belem and Manaus markets. Newcomers often find the aroma a little overpowering at first, but soon acquire a liking for it. This volatile aroma could be extracted and might find a market in the flavor and perfume industry. Yields are low in the field (Calzavara 1987) and there is only about 40% pulp in most fruit. Seedless fruit are known with larger amounts of pulp. However, the seed can be made into a number of chocolate-like products and so could become a useful byproduct if large scale production becomes viable (Arkcoll and Clement 1988). Selection for higher yield and resistance to witches broom is needed (FAO 1986).

Couepia longipendula (Egg nut)

Apart from the major Brazilian nuts, (cashew and brazil) there are many other interesting examples. One of these is *Couepia longipendula* (egg nut) because of its excellent flavor. This large tree is common in the forest around Manaus but although widely eaten in the rural areas, it never reaches the local market so is little known. The shell is hard and thick requiring an ax to break it. Nuts with thinner shells are said to exist in the forest. Trees are rather slow growing so grafting onto the more vigorous rootstock of *C. subcordata* is being considered (FAO 1986). The kernels are rich in oil which appears to have some unusual polyunsaturated fatty acids.

Couma utilis (Sorva)

Over 5000 t of sorva latex are exported from this plant each year as a substitute for chicle gum. Much of it is obtained by destructive tapping of wild trees. Because these are being decimated quickly, *Achras sapota* trees are slow growing and increasingly rare and industrial substitutes are contaminated with heavy metals, there is considerable interest in establishing plantations of *C. utilis*. A few experimental trees have grown very fast on poor soil but tapping yields have not been obtained yet. The tree is also very decorative and the good flavored fruit are sold in local markets. The fruit might become a useful subproduct of latex plantations, however, they are too soft and not thought to be interesting enough to consider more seriously in their own right (FAO 1986).

Paullinia cupana (Guaraná)

Roasted seeds of this plant are ground up to make an interesting cola type drink called guaraná. Over 1000 t are now produced annually in Brazil on about 5000 ha of poor oxisols. Vegetative propagation of selected plants is starting to increase yields and the local market is now thought to be saturated. An export drive is now in progress and seems to be having some success, especially in Japan. The drink owes much of its popularity to the stimulation produced by its high caffeine content and the widely held belief in its rejuvenating and aphrodisiacal properties (Cavalcanti 1988). Well formulated products can be very good although several of the most popular brands contained very little or no real guarana until recent legislation, aimed at supporting growers, made the inclusion of a small amount compulsory.

Stevia rebaudiana (Stevia)

Dried leaves from this small shrub from the south of Brazil, have been used as a local sweetener and cure-all for generations. The main active ingredient, stevioside, is said to be up to 300 times as sweet as sucrose. Extraction processes have been developed in Japan and Brazil and over 100 t/year sold in a purified form until recently when doubt has been cast over its toxicity and the mutagenicity of the metabolite, steviol (Pezzuto et al. 1985, S. Cascon pers. commun.). Studies are in progress to clarify this situation and some derivatives that are believed to be safe, have been synthesized and patented (Dubois et al. 1984). About a 100 ha are now planted annually in Brazil to satisfy the local demand, mainly by natural health shops for dried leaves. Yields of 2 to 3 t/ha of leaf with about 10% stevioside are obtained.

Bixa orellana (Annatto)

Restrictions on the use of many synthetic colorants and the relative instability of most other carotenoids, are leading to the increasing use of bixin, especially in the dairy industry. World production, estimated at about 3,000 t of annatto seed in 1983 (Anand 1983), is now thought to have risen rapidly to over 10,000 t, about half of which comes from Brazil. Until recently, annatto (or urucum as it is known in Brazil) was little more than a back garden crop. However, high prices and the good yields have resulted in a few farmers planting it on a larger scale. Yields, after 4 years, can pass 2 t/ha with 0.9 to 6.9% (average about 2.5%) bixin covering the seeds in a sticky resin (Nicholson 1964, I. Guimaraes pers. commun.). Yields from seedling trees are very variable as the crop is cross pollinated. Variation in the exact composition of the colorants in the final extracted products limits marketability. Vegetative propagation is easy and should make rapid advances possible especially if the crop is selected for a combination of yield and bixin content. The relatively small market for colorants could quickly become saturated so there is interest in the potential of this rustic perennial crop as an alternative grain for growing on exhausted tropical soils. The high yield potential despite any scientific attempts at improvement, makes it a very promising crop.

CONCLUSIONS

The above species have been identified by a series of multidisciplinary criteria as some of the best Brazilian options for development into new crops. They are found in various stages of development from early germplasm collection to small commercial plantations. Attention is drawn to some of the missing data and problems that they face if they are to overcome the risks of early commercial plantations and make the large jump from botanical curiosities to useful crops. Appropriate research is now underway to collect the missing data and to resolve the problems, however it is bedeviled by a lack of continuity. Germplasm maintenance and work with tree crops, especially breeding, are very long term projects that funding bodies have failed to face so much research has been wasted in the past (Arkcoll and Clement 1989). Thought is needed on how one forms and keeps a multidisciplinary team together over many years in countries with wildly fluctuating economies and poor working conditions.

It is also well known that few crops have been successfully exploited on a large scale near their center of diversity because of indigenous pests and diseases, so that local research will probably benefit other regions of the globe. Thus, improvements in the exchange of germplasm are important if many new crops are to be fully evaluated and developed.

Horsechestnut

Aesculus hippocastanum L.

Other common names.—Hippocastanum, bongay, konker-tree

Habitat and range.—This tree is largely cultivated in this country as an ornamental shade tree and occasionally escapes from cultivation.

Description.—The horsechestnut is a rather large tree, usually reaching 40 feet or more in height. The large leaves are composed of five to seven leaflets from 4 to 8 inches long, pointed, and broader at the top than at the base. In June it produces handsome flower clusters sometimes a foot in length, consisting of large white flowers spotted with yellow and red. The fruit is round and prickly and contains a large shining brown nut.

Part used.—Horsechestnut bark is collected in autumn, and preference is given to the bark from the younger branches.

Figure 66.—Horsechestnut (*Aesculus hippocastanum*)

Mushroom

Agaricaceae *Agaricus* sp.

Source: Magness et al. 1971

The term mushroom applies to edible, fleshy fungi, either gathered from the wild or grown in cultivation. Under cultivation, mushrooms are grown mainly in the dark, in caves or light-tight buildings, with temperature, moisture and ventilation control. The "spawn" or mycelium is seeded in specially prepared compost in beds or suitable containers. After the mycelia have spread through the compost, a layer of soil or "casing" is applied. The mushrooms, the fruiting bodies of the fungi, first appear at the soil surface 6 or more weeks after seeding with spawn, and continue to appear. They are usually harvested by cutting off the cap with a small portion of the stem before the caps have become fully expanded. Beds produce the main crops in the first 50 days after fruiting starts, but may be retained with light production for several months.

Season, seeding spawn to first harvest: 6 to 8 weeks.

Production in U.S.: 100,000 tons.

Use: Food flavoring, soups, sometimes as pot vegetable, or raw in salads.

Part of plant consumed: Fruiting "cap" and stem.

Sesbania grandiflora (L.) Pers.

Fabaceae
Agati, Corkwood tree, West Indian pea

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

The tender leaves, green fruit, and flowers are eaten alone as a vegetable or mixed into curries or salads. Flowers may be dipped in batter and fried in butter. Tender portions serve as cattle fodder, (overeating is said to cause diarrhea). Ripe pods apparently are not eaten. The inner bark can serve as fiber and the white, soft wood not too durable, can be used for cork. The wood is used, like bamboo, in Asian construction. The tree is grown as an ornamental shade tree, and for reforestation. In Java, the tree is extensively used as a pulp source. A gum resembling kino (called katurai), fresh when red, nearly black after exposure, exudes from wounds. This astringent gum is partially soluble in water and in alcohol, but applied to fishing cord, it makes it more durable. Pepper vines (*Piper nigrum*) are sometimes grown on and in the shade of the agati. According to NAS (1980a), this small tree produces firewood, forage, pulp and paper, food, and green manure and appears to hold promise for reforesting eroded and grassy wastelands throughout the tropics. It combines well with agriculture (agroforestry) in areas where trees are not normally grown and becomes an important fuelwood source. Dried and powdered bark is used as a cosmetic in Java.

Allen and Allen enumerated three undesirable features (1) short lived (2) shallow-rooted and subject to wind throw, and (3) prolific seeder, the pods often considered a litter. An aqueous extract of bark is said to be toxic to cockroaches.

Folk Medicine

Resorted to be aperient, diuretic, emetic, emmenagogue, febrifuge, laxative, and tonic, agati is a folk remedy for bruises, catarrh, dysentery, eyes, fevers, headaches, smallpox, sores, sorethroat, and stomatitis (Duke and Wain, 1981). Bark, leaves, gums, and flowers are considered medicinal. The astringent bark was used in treating smallpox and other eruptive fevers. The juice from the flowers is used to treat headache, head congestion, or stuffy nose. As a snuff, the juice is supposed to clear the nasal sinuses. Leaves are poulticed onto bruises. Rheumatic swellings are poulticed or rubbed with aqueous decoctions of the powdered roots of the red-flowered variant. In India the flowers are sacred to Siva, representing both the male and female sex organs; still I find no mention of their use as aphrodisiacs. Ayurvedics, believing the fruits to be alexeteric, laxative, and intellectually stimulating, prescribe them for anemia, bronchitis, fever, pain, thirst, and tumors; the flowers, apertif and refrigerant, for biliousness, bronchitis, gout, nyctalopia, ozoena, and quartan fever; the root for inflammation, the bark as astringent; leaves, alexeteric, anthelmintic, for epilepsy, gout, itch, leprosy, nyctalopia, and ophthalmia. Yunani consider the tonic leaves useful in biliousness, fever, and nyctalopia. Indians apply the roots in rheumatism, the juice of the leaves and flowers for headache and nasal catarrh. Mixed with stramonium and pasted, the root is poulticed onto painful swellings. In Amboina, flower juice is squeezed into the eye to correct dim vision. The bark is used in infusions for smallpox. Cambodians consider the flowers emollient and laxative, the bark for diarrhea, dysentery, and paludism. Malayans apply crushed leaves to sprains and contusions. They gargle with the leaf juice to cleanse the mouth and throat. In small doses, the bark is used for dysentery and sprue, in large doses, laxative, in still larger doses, emetic. Pounded bark is applied to scabies. Philippines use the pounded bark for hemoptysis. The powdered bark is also recommended for ulcers of the mouth and alimentary canal. In Java, the bark is used for thrush and infantile disorders of the stomach. Leaves are chewed to disinfect the mouth and throat.

Chemistry

Per 100 g, the leaf is reported to contain 73.1 g H_2O, 8.4 g protein, 1.4 g fat, 11.8 g NFE, 2.2 g fiber, 3.1 g ash, 1,130 mg Ca, 80 mg P, 3.9 mg Fe, 9,000 IU vit. A, 0.21 mg thiamine, 0.09 mg riboflavin, 1.2 mg niacin, and 169 mg ascorbic acid. Leaves contain (ZMB) per 100 g, 321 calories, 36.3 g protein, 7.5 g fat, 47.1 g carbohydrate, 9.2 g fiber, 9.2 g ash, 1684 mg Ca, 258 mg P, 21 mg Na, 2,005 mg K, 25,679 μg β-carotene equivalent, 1.00 mg thiamine, 1.04 mg riboflavin, 9.17 mg niacin and 242 mg ascorbic acid. The flowers (ZMB) contain per 100 g, 345 calories, 14.5 g protein, 3.6 g fat, 77.3 g carbohydrate, 10.9 g fiber, 4.5 g ash, 145 mg Ca, 290 mg P, 5.4 mg Fe, 291 mg Na, 1,400 mg K, 636 μg β-carotene equivalent, 0.91 mg thiamine, 0.72 mg riboflavin, 14.54 mg niacin, and 473 mg ascorbic acid. Seeds (ZMB) contain 36.5% CP, 7.4% fat, 51.6% total carbohydrate, and 4.5% ash. The seed oil contains 12.3% palmitic, 5.2% stearic, 26.2% oleic, and 53.4% linoleic acids. The seed testa, which constitutes 20% of the seed, contains 5.2% moisture, 1.3% ash, 0.8% fat, 2.7% CF, 0.1% free reducing sugars, 1.4% sucrose, 2.8% nitrogen, 6.3%

pentosans, and 65.4% carbohydrates. Yields of 33% galactomannans are reported for alkali extraction of the testae. Seeds allowed to germinate (sprouts) for 120 hours increased vit. C content from 17–166 mg/100 g. Extracellular invertase of *Rhizobia japonicum* and its role in free sugar metabolism in the developing root nodules was studied. The enzyme hydrolyzed sucrose extracellularly, and its release was substrate inducible. 0.1 m β-mercaptoethanol released the cell-bound form of this enzyme. The production of invertase was low when glucose, galactose, mannose, fructose, and farrinose were used as carbon sources in the growth medium. In the developing nodules sucrose was the major sugar. The content of fructose was low in comparison with that of glucose, suggesting that in the nodules the fructose is converted to glucose prior to its entry into the bacterial cell. The content of glucose synchronized with the pattern of change in the activity of invertase in the nodules (Singh et al, 1980).

Description

A small erect quick-growing short-lived soft-wooded tree to 10 m tall, 25 cm DBH, sparsely branched. Bole straight and cylindrical, the wood white and soft. Bark light gray, corky, deeply furrowed. Leaves pinnate, 15–30 cm long, with 16–30 pairs of linear oblong leaflets. Racemes 2.5 cm long. Flowers 2–4, white to pink, pendulous the corolla 7–9 cm long. Pods 50–60 cm long.

Germplasm

Reported from the Indochina-Indonesia Center of Diversity, agati, or cvs thereof, is reported to tolerate drought, heavy soils, poor soil, and water-logging. Widely cultivated as ornamental or curio vegetable in tropical Asia. ($2n$ = 14, 24).

Distribution

Native to many Asian countries, e.g., India, Malaysia, Indonesia, and the Philippines from sea level to 800 m, agati commonly grows on dikes between rice paddies, along roadsides, and in backyard vegetable gardens. It has been widely distributed in southern Florida and the West Indies and from southern Mexico through most countries of Central America down to South America. Cultivated in Mauritius (NAS, 1980a).

Ecology

Apparently frost-sensitive, this species seems limited to the tropics. Ranging from Tropical Dry through Tropical Moist Forest Life Zones, agati is reported to tolerate annual precipitation of 4.8 to 22.5 dm (mean of 11 cases = 15.1), annual temperature of 24.3 to 26.7°C (mean of 8 cases = 25.6), and pH of 6.6 to 8.5.

Cultivation

Propagated readily by seeding or cuttings, requiring little maintenance. It has been aerially seeded, apparently with success. For reforestation, Mendoza (1980) recommends spacing cuttings ca 1 m long at 4 x 4 m. The saplings could serve as a nurse crop for mahogany, Banquet pine, etc. Cuttings should be set out at the beginning of the rainy season. When grown as shade plant for coconut seedlings, agati is sown in India in June and July, putting 3–4 seed per hole in a narrow channel, 30 cm x 30 cm, ca 1 m from the coconut seedlings.

Harvesting

When cultivated for fodder, agati is usually cut when ca 1 m tall. Indonesian foresters, growing the species for fuelwood, harvest on a 5-year rotation. One hectare can yield three m^3 of stacked fuelwood in a 2-year rotation. After the plant is harvested, shoots resprout with such vigor that they seem irrepressible. The tree's outstanding quality is its rapid growth rate, particularly during its first 3 or 4 years (NAS, 1980a).

Yields and Economics

Planted at 90 cm intervals, an agati plant yields 4.5–9.1 kg lvs/yr, which translates to ca 12,000 plants per hectare yielding 50–100 MT leaves per year per hectare (C.S.I.R., 1948–1976), about 75% of which is water, suggesting DM yields of 12–25 MTha. Javanese have obtained 55 MT green matter per ha in 6–7 months. On a black, poorly structured clay, pH 8.5, in Australia, agati outgrew all other species tested, attaining 4.3–5.5 (-8.3) m in one year's growth.

Energy

Long been used as firewood in Southeast Asia, has been planted in several areas in Indonesia to provide fuel and other products in "turinisation" projects (after turi, the indigenous name). However, the wood is white, soft, and has a rather low specific gravity of about 0.42, which is poor for fuelwood. Wood yields of 20–25 m^3 per ha per year are commonly achieved in plantations in Indonesia. Even when planted only along the edges of agricultural fields, as in Java, yields of 3 m^3 of stacked firewood per ha from 2-year rotation periods have been recorded. The wood weighs 512 kg m^3. Charcoal is used for gunpowder (C.S.I.R., 1948–1976). If 25 MT of dry leaves are available, then certainly there must be 5–10 MT stem as well, all of which could be diverted to energy.

Biotic Factors

Described as very susceptible to nematodes, agati is said to have been damaged by birds and grasshoppers in northern Australia. *Colletotrichum capsici* causes seedling blight, forming elongated or oblong cankers on the collar region of affected seedlings. The cankers, controlled with a Bordeaux spray, have black bristle-like tufts of setae. Nematodes include *Heterodera trifolii* and *Meloidogyne* sp. (Golden, p.c. 1984). *Cercospora sesbaniae* infects agathi. The Drosophilid fly *Protostegana lateralis* is a serious pest in Tamil Nadu. The maggots bore into the tender shoots of mature plants causing a gradual wilting of affected parts. The weevil *Alcidodes buko* causes serious damage to young crop both in adult and larval stage. It bites holes through leaves and bores the stem causing gall-like swellings DDT (0.05%) and BHC dust (5%) are cheap and effective; Product 1250 and Parathion are also effective against the grub. The larvae of *Azygophleps scalaris* tunnel through the stem and eat the contents leaving only the epidermis. The plant becomes weak and breaks off at the slightest jerk. Uprooting the stumps immediately after harvesting and burning them may prove effective means of control. *Otinotus oneratus*, the common 'tree hopper' infests agati from July to February (C.S.I.R., 1948–1976). *Sesbania* seedlings are highly receptive to infection by their homologous rhizobia, but different species have restricted susceptibility profiles. Sesbania rhizobia have a rather restricted host range. Rhizobia from alfalfa, clover, lupines, peas, soybeans failed to nodulate Sesbania species and vice versa.

Ravetta, D. and A. Soriano. 1990. *Colliguaya integerrima* (Euphorbiaceae): A possible new crop for temperate deserts. p. 267. In: J. Janick and J.E. Simon (eds.), Advances in new crops. Timber Press, Portland, OR.

Colliguaya integerrima (Euphorbiaceae): A Possible New Crop for Temperate Deserts

Damian Ravetta and Alberto Soriano

Patagonia, occupying more than one third of Argentina, has an and cold climate. Large areas have no more than 150 mm of annual precipitation and very short periods without frosts. These conditions make traditional crop production impossible. Wool and meat production by extensive sheep grazing is the only economic option at the present time. The development of crops adapted to these extreme conditions, could give an economic alternative to this and other regions with similar environment constrains.

Colliguaya integerrima Gill. et Hook. ex Hook. (Euphorbiaceae), a native shrub of Patagonia Argentina and Chile, produces seeds with high drying oil content and is being evaluated as a potential new crop for this region.

Natural populations of this species from three different locations in Patagonia, Argentina were studied in order to assess seed production, oil content and quality of different type of seeds. Plants producing 400 g of seeds were not difficult to find. Proximate analysis of the seed is: 35% oil, 40% chaff, and 25% of meal (containing 51% of protein, with a lysine value of $3.17_g/16_g$ N_2. This meal was not toxic when included in mice diet. Latex production and composition is another potentially useful characteristic of *Colliguaya*. The adaptation of this species to temperate semi-deserts, together with other features such as seed attachment to the mother plant, the ease with which dormancy can be broken by chilling or storage, and the possibility of asexual propagation by rhizome cuttings, increase the interest and possibilities of domestication and cultivation of the species.

McDaniel, R.G. 1990. Agave: A new crop for the desert southwest. p. 268. In: J. Janick and J.E. Simon (eds.), Advances in new crops. Timber Press, Portland, OR.

Agave: A New Crop for the Desert Southwest

Robert G. McDaniel

A number of agave species have been cultivated throughout the world for some time. Notable among these are *Agave sisalana*, grown in plantations in Africa Asia and Brazil as a source of sisal fiber *Agave fourcroydes*, grown in Mexico and the Caribbean Islands, providing henequen fiber; *Agave tequilana* in Mexico for tequila liquor, and various species for production of hecogenin and smilagenin, pharmaceutical steroidal sapogenins.

Several multi-hectare agave plantations have been established in Southern Arizona since 1980 to evaluate growth potential of both native and introduced agave species under desert conditions. This is the first extensive evaluation of agave as a row crop in the United States. With one or two supplemental irrigations at the Marana Agricultural Center, several agave species achieved biomass accumulations greater than 100 kg over a three-year growth period. Infra-red thermal measurements indicated that all species showed CAM metabolism under periods of high temperature stress (in excess of 40°C) with adapted desert species responding more quickly to irrigation than introduced tropical species. Root and crown tissues of *A. americana,* the fastest growing species tested, contained 50% carbohydrate on a dry weight basis, which would qualify them as a viable botanical ethanol source. HPLC analyses of steroid content of these species are underway, as are fiber analyses. In summary, these data support agave as a potential multi-use crop for the and Southwest. Ability to grow with less than 30 cm rainfall per year makes agave a low input crop adaptable to large areas of this region presently not under cultivation.

Glumac, E. and J. Cowles. 1990. Chinese tallow: Multipurpose tree crop. p. 268. In: J. Janick and J.E. Simon (eds.), Advances in new crops. Timber Press, Portland, OR.

Chinese Tallow: Multipurpose Tree Crop

Edward Glumac and Joe Cowles

The Chinese tallow tree, a naturalized species that thrives and proliferates in the heavy clay soils of the Gulf coastal region, could be exploited economically if harvesting techniques and markets are established. Rapid, pest free growth of 10 t/ha-yr of dry wood make it suitable for energy cropping under a short-rotation coppicing system. The tallow tree bears seed after 3 years with yields of up to 12 t/ha-yr from mature wild trees. The seeds contain a saturated solid fat, or tallow, on the outside and an unsaturated liquid inside the kernel. Commercial and industrial raw materials obtainable from the seed are fuel oil drying oil, surfactants, soaps, emulsifiers, cocoa butter, seed meal, confections, detergents, and bioactive extracts. Other economic benefits are as a forage crop for honey production, firewood, soil reclamation, and ornamental planting.

Ming, L.C. 1999. *Ageratum conyzoides*: A tropical source of medicinal and agricultural products. p. 469–473. In: J. Janick (ed.), Perspectives on new crops and new uses. ASHS Press, Alexandria, VA.

Ageratum conyzoides: A Tropical Source of Medicinal and Agricultural Products

Lin Chau Ming

Ageratum conyzoides L., Asteraceae, is an annual herbaceous plant with a long history of traditional medicinal uses in several countries of the world and also has bioactivity with insecticidal and nematocidal acitivity. This tropical species appears to be a valuable agricultural resource.

BOTANY

Ageratum is derived from the Greek "*a geras*," meaning non-aging, referring to the longevity of the flowers or the whole plant. The specific epithet "*conyzoides*" is derived from "*kónyz*," the Greek name of *Inula helenium*, which it resembles (Kissmann and Groth 1993).

The synonyms of *A. conyzoides* include *A. album* Stend; *A. caeruleum* Hort. ex. Poir.; *A. coeruleum* Desf.; *A. cordifolium* Roxb.; *A. hirsutum* Lam.; *A. humile* Salisb.; *A. latifolium* Car.; *A. maritimum* H.B.K.; *A. mexicanum* Sims.; *A. obtusifolium* Lam.; *A. odoratum* Vilm. and *Cacalia mentrasto* Vell. (Jaccoud 1961). In Brazil, *A. conyzoides* has the following vernacular names: *catinga de bode*, *catinga de barrão, erva de são joão*, *maria preta, mentrasto, erva de são josé*, *picão roxo, erva de santa-lúcia, camará-opela, agerato, camará apeba, camará iapó, camará japê, erva de santa maria, macela de são joão, macela francesa, matruço* (Jaccoud 1961; Oliveira et al. 1993).

Ageratum ranges from Southeastern North America to Central America, but the center of origin is in Central America and the Caribbean. Most taxa are found in Mexico, Central America, the Caribbean, and Florida. *Ageratum conyzoides* now is found in several countries in tropical and sub-tropical regions, including Brazil (Baker 1965; Lorenzi 1982; Correa 1984; Cruz 1985).

Johnson (1971), classifies two subspecies, *latifolium* and *conyzoides*. Subspecies *latifolium* is found in all the Americas and subsp. *conyzoides* has a pantropical distribution. The basic chromosome number is $2n = 20$ but natural tetraploids are found. *A. conyzoides* subsp. *latifolium* is diploid and *A. conyzoides* subsp. *conyzoides* is tetraploid.

Ageratum conyzoides is an erect, herbaceous annual, 30 to 80 cm tall; stems are covered with fine white hairs, leaves are opposite, pubescent with long petioles and include glandular trichomes. The inflorescence contain 30 to 50 pink flowers arranged as a corymb and are self-incompatible (Jhansi and Ramanujam 1987; Kaul and Neelangini 1989; Ramanujam and Kalpana 1992; Kleinschimidt 1993). The fruit is an achene with an aristate pappus and is easily dispersed by wind. In some countries the species is considered a weed, and control is often difficult (Lorenzi 1982; Scheffer 1990; Kalia and Singh 1993; Lam et al. 1993, Paradkar et al. 1993; Waterhouse 1993; Kshatriya et al. 1994). Seeds are positively photoblastic, and viability is often lost within 12 months (Marlks and Nwachuku 1986; Ladeira et al. 1987). The optimum germination temperature ranges from 20 to 25°C (Sauerborn and Koch 1988). The species has great morphological variation, and appears highly adaptable to different ecological conditions.

PHYTOCHEMICAL CHARACTERISTICS

There is high variability in the secondary metabolities of *A. conzyoide* which include flavonoids, alkaloids, cumarins, essential oils, and tannins. Many of these are biologically active. Essential oil yield varies from 0.02% to 0.16% (Jaccoud 1961). Vyas and Mulchandani (1984) identified conyzorigum, a cromene. Borthakur and Baruah (1986) identified precocene I and precocene II, in a plant collected in India. These compounds have been shown to affect insect development, as antijuvenile hormones, resulting in sterile adults (Borthakur and Baruah 1987). Ekundayo et al. (1988) identified 51 terpenoid compounds, including precocene I and precocene II. Gonzales et al. (1991) found 11 cromenes in essential oils, including a new cromene, 6-angeloyloky-7-methoxy-2,2-dimethylcromen. Vera (1993), in Reunion, found ageratocromene, other cromenes, and beta cariophylene in its essential oil. Mensah et al. (1993) and Menut et al. (1993) reported similar yields of precocene I in the essential oil of plants collected in Ghana.

Vyas and Mulchandani (1986), in India, identified flavones, including some considered new such as *ageconyfavones* A, B, and C. Horrie et al. (1993) reported hexametoxyflavone. Ladeira et al. (1987) in Brazil, reported three cumarinic compounds, including 1-2 benzopirone. The species contains alkaloids, mainly the pirrolizidinic group, which suggest that it may be a good candidate for pharmacological studies. Trigo et al. (1988) found several alkaloids, including 1,2-desifropirrolizidinic and licopsamine which can have hepatotoxic activity. Alkaloids also were found by Weindenfeld and Roder (1991) in a hexane extract of *A. conyzoides* in Africa.

FOLK MEDICINAL USES AND PHARMACOLOGICAL STUDIES

A. conyzoides is widely utilized in traditional medicine by various cultures worldwide, although applications vary by region. In Central Africa it is used to treat pneumonia, but the most common use is to cure wounds and burns (Durodola 1977). Traditional communities in India use this species as a bacteriocide, antidysenteric, and antilithic (Borthakur and Baruah 1987), and in Asia, South America, and Africa, aqueous extract of this plant is used as a bacteriocide (Almagboul 1985; Ekundayo et al. 1988). In Cameroon and Congo, traditional use is to treat fever, rheumatism, headache, and colic (Menut et al. 1993; Bioka et al. 1993). In Reunion, the whole plant is used as an antidysenteric (Vera 1993). The use of this species in traditional medicine is extensive in Brazil. Aqueous extracts of leaves or whole plants have been used to treat colic, colds and fevers, diarrhea, rheumatism, spasms, or as a tonic (Penna 1921; Jaccoud 1961; Correa 1984; Cruz 1985; Marques et al. 1988; Negrelle et al. 1988; Oliveira et al. 1993). *A. conyzoides* has quick and effective action in burn wounds and is recommended by Brazilian Drugs Central as an antirheumatic (Brasil 1989).

Several pharmacological investigations have been conducted to determine efficacy. Duradola (1977) verified inhibitory activities of ether and chloroform extracts against in vitro development of *Staphylococus aureus*. Almagboul et al. (1985), using methanolic extract of the whole plant, verified inhibitory action in the development of *Staphylococus aureus*, *Bacillus subtilis*, *Eschericichia coli*, and *Pseudomonas aeruginosa*. Bioka et al. (1993) reported effective analgesic action in rats using aqueous extract of *A. conyzoides* leaves (100 to 400 mg/kg). Assays realized in Kenia, with aqueous extract of the whole plant, demonstrated muscle relaxing activities, confirming its popular use as an antispasmotic (Achola et al. 1994).

In Brazil, assays conducted by State University of Campinas and Paraiba Federal University) showed promising results. Marques Neto et al. (1988) in clinic trials with patients with arthrosis, administered aqueous extract of the whole plant, and reported analgesic effect in 66% of patients and improvement in articulation mobility in 24%, without side effect. Mattos (1988), using aqueous extract of the whole plant, verified effective clinical control of arthrosis, reporting a decrease in pain and inflammation or improvement in articulation mobility, after a week of treatment.

BIOACTIVITY

Ageratum conyzoides has bioactive activity that may have agricultural use, as shown by several research investigations in different countries. Pereira in 1929, cited by Jaccoud (1961), reported use of the leaves as an insect (moth) repellent. The insecticide activity may be the most important biological activity of this species. The terpenic compounds, mainly precocenes, with their antijuvenile hormonal activity are probably responsible for the insecticide effects.

Assays conducted in Colombia by Gonzalez et al. (1991) showed activity of this species against

Musca domestica larvae, using whole plant hexane extract. Vyas and Mulchandani (1980) reported the action of cromenes (precocenes I and II), isolated from *Ageratum* plants, which accelerate larval metamorphosis, resulted in juvenile forms or weak and small adults.

Ekundayo et al. (1987) also demonstrated the juvenilizing hormonal action of precocene I and II in insects, the most common effect being precocious metamorphosis, producing sterile or dying adults. Raja et al (1987), using *A. conyzoides* methanolic extract from fresh leaves (250 and 500 ppm) in the fourth instar of *Chilo partellus* (Lepidoptera, Pyralidae), a sorghum pest, observed the presence of a dark stain in the insects' cuticle and immature pupae formation, both symptoms of deficiency of juvenile hormone.

A. conyzoides also induces morphogenetic abnormalities in the formation of mosquitoes larvae (*Culex quinquefasciatus*, *Aedes aegypt*, and *Anopheles stephensi*). This has been verified using petroleum ether extracts (5 and 10 mg/L) of the whole plants. The larvae showed intermediary stages between larvae–pupae, discolored and longer pupae, as well as incompletely developed adults (Sujatha et al. 1988). Extracts of the flowers of this species showed activity against mosquitoes (*Anopheles stephensi*), in the last instar, showing DL 50 with 138 ppm (Kamal and Mehra 1991).

Cetonic extracts of the species produced significant effects against the mosquito, *Culex quinquefasciatus*, in India, when applied to fourth instar larvae and adult females. In larvae, the extracts produced altered individuals, intermediate between larvae and pupae, unmelaninized and with inhibition of development, as well as adults with deformed wings muscles. In female adults, there was loss of fecundity, lower eggs production, and production of defective eggs (Saxena et al. 1992). Similar results were observed in larvae *of Anopheles stephensi* and *Culex quinquefasciatus* in others essays, confirming the antijuvenile potential of *A. conyzoides* (Saxena and Saxena 1992; Saxena et al. 1994).

The species also has potential use in controlling other pests. Shabana et al. (1990), using aqueous extract of the whole plant, verified reduction of larvae emergence of *Meloidogyne incognita*. Pu et al. (1990) and Liang et al. (1994), verified that plants of *A. conyzoides* in *Citrus* orchards sheltered predators of the spider *Panonychus citri*, suggesting that its development in orchards is beneficial. Other *Citrus* spiders populations, *Phyllocoptruta oleivora* and *Brevipalpus phoenicis* were decreased with maintenance of *A. conyzoides* in the orchards and a reduction of leprosy virus was noted (Gravena et al. 1993)

The presence of *A. conyzoides* can also be used as an seed inhibitor, decreasing development of several herbaceous plants. Jha and Dhakal (1990) in Nepal, reported that an aqueous extract of the aerial part or roots of this species (15 g of aerial part or 3 g of roots in 100 ml of water, during 24 h) inhibited germination of wheat and rice seeds while Prasad and Srivastava (1991) in India, reported a lower germination index in peanut seeds with aqueous extract.

CULTURAL STUDIES

Magalhaes et al. (1989) in Brazil evaluated fertilizer studies and plant density on biomass production of *A. conzyzoides.* The higher the N level, the higher the biomass production (dry weight basis). Optimum spacing was 70 cm between rows and 50 cm between plants. Biomass yields was 1.3 t (dry weight)/ha.

Correa Jr. et al. (1991) obtained biomass yields of 3.3 to 5.3 t (fresh wt)/ha. Essential oil content was 0.02% (fresh wt) and 0.16 % (dry wt) in the preflowering state. Preliminary data of Ming (1998) indicated that essential oils, higher in leaves than in flowers, peaked during early-flowering.

FUTURE POTENTIAL

There are some small pharmaceutical companies in Brazil using *A. conyzoides* as a raw material for phytochemicals. The demand is increasing year by year and this situation warrants further scientific research to develop both agricultural and medical uses. Research on medicinal plants should be focused primarily on species whose pharmaceutical activities have already been demonstrated. Positive preliminary clinical assays of *A. conyzoides* clearly demonstrate that this species may be an important economic resource in several tropical countries. The use of this species as a natural biocide or agent for pest management particularly requires further investigation.

Wheatgrasses

Gramineae, or Poaceae

Agropyron species (syn. *Thinopyrum* sp.)

Source: Magness et al. 1971

The wheatgrasses are hardy, mainly perennial, erect grasses, important especially in the Northern Great Plains. The seed heads resemble wheat heads, hence the name. They may form sods or grow in bunches. They are suitable feed for all classes of livestock. They produce growth early in the spring.

Around 150 species of *Agropyron* are known in the temperate regions of the world, about 30 in North America.

Last update September 22, 1997

Fairway wheatgrass

Gramineae, or Poaceae *Agropyron cristatum* (L.) Gaertn.

Source: Magness et al. 1971

Fairway is a bunch wheatgrass of Siberian origin more widely grown in Canada than in the United States. It generally resembles crested wheatgrass but is finer stemmed and shorter than crested and yields less forage. It is especially suited for dryland lawns and other turf planting because of its dense growth and relatively fine texture. It is also used extensively for pasture and hay in Western Canada and to a more limited extent in the Northern Great Plains and Intermountain Region in the United States.

Last update September 22, 1997

Thickspike wheatgrass

Gramineae, Poaceae *Agropyron dasystachym* (Hook.) Scribn

Source: Magness et al. 1971

This is a sod forming wheatgrass native from the Hudson Bay and Alaska south to Nevada and Colorado. Stems reach to 3 feet. The creeping rhizomes result in formation of fairly dense sod. It does well on light textured soils and is very hardy. Growth starts early and provides good pasturage while succulent, but becomes tough and wiry late in the season. It is rarely seeded but is an important native grass over a wide area.

Last update September 22, 1997

Crested wheatgrass

Gramineae *Agropyron desertorum* (Fisch. ex Link) Schult.

Source: Magness et al. 1971

This is a hardy perennial bunch grass, originally introduced from Russian Turkestan. Leaves are abundant, both at the base and along the stems. Leaves are 6 to 10 inches long, about 1/4 inch wide, flat, and slightly hairy on the upper surface. Stems are slender, 2 to 3 feet in height, growing in dense clumps. It is deep-rooted and drought resistant, well adapted to the Northern Plains and higher elevations in the Rocky Mountains. Growth starts early in spring. If cut early, hay of excellent quality is produced. This is a highly valuable grass in its area of adaptation. Stands once established will persist for many years. Propagation is by seeding.

Intermediate Wheatgrass - *Agropyrum intermedium*
Pubescent Wheatgrass - *Agropyrum intermedium* var. *trichophorum*
General information about Wheatgrasses *Agropyron* species

Around 150 species of *Agropyron* or *Thinopyrum* are known in the temperate regions of the world, about 30 in North America. The species most important in Agriculture in the United States follow:

- Crested wheatgrass *Agropyron desertorum*
- Western wheatgrass *Agropyron smithii*
- Bluebunch wheatgrass *Agropyron spicatum*
- Beardless bluebunch wheatgrass *Agropyron spicatum* f. *inerme*
- Slender wheatgrass *Agropyron trachycaulum*
- Thickspike wheatgrass *Agropyron dasystachyum*

- Fairway wheatgrass *Agropyron cristatum*
- Quackgrass *Agropyron repens*
- Streambank wheatgrass *Agropyron riparuim*
- Siberian wheatgrass *Agropyron sibiricum*
- Tall wheatgrass *Agropyron elongatum*

Last update October 30, 1997

Pubescent wheatgrass

Gramineae, Poaceae *Agropyron intermedium* var. *trichophorum* (Link) Halac.

Source: Magness et al. 1971

This is a sod-forming grass native to Europe and Asia Minor, closely related to Intermediate Wheatgrass and having the same range of adaptation. The heads and seeds of pubescent are covered with short, stiff hairs. A named variety of pubescent, Topar, is better adapted to low-fertility soils and is more drought resistant than intermediate. In palatability and general appearance pubescent is very similar to intermediate.

Last update September 22, 1997

Agropyron repens (L.) Beauv.

Gramineae, Poaceae

Quack grass

We have information from several sources:

The Herb Hunters Guide—.Sievers, A.F. 1930.

Last update Wednesday, July 08, 1998 by aw

Streambank wheatgrass

Gramineae, Poaceae *Agropyron riparium* Scribn. & Smith

Source: Magness et al. 1971

This grass, native from Alberta and British Columbia in Canada south to Nevada and Colorado, resembles thickspike wheatgrass except that leaf blades are more narrow. It develops vigorous rhizomes, resulting in dense sods. It is drought tolerant and especially valuable for erosion control. Top growth is short and it produces less forage than some other wheatgrasses. Its greatest value is for sods on airports, roadbanks and irrigation canal banks.

Last update September 22, 1997.

Siberian wheatgrass

Gramineae, Poaceae *Agropyron sibiricum* (Willd.) Beauv.

Source: Magness et al. 1971

This is a drought-resistant bunchgrass introduced from Russia in 1934. It is generally similar to crested wheatgrass but appears to do better than crested on poor sites or under other adverse conditions. For this reason it is replacing crested in some areas. The stems are finer and heads more narrow than in crested. Nutritive value and palatability are similar to those of crested.

Last update September 22, 1997

Western wheatgrass

Gramineae, Poaceae *Agropyron smithii* Rydb.

Source: Magness et al. 1971

Western wheatgrass is a perennial and sod-forming grass, native to most parts of the United States except the humid southeast. It is a dominant species in the Central and Northern Great Plains. Plant growth is vigorous, reaching 2 to 3 feet in height. Leaves are up to 12 inches long, 0.25 inch wide, rather stiff and erect. The whole plant is covered with a grayish bloom. It thrives best on rather heavy soil, but is adapted to a wide range of soil types, including alkaline soil. Both as pasturage and when cut for hay while still succulent, it is relished by all classes of livestock. The plants are usually grown from seed, but spread from underground rhizomes to form dense sods. This is a very valuable grass, both for feed and for erosion control.

Bluebunch wheatgrass

Gramineae *Agropyron spicatum* (Pursh) Scribn. and Smith

Beardless bluebunch wheatgrass

***A. spicatum* f. *inerme* (Scribn. & Smith) Beetle**

Source: Magness et al. 1971

Bluebunch wheatgrass is a drought-resistant bunchgrass native to the dry areas of the western states. It is a dominant species in the Pacific Northwest and Intermountain States. Both taxa are very similar, except the beardless lacks the awns, making the plants more palatable in late stages of growth. Plant growth is vigorous, starting early in spring. Plants may reach a height of 4 feet. Leaves are up to 10 inches long and 0.5 inch wide, flat and tending to droop. Leaves remain green throughout the summer and are palatable even when dry. Propagation is by seed.

Last update September, 1997

Slender wheatgrass

Gramineae, Poaceae *Agropyron trachycaulum* (Link) Maltex H. F. Lewis

Source: Magness et al. 1971

This is a native bunchgrass, generally distributed throughout the United States, except in the southeastern and southcentral regions. It is prevalent in the Northern Great Plains and the Rocky Mountain States. It grows to 3 feet, in dense leafy clumps or bunches, a foot or more in diameter. The flowering stems are erect and rather coarse. Most of the leaves are basal. They are up to a foot long and 0.5 inch wide. This grass furnishes abundant pasture, and a nutritious hay if harvested early. The forage also matures well on the ground, so furnishes winter grazing. Stands may easily be overgrazed, and are not as persistent as the sod-forming wheatgrasses. Propagation is by seeds.

Last update February 19, 1999 by ch

Redtop

Florin, Fine bentgrass

Gramineae, Poaceae *Agrostis alba* L.

Source: Magness et al. 1971

Redtop is a creeping perennial, related to the bentgrasses. It is now found over much of the northern United States, although originally from Europe. The stems are slender. Leaves are narrow, about 0.25 inch. The panicle is loose and pyramidal in shape, and reddish in color, which accounts for the name. Redtop is used in pasture mixes under humid conditions, also in lawns and golf greens in the Southeast. It is low in palatability, but grows and forms a sod quickly, and so protects from erosion until slower-growing grasses become established. It is rarely seeded alone.

Last update July 1, 1996 bha

Bentgrasses

Gramineae *Agrostis* sp.

Colonial bent. *A. tenuis* Sibth.
Creeping bent. *A. palustris* Huds.
Velvet bent. *A. canina* L.

Source: Magness et al. 1971

The bentgrasses are rather fine-leaved, creeping grasses, used mainly in lawns and golf putting greens over the northern half of the United States. These species were all introduced into this country from Europe. Colonial bent is most comonly used in lawns. Included here are the varieties Astoria bent and Highland bent. The creeping bents generally do not produce seed and are propagated by stolons. Seaside bent and Penncross varieties do produce seed and are propagated in that way. None of these bentgrasses is used for pasture or hay.

Ailanthus altissima (Mill.) Swingle

Syn.: *Ailanthus glandulosa* Desf.
Simaroubaceae
Tree-of-heaven, China sumac

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

A tree that will grow in Brooklyn, Washington, and Peking, this "weed tree" can be a handsome "tropical-looking" ornamental with its compound leaves sometimes overtopped by reddish to yellowish clusters of winged fruits. It is used for erosion control, shade, and shelter where few other trees will thrive. Though little used, except in poorer countries, the wood is suitable for cabinetry, cellulose manufacture, furniture, lumber, pulp, and woodwork. It is difficult to split but easy to work and polish. The wood is locally used for charcoal and firewood. Leaves have been used as adulterants of belladonna and senna. Plant parts steeped in water and said to yield an insecticidal solution.

Folk Medicine

According to Hartwell (1967–1971), the tree is used in homeopathic "remedies" for cancer. Reported to be antiseptic, astringent, bactericidal, cardiac, cathartic, deobstruent, depressant, emetic, protisticidal, taenifuge, and vermifuge, tree-of-heaven is a folk remedy for asthma, cancer, diarrhea, dysentery, dysmenorrhea, dysuria, ejaculation (premature), epilepsy, eruption, fever, gonorrhea, hematochezia, leucorrhea, malaria, metrorrhagia, sores, spasms, spermatorrhea, stomachic, tumors of the breast (China), and wet dreams (Duke and Wain, 1981). From Manchuria to the Malay Peninsula, various parts of *Ailanthus altissima* are considered to be medicinal. The fruits are used for ophthalmic diseases. In Manchuria, the fruit is a remedy for dysentery. In China, it is bechic, emmenagogue, and used for hemorrhoids. In Korea, the root bark is used for cough, gastric and intestinal upsets. The vermifuge properties do not act on round worms or earthworms. Resin extracted from the roots and leaves is a revulsive or vesicant. The disagreeable odor of the plant may cause some people to feel sleepy. The leaves, bark of the trunk, and roots are put into a wash for parasitic ulcers, itch, and eruptions (Perry, 1980)

Chemistry

Per 100 g, the seed is reported to contain 27.5–27.6 g protein and 55.5–59.1 g fat (Duke and Atchley, 1983). The bark contains oleoresin, resin, some mucilage, ceryl alcohol, ailanthin, "quassiin," calcium oxalate crystals, and isoquercetin (quercitin 3-glycoside), tannin, phlobaphene, ceryl palmitate, saponin, quassin, and neoquassin (Perry, 1980; List and Horhammer, 1969–1979). Hager's Handbook (List and Horhammer (1969–1979) adds that the leaves contain 12% tannin, quercetin, as well as isoquercetin, and the alkaloid linuthine. Seeds contain quassiin.

Toxicity

Leaves are toxic to domestic animals (Perry, 1980). Gardeners who fell the tree may suffer rashes. Mitchell and Rook's observations are more violent than my own to sniffing the leaves, "The odour of the foliage is intensely disagreeable and can cause headache and nausea...rhinitis and conjunctivitis...The pollen can cause hay fever." (Mitchell and Rook, 1979).

Description

Deciduous tree, usually dioecious, 6–10(-30) m tall; trunk 30(-100) cm or more in diameter. Bark light brown or gray, smoothish, thin, becoming rough with long fissures and dark ridges. Leaves alternate, pinnately compound 30–60 cm long, hairy when young, crushed foliage with disagreeable odor but suggestive of peanuts. Leaflets 13–41, short-stalked, broadly lanceolate, 7.5–13 cm long, 1.5–5 cm wide, acuminate, with 2–5 teeth near Insided base. Panicles large, 15–25 cm long; flowers many, 6 mm long, greenish or greenish-yellow, with 5-lobed calyx, 5 narrow petals. Male flowers with 10 stamens and disagreeable odor. Female flowers with 2–5 nearly separate pistils united at base. Samaras many, 1–5 from a flower, 3–5 cm long, 1 cm wide, with reddish or purplish-brown, flat, slightly twisted wing. Seed 1 in middle, 6 mm long, elliptical, flattened (Little, 1983).

Germplasm

Reported from the China-Japan Center of Diversity, tree-of-heaven, or cvs thereof, is reported to tolerate alkalinity, disease, drought, frost, heat, high pH, hydrogen fluoride, insects, low pH, pollution, poor soil, SO_2 and waterlogging. ($2n= 80$)

Distribution

Native to China and Taiwan, it is only fitting that missionaries should introduce the "tree-of-heaven" to Europe in 1751 and to the US in 1784. It is listed as a serious weed in Australia and is widely spread, weedlike, in all temperate climates.

Ecology

Estimated to range from Subtropical Dry to Wet through Cool Temperate Dry to Wet Forest Life Zones, tree-of-heaven is estimated to tolerate annual precipitation of 3 to 25 dm (tolerating a dry season up to 8 months), annual temperature of 10° to 20°C, and pH of 5.5 to 8.0. Growing on the smallest of city plots and rubbish heaps, this species obviously can tolerate a wide array of soils, from acid to alkaline, sand to light clay, well-drained to swampy, poor to rich. It is said to do poorly on chalky soils or compact clay (Little, 1983).

Cultivation

A prolific seeder, spreading also by root suckers and coppicing readily, we might better study how to get rid of than to cultivate this "weed tree." Planting root cuttings of male trees would eliminate the seeding problem, however, augmenting the bad odor in the process. Root suckers can be problematic in fields as well as sidewalks and buildings. Seed stratified over winter should be spring sown, covered with ca 12–15 mm soil, one kg seed yielding 6,500 usable plants (Ag-Handbook 450).

Harvesting

Perhaps the branches should be lopped for fuel before the seeds mature, stored until winter to dry. One hundred kg fruits will yield 30–90 kg seed. Seeds should be stored in sealed containers, with low moisture content, at ca 1–3°C. Trees coppice readily.

Yields and Economics

I find no yield data, but suspect that it yields as well as Paulownia in our Maryland climate. NAS (1980a) reports that it can grow 3–4 m in height during a 5-month growing season. I would estimate that 20 m^3/ha is possible for this light wood.

Energy

Like most of our herbaceous and woody weeds, this too has been suggested as an energy candidate. The yellow wood, moderately hard and heavy is used for charcoal and firewood in many countries. I have heard no reports of toxicity from the smoke.

Biotic Factors

Agriculture Handbook 165 lists the following as affecting this species: *Armillaria mellea* (mushroom root rot), *Botryodiplodia ailanthi* var. *chromogena, Camarosporium berkeleyanum, Cercospora glandulosa* (leaf spot), *Colletotrichum tertium, Coniothyrium insitivum, Cytospora ailanthi, Daedalea unicolor* (butt rot), *Diaporthe medusaea, Dimerosporium robiniae* (black mildew), ?*Diplodia ailanthi* (twig blight), *D. natalensis* (twig blight), *Eutypella glandulosa, E. microcarpa, Fusarium lateritium* (twig blight), *Gloeosporium ailanthi* (leaf spot), *Guignardia ailanthi*, and *Haplosporella ailanthi*. Tent caterpillars are occasionally a problem in the US, completely defoliating, but rarely, if ever, killing the trees.

Air potato

Dioscoreaceae *Dioscorea bulbifera* L.

Source: Magness et al. 1971

This relative of the yam is a tall-climbing, twining herb with alternate, heart-shaped leaves. It forms large tubers of variable size and shape in the axils of the leaves. These may attain several pounds in weight and are palatable and potato-like in flavor. The plant is native to South Asia and is cultivated to a limited extent in tropical and subtropical areas.

Food and feed crops of the United States—Magness, J.R., G.M. Markle, C.C. Compton. 1971.

Albizia falcataria (L.) Fosberg

Syn.: *Albizia falcata* (L.) Backer.
Albizia moluccana Riq.
Mimosaceae
Molucca Albizia

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Timber tree, "one of the quickest-growing trees of Malaysia. It is highly regarded as shade tree, sometimes used for coffee shade. It has also been used to shade tea in Java, but its rapid growth may damage the tea during drought. It has been suggested as cover for mine spoil. The wood is described as soft but suitable for tea boxes. In Hawaii during the 1970's, about 1,000,000 board feet were rotary peeled and processed for core stock. It is used for matches, match boxes, packing cases, lightweight pallets, shelves and other general uses for certain grades of paper. It can substitute for pinewood as a pulping source. Pulp: The fiber averages 1.15 mm long with thin walls, giving it flexibility and good fiber to fiber bonding in paper. The soft, low-density wood is easy to chip and yields much pulp with relatively low chemical input. Because of its light color, only minimum bleaching is required to achieve a good white paper. The woods are nonsiliceous, usually light colored with some open pores, and produce a sawdust that may cause sneezing. The wide ranging roots are said to taint the water supply with their peculiar nauseous odor.

Folk Medicine

No data uncovered.

Chemistry

Mitchell and Rook (1979) report respiratory problems in people working with the wood.

Description

Tall deciduous tree to 30 m tall, 1 m in diameter. Leaves alternate, bipinnate, 23–30 cm long, rufose pubescent, the pinnae 20–24, 5–10 cm long, each with 30–40 paired leaflets, sessile, obliquely oblong, 6–12 mm long, 3–5 mm broad, shortly acute. Panicles large, 20–25 cm long, lateral, the numerous flowers sessile, white, ca 10–12 mm long; the calyx 5-toothed, corolla 5-lobate, ca 6 mm long; stamens filiform, more than 12 mm long; ovary narrow, the style filiform. Pods 10–13 cm long, 2 cm wide, flat, acute, green, turning brown, papyraceous, dehiscent. Seeds 15–20 per pod, reniform to oblong, ca 6 mm long, brown (Little, 1983). Seed ca 46,000/kg.

Germplasm

Reported from the Indochina-Indonesia Center of Diversity, Molucca albizia, or cvs thereof, is reported to tolerate poor soils. With a superficial root system, it is subject to windthrow (Duke, 1978).

Distribution

Native to the eastern islands of the Indonesian archipelago (Moluccas) and New Guinea, this species has been spread to Southeast Asia from Burma to the Philippines, and introduced locally in tropical Africa and America.

Ecology

Tree seems to thrive on many soils, alluvial soils, laterites, sandy mining soil, and white sands. Ranging from Subtropical Moist to Wet through Tropical Moist to Wet Forest Life Zones, probably tolerates annual precipitation of 20 to 45 dm annual temperature of 20 to 28°C. Flowering in Dec.–Jan. in Sri Lanka. NAS (1979) says it needs at least 15 rainy days during the driest 4 months.

Cultivation

The hard seeds may require scarification. Trees can be closely spaced at 1,000–2,000 trees/ha so that trunk grows straight and the crown closes quickly, shading out weeds.

Harvesting

Growing fast enough to be considered a cash crop, it is harvested in the Philippines after 7 or 8 years, then every 8 years from the coppice. The wood is soft, light-colored and has a specific gravity of 0.30–0.35.

Yields and Economics

Trees 2 years old may attain 10 m height, 15 cm DBH, while 10-year old trees may attain 30 m and 60 cm. Young plantations have yielded mean annual increment of 25–40 m^3/ha is more than 50 m^3 wood/yr. However, a mean annual increment of 40 m^3/yr is more likely in 8–12 yr rotations. Palit reports yield potential of 40 m^3/yr at 3–5 yrs in North Bengal, assuming 50% Survival and establishment at 2 x 2 m.

Energy

In a 9-year old stand, the above ground biomass was 102 MT/ha, the leaf biomass was 1.6 MT, leaf litter ca 5.2 MT making up ca 62% of the total litter. Annual net productivity was ca 20 MT/ha, productivity worthy of investigation for energy potential, especially if the tree has a high rate of N-fixation. These data derive from a Mindanao site with annual precipitation ca 45 dm, annual temperature ca 27°C, elevation 50–100 m on reddish brown ratozol over andesite. In a head-on study, the Albizia biomass compares with 18 MT for Gmelina plantation and 14 MT/ha for dipterocarp forest (Kawahara et al, 1981). Annual stem increment was maximum in three-year old plantations, tapering off thereafter. Nodules of N-fixing bacteria occur on the roots. Reported yields run from 2.6–55 m^3/ha/yr (Webb et al., 1980; Fenton et al., 1977).

Biotic Factors

On the Malayan Peninsula, the black lotong monkey (Semnopithecus) eats the shoot tips, sometimes to the extent of defoliating and killing the tree. The tree has been known to survive in the Asian weed, *Imperata*, but cannot be depended on to grow in thick lalang or kill out that grass. The tea pest, Helopeltis, can live on it. There have been frequent attacks by caterpillars, deer and monkey in Indonesian plantations adjacent to rainforests. Browne (1968), lists: Fungi. *Armillaria mellea, Calonectria theae, Corticium salmonicolor, Fomes noxius, Ganoderma lucidum, G. pseudoferreum, Helicobasidium compactum, Irpex subvinosus, Macrophomina phaseoli, Nectria pulcherrima, Physalospora rhodina, Pleiochaeta albiziae, Poria hypolateritia, Thanatephorus cucumeris, Ustulina deusta*. Acarina. *Tetranychus telarius*. Coleoptera. *Hypomeces squamosus,* *Xyleborus fornicatus, Xylosandrus morigerus, Xystrocera globosa*. Hemiptera *Ferrisia virgata, Parthenolecanium persicae*. Lepidoptera. *Achaea janata, Ericeia inangulata, Hypanartia blanda, H. hecabe, Indarbela quadrinotata, Rhesala moestalis, Semiothisa emersaria, Zeuzera coffeae*. Nematoda. *Meloidogyne* spp., *Pratylenchus coffeae*. Mammalia. *Callosciurus notatus, Tupaia glis*.

Albizia lebbek (L.) Benth.

Mimosaceae
East Indian Walnut, Siris Tree, Kokko

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

A fast growings nitrogen-fixing, heavy shade tree, recommended for reforestation and firewood plantations. Often planted as an avenue tree or as shade for coffee and tea. The wood is hard and strong, resembling walnut, and non siliceous. It produces a sawdust that may cause sneezing. Specific gravity 0.61; Air Dry Weight 39 lb/cu ft (ca 630 kg/cu m). The heartwood calorific value is 5,166 cals. Strong and elastic, the wood is used for cabinet wood, furniture and veneer, and serves well as firewood. The burr wood is prized for veneer. Bark has served for tanning. Foliage can be used as fodder. In the Sudan, goats eat fallen leaves and flowers. Bark containing saponin can be used in making soap, and containing tannin, can be used for tanning; used e.g. in Madras to tan fishing nets. It produces a gum which can be sold deceitfully as gum arabic. Host of the lac insect.

Folk Medicine

According to Hartwell (1967–1971), the tree is used in folk remedies for abdominal tumors, in bolmes, enemas, ghees or powders. Reported to be astringent, pectoral, rejuvenant, and tonic, the siris tree is a folk remedy for boils, cough, eye ailments, flu, and lung ailments. The seed oil is used for leprosy, the powdered seed to scrofulous swellings. Indians use the flowers for spermatorrhea.

Chemistry

According to Roskoski et al (1980), studying Mexican material, the seeds contain 9.47% humidity, 3.57% ash, 33.60% crude protein, 3.13% crude fat, 13.17% crude fiber, 35.30% carbohydrates with a 78.25% in vitro digestibility. The pods contain 6.99% humidity, 5.47% ash, 17.86% crude protein, 2.6% crude fat, 45.08% crude fiber, and 22.00% carbohydrates with a 76.56% in vitro digestibility. The foliage contains 3.57% humidity, 7.06% ash, 28.87% crtide protein, 5.42% crude fat, 31.75% crude fiber, 23.33% carbohydrates, and 83.55% in vitro digestibility. Prohibitive levels of toxic compounds were not detected in any of the plant parts analyzed. Gohl (1981) tabulates the following nutritive data:

Nutritive Data On *Albizia lebbek* (Gohl, 1981)

		As % of dry matter						
	DM	CP	CF	Ash	EE	NFE	Ca	P
Fresh leaves, India	39.6	18.1	26.5	8.0	4.7	42.7	2.02	0.14
Fresh leaves, Pakistan	31.7	22.0	26.5	7.0	10.0	34.5	1.84	0.20
Pods, Thailand	91.5	21.1	23.0	4.6	4.6	46.7		

		Digestibility (%)				
	Animal	CP	CF	EE	NFE	ME
Leaves	Zebu	64.5	62.2	44.6	37.6	1.84

Seeds have yielded 5.3–6.8% fixed oil or fat, the endosperm 11%. The oil contains 9.6% stearic, 10.9% arachidic, 39.3% oleic, and 32.9% linoleic acid (Watt and Breyer-Brandwijk, 1962). Bark contains 5–15% tannin (leaves contain ca 4%) and saponins. The saponin from the seed yields oleanolic acid and albizziagenin. Wood workers have reported upper respiratory problems following involvement with this species (Mitchell and Rook, 1979).

Description

Deciduous tree to 30 m tall, with a dense shade-producing crown. Bark smoothish, light whitish or greenish gray. Leaves alternate, twice compound, with 2–4 pairs of pinnate pinnae, each with 4–10 pairs of leaflets, the ultimate leaflets entire, arcuate, oblong. Flowers white, with greenish stamens, in clusters resembling a white powder puff. Pods flat, reddish brown, several seeds, often rattling in the breeze. In Puerto Rico, flowers April to September, fruiting year-round, the fruits more prominent probably in the dry season.

Germplasm

Siris tree, or cvs thereof, is reported to tolerate alkalinity, some drought, laterite, very light frost, saltspray, and sand ($2n = 26$).

Distribution

According to the NAS (1980) this is native to tropical Africa, Asia, and northern Australia, widely planted and naturalized throughout the tropics.

Ecology

Ranging from Tropical Thorn to Tropical Wet through Subtropical Thorn to Wet Forest Life Zones, siris tree is reported to tolerate annual precipitation of 4.8 to 23.4 dm (mean of 17 cases = 14.6) and annual temperature of 23.3 to 26.6°C (mean of 12 cases = 25.5) (EBL computer printout).

Cultivation

Immerse seed in boiling water, cool; soak for 24 hours, sowing in loam in wrapped pots 10 x 15 mm. Move seedlings to partial shade, watering and spraying as needed. Harden off for 2–3 months. Outplant at 3 x 3 or 4 x 4 m when at least 30 cm tall, at beginning of rainy season (Fabian, 1981).

Harvesting

Trees coppice well.

Yields and Economics

Studying Mexican material, Roskoski et al (1980) concluded that there were 8.60 (+/- 3.5) moles N_2 fixed per gram of nodule per hour, about 1/3 the hourly rate of *Acacia pennatula*, whose N_2 fixation rate was pegged at 34 kg/ha/yr.

Energy

Curtis and Duke (1982) report wood yields of 5 m^3/ha/yr, but Webb et al. (1980) report yields of 18–28 m^3. Krishnamurti (1974), suggesting the tree as a new alcohol source, notes that the ripe fruit has been found to contain 15% moisture, 17% reducing sugar, and 38% total reducing sugar as glucose. One hundred grams fruit crushed and fermented whole with addition of water and a pure culture of distillery yeast, gave a net yield of 20.5 cc of absolute alcohol, 82% of the theoretical yield, corresponding to about 170 liters alcohol per MT. With fruit yields of 10 MT possible, that suggests a renewable yield of 1,700 liters per hectare, or more than 10 barrels from the fruits alone.

Biotic Factors

Left standing or as logs, the timber is subject to borer and fungal attack (C.S.I.R., 1948–1976). Sapwood is liable to borer and termite attack, but is immune to dry rot (Watt and Breyer-Brandwijk, 1962). Browne (1968) lists: Viruses. Albizia Mosaic Virus. Fungi. *Ascochyta sacardiana, Camptomeris albizziae, Clitocybe tabescens, Fomes noxius, Fomes robiniae, Ganoderma lucidum, Helminthosporium albiziicolum, Irpex flavus, Nectria ditissima, Phellinus gilvus, Ravenelia sessilis, phaerophragmium acaciae, Uredo ngamboensis*. Angiospermae. *Cuscuta reflexa, Loranthus* sp. (?), *Tapinanthus* sp. Coleoptera. *Amblyrrhinus poricollis, Apate terebrans, Batocera rufomaculata, Bruchidius uberatus, Bruchus pisorum, Caryedon serratus, Trachys bali, Xystrocera globosa*. Hemiptera. *Drosicha stebbingi, Eurybachys tomentosa, Halys dentatus, Kerria lacca, Oxyrhachis tarandus, Parlatoreopsis chinensis, Parthenolecanium persicae, Rastrococcus iceryoides*. Lepidoptera. *Eriboea athamas, Hypanartia blanda, Orgyia postica, Pandesma quenavadi, Rhesala imparata, Rhesala moestalis, Sataspes infernalis, Stathmopoda basiplectra*. Mammalia. *Lepus nigricollis*. Nematoda. *Meloidogyne javanica, M*. sp., *Radopholus similes*.

Albizia Procera (Roxb.) Benth

Mimosaceae
Tall Albizia

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Tree cultivated for shade and timber. Wood rather similar to *Albizia lebbeck* but lighter and softer (sp. gra. 0.60 air dry weight of sapwood ca 460 kg/m^3 of heartwood 640 kg/m^3). The heartwood is durable even in exposed situtations. It can be worked to a good surface that polishes well. Wood is used chiefly for construction, furniture, carts and carriages, cane crushers, carvings, boats and oars, rice pounders, and, of course, fuel. In Australia, the tree is reagarded as a good cattle feed and as a sign of good country for farming sugarcane. Leaves said to be insecticidal (Kirtikar and Basu, 1975). Bark used for fish poison. The tree yields a reddish-brown gum.

Folk Medicine

Leaves are poulticed onto ulcers in India. Bark considered useful in pregnancy and stomachache. Bark given with salt as a medicine for water buffalo.

Chemistry

Bark, leaf, and root contain saponin. Hydrolysis of the saponin yields machaerinic acid. Tree contains some HCN. Leaf and fruit have given positive tests for haemolysis. A new pentacyclic triterpenic acid, procera acid, was isolated from the seed (List & Horhammer, 1969–1979). The gum contains aldobiuronic acid and the disaccharide 3-0-D-galactopyranosyl-L-arabinose. Degraded gum from *Albizia procera* contains D-galactose, D-mannose, D-glucuronic acid, and 4-0-mehtyl-D-glucuronic acid. Complete methylation and subsequent hydrolysis of the product afford 2,4-di-0-methyl-D-galactose (3 moles), 3,4,6-tri-0-methyl-L-arabinose. Perceragenin $C_{30}H_{46}O_4$ is reported from the seed (List and Horhammer, 1969–1979).

Description

An erect, slightly pubescent or nearly glabrous tree, 10–25 m high. Leaves about 40 cm long; pinnae about 4–12, 15–20 cm long; leaflets 12–20, oblong-elliptic, rounded or retuse, 2–5 cm long, oblique. Panicles terminal or in the upper axils, up to 20 cm long, diffuse; flowers 1–1.5 across. Pod long, thin, smooth, flattened, 10–15 cm long, 2–2.4 cm broad, containing 8–10 seeds (Li, 1963).

Germplasm

Reported from the Indochina-Indonesia and Hindustani Centers of Diversity, tall albizia, or cvs thereof, is reported to tolerate drought, and stony, dry, and shallow soils. ($2n = 26$)

Distribution

Native to tropical Asia and Australia, now widely cultivated in the tropics.

Ecology

Ranging from Tropical Very Dry through Tropical Moist Forest Life Zones, tall albizia is reported to tolerate annual precipitation of 8.8 to 29 dm (mean of 25 cases = 16.8) and annual temperature of 24.7 to 26.3°C (mean of 12 cases 25.3).

Cultivation

Soak seed a few seconds in boiling water (removed from source of heat) and soak overnight. Directly sow seed in prepared pots (in 10–15 mm polyethylene bags) using 50:50 sandy loam:potting soil. Spray insecticides twice a month for two months and as often as necessary thereafter. Place seedlings in shade, watering at least every other day. Harden off after 3–4 months. Regulate exposure to sun and water until seedlings are hardened. Space at 3 x 3 m, marking with Stakes. Set out in early morning and/or late afternoon at beginning of rainy season, when seedlings are about 4–7 months old (Canopy, 1981). Trees are easily propagated, using seedlings or stumps (NAS, 1979).

Harvesting

Tree is cut as needed for fuel, timber, or charcoal.

Yields and Economics

Should yield about like *Albizia lebbeck*. In Java, annual wood production of 10 m3/ha is recorded. Trees may attain 1 m DBH at 12 years, 2 m at 30 years.

Energy

Pods and fallen leaves may be considered as undesirable litter or as potential energy sources. It seems probable that if *Albizia lebbeck* fruits can yield 10 barrels of ethanol per hectare, this species could do as well. The species was increased in Puerto Rico during the 1940's because it seemed "a promising rapid-growing fuelwood species for the coastal and lower mountain regions."

Biotic Factors

Wood is relatively resistant to attack by dry-wood termites. Most of the Puerto Rican introductions have suffered severely from a fungus disease which causes disback or death (Little and Wadsworth, 1964). Browne (1968) lists: Fungi. *Ganoderma applanatum, Ganoderma lucidum, Nectria haematococca, Phellinus gilvus, Polyporus anebus, Ravenelia clemensiae, Ravenelia indica, Ravenelia sessiles, Sphaerophragmium acaciae*. Coleoptera. *Apate terebrans, Bruchidius uberatus, Sinoxylon anale, Xystrocera globosa*. Hemiptera. *Arytaina ramakrishni, Kerria lacca, Oxyrhachis mangiferana*. Isoptera. *Ancistrotermes amphidon, Coptotermes curvignathus*. Lepidoptera. *Archips micaceanus, Ascotis selenaria, Cusiala raptaria, Heliothis zea, Hypanartia hecabe, Hyposidra successaria, Indarbela quadrinotata, Platypeplus aprobola, Polydesma umbricola, Rhesala imparata, Rhesala inconcinnalis, Rhesala moestalis, Semiothisa emersaria, Semiothisa pluviata, triglina scitaria*. Orthoptera. *Schistocera gregaria*.

Aletris

Aletris farinosa L.

Figure 1.—Aletris (*Aletris farinosa*)

Other common names.—Stargrass, blazing star, mealy starwort, starwort unicorn root, true unicorn root, unicornplant, unicorn's-horn, colicroot, devil's-bit, ague grass, ague root, aloeroot, crow corn, huskwort. Some of the common names are also used in connection with Helonias (*Chamaelirium luteum* (L.) A. Gray), which causes much confusion, although the two plants do not bear any close resemblance. It is best, therefore, to designate it as Aletris, under which name it is best known in the drug trade.

Habitat and range.—Aletris occurs in dry, generally sandy soil, from Maine to Minnesota, Florida, and Tennessee.

Description.—This plant is an erect slender herb 1 1/2, to 3 foot tall with leaves only at the base. These are grasslike, of a yellowish green color, and from 2 to 6 inches long. They surround the base of the stem in the form of a star, in this respect differing distinctly from starwort (*Chamaelirium luteum*), with which it is sometimes confused, as stated. The erect, flowering spike produced from May to July bears white urn-shaped flowers sometimes tinged with yellow.

Other species.—Three other species of Aletris, namely, *Aletris aurea* Walt., *A. lutea* Small. and *A. obovata* Nash, bear much resemblance to *A. farinosa* and are for this reason no doubt frequently collected with the latter.

Part used.—The rootstock, which should be collected in autumn.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Aleurites fordii Hemsl.

Euphorbiaceae
Tung-Oil Tree

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Tung trees are cultivated for their seeds, the endosperm of which supplies a superior quick-drying oil, utilized in the manufacture of lacquers, varnishes, paints, linoleum, oilcloth, resins, artificial leather, felt-base floor coverings, and greases, brake-linings and in clearing and polishing compounds. Tung oil products are used to coat containers for food, beverages, and medicines; for insulating wires and other metallic surfaces, as in radios, radar, telephone and telegraph instruments.

Folk Medicine

No data available.

Chemistry

The fruit contains 14–20%; the kernel, 53–60%; and the nut, 30–40% oil. It contains 75–80% α-elaeo stearic, 15% oleic-, ca 4% palmitic-, and ca 1% stearic-acids. Tannins, phytosterols, and a poisonous saponin are also reported (List and Horhammer, 1969–1979).

Description

Trees up to 12 m tall and wide, bark smooth, wood soft; leaves dark green, up to 15 cm wide, heart-shaped, sometimes lobed, appearing usually just after, but sometimes just before flowering; flowers in clusters, whitish, rosethroated, produced in early spring from terminal buds of shoots of the previous season; monoecious, male and female flowers in same inflorescence, usually with the pistillate flowers surrounded by several staminate flowers; fruits spherical, pear-shaped or top shaped, green to purple at maturity, with 4–5 carpets each with one seed; seeds usually 4–5, but may vary from 1 to 15, 2–3.2 cm long, 1.3– 2.5 cm wide, consisting of a hard outer shell and a kernel from which the oil is obtained. Fl. Feb.–Mar.; fr. late Sept. to early Nov.

Germplasm

High-yielding cultivars continue to be developed. Some of the best varieties released by the USDA for growing in southern, United States are the following:

'Folsom': low-heading, high productivity; fruits large, late maturing, turning purplish when mature, containing 21% oil; highest resistance to low temperature in fall.

'Cahl': low-heading, productive; fruits large, 20% oil content; matures early, somewhat resistant to cold in fall.

'Isabel': low-heading, high productive; fruits large, maturing early, 22% oil content.

'La Crosser: High-heading, exceptional productivity; fruits small, late maturing, tending to break segments if not harvested promptly, 21–14% oil content; a very popular variety.

'Lampton': outyields all other varieties; very low-heading; fruits large, early maturing; 22% oil content.

Several other species of *Aleurites* are used to produce tung-oil, usually of low quality. *Aleurites cordata*, Japanese wood-oil tree; *A. moluccana*, Candlenut or lumbang tree; *A. trisperma*, Soft Lumbang tree; none of which can be grown commercially in the United States. *Aleurites montana*, Mu-tree, is the prevailing commercial species in South China and could be grown in Florida. ($2n$ = 22)

Distribution

Native to central and western China, where seedlings have been planted for thousands of years; planted in southern United States from Florida to eastern Texas.

Ecology

Ranging from Subtropical Dry to Moist through Tropical Very Dry to Dry Forest Life Zones, this species is reported to tolerate annual precipitation of 6.4–17.3 (mean of 8 cases = 12.,3), temperature of 18.7–26.2°C (mean of 8 cases 22.5), pH of 5.4–7.1 (mean of 4 cases = 6.4) (Duke, 1978, 1979). Tung trees are very exacting in climatic and soil requirements. They require long, hot summers with abundant moisture, with usually at least 112 cm of rainfall rather evenly distributed through the year. Trees require 350–400 hours in winter with temperatures 7.2°C or lower; without this cold requirement, trees tend to produce suckers from the main branches. Vigorous but not succulent growth is most cold resistant; trees are susceptible to cold injury when in active growth. Production of tung is best where day and night temperatures are uniformly warm. Much variation reduces tree growth and fruit size. Trees grow best if planted on hilltops or slopes, as good air-drainage reduces losses from spring frosts. Contour-planting on high rolling land escapes frost damage. Tung makes its best growth on virgin land. Soils must be well-drained, deep aerated, and have a high moisture-holding capacity to be easily penetrated by the roots. Green manure crops and fertilizers may be needed. Dolomitic lime may be used to correct excessive acidity; pH 6.0–6.5 is best; liming is beneficial to most soils in the Tung Belt, the more acid soils requiring greater amounts of lime.

Cultivation

Tung trees may be propagated by seed or by budding. Seedlings generally vary considerably from parent plants in growth and fruiting characters. Seedlings which have been self-pollinated for several generations give rather uniform plants. Only 1 out of 100 selected 'mother' tung trees will produce seedlings sufficiently uniform for commercial planting. However, a `mother' tree proven worthy by progeny testing may be propagated by budding. The budded trees, which are genetically identical with the original tree, will provide an adequate supply of seed satisfactory for planting. Seedlings are used for the root system for budded trees. Buds from 'mother' trees are inserted in stems of 1-year old seedlings, 5–7.5 cm above surface of the soil. Later, original seedling top is cut off and a new top grown for p the transplanted bud, making the tops of budded trees parts of the parent tree. Usually seedling trees outgrow budded trees, but budded trees produce larger crops and are more uniform in production, oil content and date of fruit maturity. Tung seed are normally short-lived and must be planted during the season following harvest. Seeds are best hulled before planting, as hulls retard germination. Hulled seed may be planted dry, but soaking in water for 5–7 days hastens germination. Stratification, cold treatment or chemical treatment of seeds brings about more rapid and uniform germination. Dry-stored seed should be planted no later than February; stratified seed by mid-March; coldtreated and chemical treated seed by early April. Seed may be planted either by hand or with a modified corn-planter, the seed spaced 15–20 cm apart, about 5 cm, in rows 1.6 m apart, depending on the equipment to be used for cultivation and for digging the trees. Seeds germinate in 60 days or more, hence weed and grass control may be a serious problem. As soon as seedlings emerge, a side-dressing of fertilizer (5–10–5) with commercial zinc sulfate should be applied. Fertilizer is applied at rate of 600 kg/ha, in bands along each side of row, 20 cm from seedlings and 5–7.5 cm deep. Other fertilizers may be needed depending on the soil. Most successful budding is done in late August, by the simple shield method, requiring piece of budstock bark, including a bud, that will fit into a cut in the rootstock bar, a T-shaped cut is made in bark of rootstock at point 5–7.5 cm above ground level, the flaps of bark loosened, shield-bud slipped inside flaps and the flaps tied tightly over the transplanted bud with rubber budding stripe, 12 cm long, 0.6 cm wide, 0.002 thick. After about 7 days, rubber stripe is cut to prevent binding. As newly set buds are susceptible to cold injury, soil is mounded over them for winter. When growth starts in spring, soil is pulled back and each stock cut back to within 3.5 cm of the dormant bud. Later, care consists of keeping all suckers removed and the trees well-cultivated. Trees are transplanted to the orchard late the following winter. Spring budding is done only as a last resort if necessary trees are not propagated the previous fall. Trees may be planted 125–750 ha. When trees are small, close planting in rows greatly increases the bearing surface, but at maturity the bearing surface of a crowded row is about the same as that of a row with trees farther apart. However, it is well to leave enough space between row for orchard operations. In contourplanting, distances between rows and total number of trees per hectare vary; rows 10–12 m apart, trees spaced 3.3–4 m apart in rows, 250–350 trees/ha. Tops of nursery trees must be pruned back to 20–25 cm at planting. As growth starts, all buds are rubbed off except the one strongest growing and best placed on the tree. A bud 5 cm or more below top of stump is preferred over one closer to top.

Harvesting

Tung trees usually begin bearing fruit the third year after planting, and are usually in commercial production by the fourth or fifth year, attaining maximum production in 10–12 years. Average life of trees in United States is 30 years. Fruits mature and drop to ground in late September to early November. At this time they contain about 60% moisture. Fruits must be dried to 15% moisture before processing. Fruits should be left on ground 3–4 weeks until hulls are dead and dry, and the moisture content has dropped below 30%. Fruits are gathered by hand into baskets or sacks. Fruits do not deteriorate on ground until they germinate in spring.

Yields and Economics

Trees yield 4.5–5 MT/ha fruits. An average picker can gather 60–80 bushels of fruits per day, depending on conditions of the orchard. Fruits may be gathered all through the winter season when other crops do not need care. Because all fruits do not fall at the same time, 2 or more harvestings may be desirable to get the maximum yield. Fruits are usually sacked, placed in crotch of tree and allowed to dry 2–3 weeks before delivery to the mill. Additional drying may be done at the mill, but wet fruits contain less oil percentage-wise and prices will be lower. Prices for tung oil depend on price supports, domestic production, imports and industrial demands. World production in 1969 was 107,000 MT of tung nuts; in 1970, 143,000; and projected for 1980, 199,000. Wholesale prices are about \$0.276/kg; European import prices, \$0.335/kg. Growers receive about \$51.10/ton of fruit of 18.5% oil content to about $63.10/ton for fruits of 22% oil content. Major producing countries are mainland China and South America (Argentina and Paraguay); United States and Africa much less than the others. U.S. Bureau of Census figures 1,587,000 pounds of tung oil were consumed during February of 1982, representing a 1,307,000 pound drop from January. The largest application for the oil is paint and varnish, which accounted for 566,000 pounds of total consumption in February (CMR, April 26, 1982).

Energy

During World War II, the Chinese used tung oil for motor fuel. It tended to gum up the engines, so they processed it to make it compatible with gasoline. The mixture worked fine (Page, 1981).

Biotic Factors

Bees are needed to transfer pollen from anthers to pistil. When staminate and pistillate flowers are on separate trees, one staminate tree for 20 pistillate trees should be planted in the orchard. Pollination can occur over several days. Tung trees are relatively free of insects and diseases, only a few causing losses serious enough to justify control measures: as *Botroyosphaeria ribis, Clitocybe tabescens, Mycosphaerella aleuritidis, Pellicularia koleroga, Physalospora rhodina* and the bacterium, *Pseudomonas aleuritidis*. Other bacteria and fungi reported on tung trees are: *Armillaria mellea, Botryodiplodia theobromae, Cephaleures virescens, Cercospora aleuritidis, Colletotrichum gloeosporioides, Corticium koleroga, Fomes lamaoensis, F. lignosus, Fusarium heterosporum* forma *aleuritidis, F. oxysporum, F. scirpi, F. solani, Ganoderma pseudoferreum, Cloeosporium aleuriticum, Glomerella clngulata, Pestalotia dichaeta, Phyllosticta microspore, Phytomonas syringas, Phytophthora omnivora, Ph. cinnamomi, Poria hypolateritia, Pythium aphanidermatum, Rhizoctonia solani, Septobasidium aleuritidis, S. pseudopedicellatum, Sphaerostilbe repens, Uncinula miyabei*, var. *aleuritis, Ustilina maxima, U. zonata*. Insect pests are not a serious problem, since fruit and leaves of tung trees are toxic to most animal life. Nematodes *Meloidogyne* spp. have been reported (Golden, p.c. , 1984).

Aleurites moluccana (L.) Willd.

Syn.: *Aleurites triloba* Forst.
Croton moluccanus L.
Euphorbiaceae
Candlenut oil tree, Candleberry, Varnish tree, Indian or Belgaum walnut

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Seed yields 57–80% of inedible, semi-drying oil, liquid at ordinary temperatures, solidifying at -15°C, containing oleostearic acid. Oil, quicker drying than linseed oil, is used as a wood preservative, for varnishes and paint oil, as an illuminant, for soap making, waterproofing paper, rubber substitutes and insulating material. Seeds are moderately poisonous and press cake is used as fertilizer. Kernels when roasted and cooked are considered edible; may be strung as candlenuts. Oil is painted on bottoms of small crafts to .protect against marine borers. Tung oil, applied to cotton bolls, stops boil weevils from eating them. Also prevents feeding by striped cucumber beetle.

Folk Medicine

Bark used on tumors in Japan. The oil is purgative and sometimes used like castor oil. Kernels are laxative stimulant, and sudorific. The irritant oil is rubbed on scalp as a hair stimulant. In Sumatra, pounded seeds, burned with charcoal,are applied around the navel forcositiveness. In Malaya, the pulped kernel enters poultices for headache, fevers, ulcers, and swollen joints. In Java, the bark is used for bloody diarrhea or dysentery. Bark juice with coconut milk is used for sprue. Malayans apply boiled leaves to the temples for headache and to the pubes for gonnorhea

Chemistry

The oil cake, containing ca 46.2% protein, 4.4% P_2O_5, and 2.0% K_2O, is said to be poisonous. A toxalbumin and HCN have been suggested. Bark contains ca 4–6% tannin. Oil also contains glycerides of linolenic, oleic and various linoleic acids. Per 100 g, the seed is reported to contain 626 calories, 7.0 g H_2O, 19.0 g protein, 63.0 g fat, 8.0 g total carbohydrate, 3.0 g ash, 80 mg Ca, 200 mg P, 2.0 mg Fe, 0 mg beta-carotene equivalent, 0.06 mg thiamine, and 0 mg ascorbic acid.

Description

Medium-sized tree, up to 20 m tall, ornamental, with widespreading or pendulous branches; leaves simple, variable in shape, young leaves large, up to 30 cm long, palmate, with 3–7 acuminate lobes, shining, while leaves on mature trees are ovate, entire, and acuminate, long-petioled, whitish above when young, becoming green with age, with rusty stellate pubescence beneath when young, and perisiting on veins and petiole; flowers in rusty-pubescent panicled cymes 10–15 cm long; petals 5, dingy white or creamy, oblong, up to 1.3 cm long; ovary 2-celled; fruit an indehiscent drupe, roundish, 5 cm or more in diameter, with thick rough hard shell making up 64–68% of fruit, difficult to separate from kernels; containing 1 or 2 seeds. Fl. Apr.–May (Sri Lanka).

Germplasm

Reported from the Indochina-Indonesia Center of Diversity, *Aleurites moluccana* or cvs thereof is reported to tolerate high pH, low pH, poor soil, and slope (Duke, 1978) ($2n$ = 44, 22)

Distribution

Native to Malaysia, Polynesia, Malay Peninsula, Philippines and South Seas Islands; now widely distributed in tropics. Naturalized or cultivated in Malagasy, Sri Lanka, southern India, Bangladesh, Brazil, West Indies, and Gulf Coast of United States.

Ecology

Candlenut trees thrive in moist tropical regions, up to 1,200 m altitude. Ranging from Subtropical Dry to Wet through Tropical Very Dry to Wet Forest Life Zones, *Aleurites moluccana* is reported to tolerate annual precipitation of 6.4 to 42.9 dm (mean of 14 cases = 19.4) annual temperature of 18.7 to 27.4°C (mean of 14 cases = 24.6) and pH of 5.0 to 8.0 (mean of 7 cases = 6–4). (Duke,1978, 1979)

Cultivation

Usually propagated from seed, requiring 3–4 months to germinate. Seedlings planted 300/ha. Once established, trees require little to no attention.

Harvesting

Bears two heavy crops each year, harvested when mature. Kernels adhere to sides of shell and are difficult to separate.

Yields and Economics

In plantations yields are estimated at 5–20 MT/ha nuts, each tree producing 30–80 kg. Oil production varies from 15 to 20% of nut weight. Most oil produced in India, Sri Lanka and other tropical regions is used locally and does not figure into international trade. In the past, oil has sold for 12–14 pounds per ton in England. According to the Chemical Marketing Reporter (June 8, 1981), tung oil prices (then ca 0.65/lb.) are likely to rise in the near future if demand remains adequate and Argentinean and Parguayan suppliers pressure the U.S. market by charging high prices for replacement oil. U.S. imports for the first quarter of 1981 were 58% higher than 1980, despite the absence of Chinese tung from the market.

Energy

Nut yields at 80 kg/tree, spaced at 200 trees per hectare, would suggest 16 MT/ha/yr, about 20% of which (3 MT) would be oil, suitable, with modification, for diesel uses, the residues for conversion to alcohol or pyrolysis. Fruit yields may range from 4–20 MT/ha/yr. Commercial production of oil yields 12–18% of the weight of the dry unhulled fruits, the fruits being air-dried to ca 12–15% moisture before pressing (Univ. Fla. Bul. 221, 1935). Oil yields as high as 3, 100 kg/ha have been reported. The pomace contains 4.5–5% oil. This suggests that the "chaff factor" might be ca 0.8. As of June 15, tung oil was $0.65/lb, compared to $0.38 for peanut oil, $1.39 for poppyseed oil, $0.33 for linseed oil, $0.275 for coconut oil, $0.265 for cottonseed oil, $0.232 for corn oil, and $0.21 for soybean oil (Chemical Marketing Reporter, June 15, 1981). At $2.00 per gallon, gasoline is roughly $0.25/lb.

Biotic Factors

Following fungi are known to attack candlenut-oil tree: *Cephalosporium* sp., *Clitocybe tabescens, Fomes hawaiensis, Gloeosporium aleuriticum, Physalospora rhodina, Polyporus gilvus, Pythium ultimum, Sclerotium rolfsii, Sphaeronema reinkingii, Trametes corrugata, Xylaria curta, Ustulina deusta*. Nematodes include *Meloidogyne* sp. (Golden, p.c. 1984).

Aleurites montana (Lour.) Wils.

Anacardiaceae
Wood-oil tree, Mu-oil tree

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Kernels yield a valuable drying oil, largely used in paints, varnishes and linoleums. Also used locally for illumination and lacquer-work. Varnish made from this plant possess a high degree of water-resistance, gloss and durability. There are only slight differences between the oils of *A. montana* and *A. fordii*.

Folk Medicine

The oil is applied to furuncles and ulcers.

Chemistry

The oil content of the seed is ca 50–60%. Oil consists chiefly of glycerides of beta-elaeostearic and oleic acids, and probably a little linoleic acid. Oil cake residue is poisonous and is only fit for manuring.

Description

A small tree about 5 m tall, much-branched, partially deciduous, dioecious; leaves simple, ovate or more or less cordate, apex cuspidate, about 12 cm long, 10 cm broad, sometimes larger and 3-lobed; leaf-blade with 2 large, conspicuous glands at base, petiole up to 24 cm long; flowers monoecious, petals large, white, up to 3 cm long; fruits egg-shaped, 3-lobed, wrinkled, about 5 cm in diameter, pointed at summit, flattened at base, generally with 3 or 4 oneseeded segments, the outer surface with wavy transverse ridges, the pericarp thick, hard and weedy. Fl. and fr. March.

Germplasm

($2n = 22$)

Distribution

Native to South China and in some of the S. Shan States (Burma). Introduced and cultivated successfully in Indochina where it has replaced *A. fordii*; Malawi, and in cooler parts of Florida, and other tropical regions.

Ecology

Ranging from Warm Temperate Moist to Tropical Dry to Moist Forest Life Zones, the mu-oil tree tolerates annual rainfall of 8.7–20.2 dm (mean of 7 cases = 14.5), annual temperatures of 14.8–26.5 (mean of 7 cases = 22.1°C), and pH of 5.5–8.0 (mean of 4 cases = 6.4). Adapted to subtropical regions and high elevations with moderate rainfall. Mainly a hillside species, but can thrive ded the area is well-drained. Maximum temperature 35.5°C, minimum temperature 6°C. It is frost-tender, and does not require a low temperature (below 3°C) as tung-oil trees (*A. fordii*) do, so can be grown in warmer regions. In Assam, grown where rainfall is 175–275 cm annually; in Mysore at elevations of 800–1,000 m with annual rainfall of 150 cm. Grows well in alluvial soils and is not very exacting in its soil requirements, but in richer soils the growth is more vigorous. A slightly acid soil is preferable.

Cultivation

Trees are propagated from seeds or by budding. In Malawi, propagation is by budding from high yielding clones. Seeds are usually planted in nursery and may take from 2 to 3 months to germinate. When seedlings are about I year old, they are planted out, spaced 6.6 x 6.6 m or more. Cultural practices are similar to those for *A. fordii*. As soon as the seedlings emerge, a sidedressing of fertilizer (5-10-5) of nitrogen and phosphorus along with commercial zinc sulfate should be applied. Fertilizer is applied at rate of 600 kg/ha, in bands along each side of row, 20 cm from seedlings and 5–7.5 cm deep. Other fertilizers may be needed depending on the soil. According to Spurling and Spurling (1974), N is the most important nutrient for tung in Malawi, irrespective of climate or soil. Most successful budding is done in late August, by the simple shield method, requiring a piece of budstick bark, including a bud, that will fit into a cut in the rootstock bark. A T-shaped cut is made in bark of rootstock at point 5–7.5 cm above ground level, the flaps of bark loosened, shield-bud slipped inside flaps and the flaps tied tightly over the transplanted bud with rubber budding strip 12 cm long and 0.6 cm wide. After about 7 days, rubber strip is cut to prevent binding. As newly set buds are susceptible to cold injury, soil is mounded over them for winter. When growth starts in spring, soil is pulled back and each stock cut back to within 3.5 cm of the dormant bud. Later care consists of keeping all suckers removed and the trees well-cultivated. Trees may be planted 125–750/ha. When trees are small, close planting in rows greatly increases the bearing surface, but at maturity the bearing surface of a crowded row is about the same as for a row with trees further apart. However, it is well to leave enough space between rows for orchard operations. In contour-planting, distances between rows and total number of trees per hectare vary; rows 10–12 m apart, trees spaced 3.3–4 m apart in rows, 250–350 trees/ha. Tops of trees must be pruned back to 20–25 cm at planting. As growth starts, all buds are rubbed off except the one strongest growing and best placed on the tree. A bud 5 cm or more below top of stump is preferred over one closer to top.

Harvesting

Trees begin bearing 2–5 years after transplanting with maximum production reached in 8 years and continuing for 40 years. In northern Burma, it has been observed to be more vigorous and disease-resistant than *A. fordii*. In Indochina, it has been successfully planted and its oil is now being produced on commercial scale, replacing that of *A. fordii*. Fruits mature and drop to ground in late September to early November. They are gathered and dried to 15% moisture before processing. Fruits should be left on ground 3–4 weeks until hulls are dead and dry, and the moisture content has dropped below 30%; fresh they are about 60% moisture. Fruits are gathered by hand into baskets or sacks.

Yields and Economics

A. montana is reported to give much higher yields of fruits than *A. fordii*. The percentage of kernels in the seeds is about 56%, and of oil in the kernels, about 59.3%. Major producers of the oil from *A. montana* are Burma, Indochina (Vietnam, Cambodia, Laos), Malawi, Congo, East Africa, South Africa, Malagasy Republic, India, and U.S.S.R. It has been considered for introduction in Florida.

Energy

Yields of oil per tree in China is reckoned to be about 3.2 kg; in Florida, 4.5–9 kg. Trees yield about 45–68 kg nuts/year, these yielding about 35–40% oil. In one Malawi trial, N treatments gave an increase of 519 kg/ha dry seed over a trial mean of 1070 kg/ha. With tung cake and ammonium sulphate, air dry tung seed yields of 12–17 year old trees was 2013 to 2367 kg/ha, of 6–9 year olds 766–1546 kg/ha (Spurling and Spurling, 1974).

Biotic Factors

Fungi reported on *A. montana* include the following: *Armillaria mellea, Botryodiplodia theobromae, Botryosphaeria ribis, Cephaleuros mycoidea, C. virescens, Cercospora aleuritidis, Colletotrichum gloeosporioides* var. *aleuritidis, Corticium oleroga, C. solani (Rhizoctonia solani), Corynespora cassiicola, Diplodia theobromae, Fusarium arthrosporioides, F. lateritium, Glomerella cingulata, Haplosporella aleurites, Mycosphaerella aleuritidis, Periconia byssoides, Pestalotiopsis disseminata, P. glandicola, P. japonica, P. versicolor, Pestalotia dichaeta, Phyllosticta microspora, Pseudocampion fasciculatum, Rhizoctonia lanellifera, Schizophyllum commune, Thyronectria pseudotrichia, Trametes occidentalis, Ustilin zonata*.

Neglected Crops: 1492 from a Different Perspective. 1994. J.E. Hernándo Bermejo and J. León (eds.). Plant Production and Protection Series No. 26. FAO, Rome, Italy. p. 303-332

Neglected horticultural crops

The authors of this chapter are F. Nuez (Department of Biotechnology, ETSIA, Valencia, Spain) and J.E. Hernández Bermejo (Córdoba Botanical Garden, Córdoba, Spain).

The authors wish to thank S. Zaragoza, V. Castell and P. Cornejo for their bibliographical contribution.

In the chapter on the processes and causes of the marginalization of Iberian crops, more than 20 horticultural crops are mentioned which could be considered to be in this situation. The authors have selected eight which will be dealt with in detail. Selection was based on a stricter identification of their marginalized nature and choosing from various taxonomic groups that would allow a detailed view of the problem.

Rocket (*Eruca sativa*), garden cress (*Lepidium sativum*), purslane (*Portulaca oleracea*), borage (*Borago officinalis*), alexanders (*Smyrnium olusatrum*), scorzonera or black salsify (*Scorzonera hispanica*), spotted golden thistle (*Scolymus maculatus*) and Spanish salsify or Spanish oyster plant (*Scolymus hispanicus*) are the eight species selected.

Rocket

(*Eruca saliva*)

Botanical name: *Eruca sativa* Miller

Family: Brassicaceae = Cruciferae

Common names. English: rocket, salad rocket, garden rocket; Spanish: oruga, oruga común, eruca, roqueta común; Catalan: ruqueta; Basque: bekarki; Portuguese: eruca, rúcula, fedorenta, pinchão (Brazil); French: roquette

Origin of the name

The semantic origin of this plant's name alludes to the oldest crops of the Near East. The Persian *girgir* and Acadian *gingiru* gave the Aramaic, Hebrew and Syrian *gargira*, and from these the Arabic *yiryir* and Latin *eruca*, from which, through Spanish, the words "roqueta" and "oruga" of present-day Spanish appeared.

Properties and uses

This plant is considered to be an excellent stomachic, stimulant and aphrodisiac, and is also used as a diuretic and antiscorbutic. The leaves have a bitter flavour which is made milder by cooking or frying. The seeds are hot, although rather less so than mustard seeds. It contains glucosides, such as allyl sulphocyanate, mineral salts and vitamin C. The oil of the seed contains erucic acid.

Rocket was always considered to be a potent aphrodisiac. In classic antiquity, it was consecrated to Priapus and was planted at the foot of the statue of this deity dedicated to the procreative potential of males. Dioscorides warns that, eaten raw, it stimulates lust and that the seeds have the same power. Columela also refers to its sexually stimulating effect, but is also very well acquainted with its cultivation technique: "...and rocket and basil also remain in the place where they have been sown and require no other care than manuring and weeding. Moreover, they can be sown not only in autumn, but also in spring...." The Hispano-Romans also compared the aphrodisiac power of rocket precisely with the anaphrodisiac power of lettuce. In Hispano-Visigoth culture, Isidoro de Sevilla supports the use and knowledge of this plant's powers: "... rocket is, so to speak, inflammatory, since it has burning properties and, if consumed frequently in the diet. arouses the sexual appetite. There are two species. one of which is in habitual use while the other is wild with a more bitter taste. Both stimulate sexual appetite."

Irrespective of these effects, rocket has been eaten basically as a vegetable (leaves) and as a spice (leaves and seeds). It is thus an ingredient of misticanza" (mixed salad), a speciality eaten in Rome since the very foundation of that city. Hispano-Arab agronomists also mention its cultivation. for instance Ibn Hayyay (eleventh century). Ibn Wafid (eleventh and twelfth century) and. of course, Ibn al-Awwam (twelfth century). The latter author mentions the plant's use as a flavouring for musts and syrups, the seed being ground and scattered over the surface of the earthenware jars containing the syrup. He also mentions its flowers being used in a similar way. In the sixteenth century, Alonso de Herrera's *Tratado de agricultura* contains no mention of rocket.

It is used to make sauces in which the leaves are mixed with sugar or honey, vinegar and toasted bread (rocket sauce). In Italy, it is eaten boiled with spaghetti, and then seasoned with garlic and oil. In Spain, it is traditionally used in La Roda and Montealegre del Castillo (Al bacete) in the preparation of *gazpachos* of La Mancha, an ancestral dish which includes the meat of partridge and rabbit and unleavened bread (*gazpacho*), with lightly fried rocket. Some authors relate this tradition to primitive fertility rituals.

Nowadays it still remains very much appreciated in various countries of the Mediterranean area. including Italy, Greece and Turkey, where it is eaten mainly in salads and as a garnish for meat. It goes very well with lettuce, chicory, valerian and tomato. Another recipe is potato and rocket salad. In India, it is cultivated to obtain a semi-drying oil from the seeds. At present, most of the rocket grown is for this purpose, and it is considered mainly as a potential oilseed product.

This plant's marginalization as a vegetable in Spain may have been very much connected with its condemnation because of its aphrodisiac properties.

Botanical description

Rocket is an annual herbaceous plant, growing up to 80 cm. The basal leaves occur in a rosette and are lyrate-pinnatifid (those normally eaten in salads); the caulinar leaves are lobulate or dentate. The flowers have white or light yellow petals. The siliquae measure up to 40 mm, are erect, attached to the stem, with a subcylindrical valvar portion and an ensiform face as long as the valves. The seeds measure 1.5 to 2.5 mm and are brown.

The wild form flowers from February to June and the cultivated form right into mid-summer. It is allogamous with a complex system of self-incompatibility, mainly gametophytic, but with some alleles acting sporophytically. The existence of genie male sterility has been verified. The chromosome pattern is $2n = 2x = 22$.

Figure 37. Horticultural crops: A) rocket (*Eruca saliva*), detail of fruit in the silicle; B) garden cress (*Lepidium sativum*), detail of fruit in the silicle; C) purslane (*Portulaca oleracea*)

Ecology and phytogeography

Rocket grows spontaneously in places modified by humans: abandoned gardens, waysides, tips and among rubble. It prefers hot, dry climates.

It is distributed all around the Mediterranean, extending to central Europe in the north and as far as Afghanistan and northern India in the east. It has reverted to the wild state in North America, South Africa and Australia. Vavilov described it in central Asia, the Near East and the Mediterranean, the latter being considered its main centre of origin.

It is cultivated mainly in India, and is grown more rarely in Turkey and Greece. It is also cultivated in Italy. In countries such as Spain, France and Great Britain, cultivation is rare.

Genetic diversity

The biggest collections of rocket germplasm are to be found at the Institute of Germplasm in Bari, Italy, at the NBPGR in New Delhi, India, at the Haryana Agricultural University in India and at the VIR in St Petersburg.

There are also smaller collections in Kabul in Afghanistan, Saskatoon in Canada, Gaersleben and Braunschweig in Germany, Tapioszele in Hungary, Islamabad in Pakistan, Blonie in Poland and Alnarp in Sweden. A small collection of species of *Eruca*, including *E. sativa*, is to be found at the Universidad Politécnica de Madrid and there is also germplasm from wild populations of the genus at the Córdoba Botanical Garden.

Collecting expeditions have continued. In 1985, 25 samples of indigenous germplasm of *E. sativa* were collected in the northeastern Sudan.

In an analysis using the D^2 statistic of Mahalanobis, out of 99 lines of rocket no correlation was found between genetic diversity for 12 characters associated with production and geographical origin.

There is wide variability as regards the characters of the siliqua and its stability, and a strong interaction with the cultivation conditions. Similarly, there is wide genetic variability for seed production per plant and related characters.

An important group of studies is attempting to use *E. sativa* as a genetic resource for improving other crucifers. In this way, intergeneric hybrids have been obtained with *Raphanus sativus, Brassica campestris* and *B. oleracea*. Somatic hybrids have been obtained through the fusion of protoplasts with *B. napus* and *B. juncea*.

There are lines of rocket (T27) known which are resistant to mustard aphid and tolerant of several stress conditions as well as *Fusarium oxysporum*. Such lines may also be a source of genes that are transferable to species of *Brassica*.

Cultivation practices

Rocket is a very hardy plant which requires little care. It is generally sown direct in late winter or early spring, in shallow furrows. To encourage emergence, it is advisable to cover with light sieved soil. It requires little irrigation and manuring. It is usually hoed by hand.

The young leaves are harvested in spring.

Prospects for improvement

The use of rocket as a vegetable, salad or spice has been marginalized, possibly for moral or religious reasons, and its recovery is limited by local gastronomic tradition, which is not always able to appreciate its characteristic bitter flavour. This is due to glucosinolates and the high content of mineral salts.

The development of cultivars with a low allyl sulphocyanate content does not appear to be an improvement objective since, even though the plant would be rendered innocuous, it would lose its individual identity.

In fact, a wide variability has been observed as regards both erucic acid content and glucosinolate content in 128 rocket specimens from Pakistan. Rocket already has a low content of these constituents, and the local inhabitants clearly distinguish this species from other more bitter crucifers. Its use can be increased only through the promotion of the traditional dishes in which it appears.

The use of agronomic techniques such as nitrogen fertilization and shading would enable younger, more juicy rosettes to be obtained which have a milder taste and are more palatable.

The work on genetic improvement for the use of "rocket" as a vegetable is very limited, if we exclude the development of in vitro cultivation, which has made it possible to regenerate normal diploid plants from isolated protoplasts of leaf mesophyll.

Garden Cress

(*Lepidium sativum*)

Botanical name: *Lepidium sativum* L.

Family: Brassicaceae = Cruciferae

Common names. English: cress, common cress, garden cress, land cress, pepper cress; Spanish: mastuerzo, mastuerzo hortense, lepidio, berro de jardín (Spain), berro de tierra, berro hortense (Argentina), escobilla (Costa Rica); Catalan: morritort, morrisá, Portuguese and Galician: masturco, mastruco, agrião-mouro, herba do esforzo; Portuguese: mastruco do Sul, agrião (Brazil); Basque: buminka, beatzecrexu

Origin of the name

Cultivation of this species, which is native to Southwest Asia (perhaps Persia) and which spread many centuries ago to western Europe, is very old, as is shown by the philological trace of its names in different Indo-European languages. These include the Persian word *turehtezuk*, the Greek *kardamon*, the Latin nasturtium and Arabic *tuffa'* and *hurf*. In some languages there is a degree of confusion with watercress. It seems that the meaning of the word nasturtium (*nasum torcere*, because its smell causes the nose to turn up) must have been applied initially to garden cress, as both Pliny and Isidoro de Sevilla explain. The confusion remains with the terms used by the Hispano-Arabs. The word *hurf* is applied without distinction to watercress and garden cress (several species certainly of up to three different genera: *Nasturtium*, *Lepidium* and *Cardaria*). Thus the medieval agronomists of Andalusia went as far as differentiating between several *hurf*, such as *hurf abyod*, *hurf babili*, *hurf madani*....

Properties, uses and cultivation

Xenophon (400 BC) mentions that the Persians used to eat this plant even before bread was known. It was also familiar to the Egyptians and was very much appreciated by the Greeks and Romans, who were very fond of banquets rich in spices and spicy salads. Columela (first century) makes direct reference to the cultivation of garden cress. In *Los doce libros de Agricultura*, he writes: " ...immediately after the calends of January, garden cress is sown out... when you have transplanted it before the calends of March, you will be able to harvest it like chives, but less often... it must not be cut after the calends of November because it dies from frosts, but can resist for two years if it is hoed and manured carefully... there are also many sites where it lives for up to ten years" (Book XI). The latter statements seem to indicate that he is also speaking of the perennial species *L. latifolium*, as *L. sativum* is an annual.

Almost all of the Andalusian agronomists of the Middle Ages (Ibn Hayyay, Ibn Wafid, Ibn alBaytar, Ibn Luyun, Ibn al-Awwam) and many of the doctors, such as Maimonides, mention garden cress. Ibn al-Awwam also includes references from Abu al-Jair, Abu Abdalah as well as from Nabataean agriculture and, among other comments, he says: "Garden cress is sown between February and April (in January in Seville). It has small seeds which are mixed with earth for sowing to prevent the wind carrying them away.... It is harvested in May and is grown between ridges, in combination/conjunction with flax cultivation."

Many of the authors of the old oriental and Mediterranean cultures emphasized the medicinal properties of cress, especially as an antiscorbutic, depurative and stimulant. Columela notes its vermifugal powers. Ibn al-Awwam refers to certain apparently antihistaminic properties, since it was used against insect bites and also as an insect repellent, in the form of a fumigant. It was perhaps Ibn al-Baytar, an Andalusian botanist (eighth century), who collected most information on its properties, summarizing the opinions of other authors such as El Farcy, who says that it incites coitus and stimulates the appetite; Ibn Massa, according to whom it dissipates colic and gets rid of tapeworms and other intestinal worms: or Ibn Massouih, who mentions that it eliminates viscous humours. Ibn al-Baytar also says that it is administered against leprosy, is useful for renal "cooling" and that, if hair is washed with garden cress water, it is "purified" and any loss is arrested.

In Iran and Morocco, the seeds are used as an aphrodisiac. In former Abyssinia, an edible oil was obtained from the seeds. In Eritrea, it was used as a dyestuff plant. Some Arab scholars have attributed garden cress's reputation among Muslims to the fact that it was directly recommended by the Prophet.

Garden cress's main use was always as an aromatic and slightly pungent plant. Not only in antiquity but also in the Middle Ages it enjoyed considerable prestige on royal tables. The young leaves were used for salads. The ancient Spartans ate them with bread. This use still continues and they are also eaten with bread and butter or with bread to which lemon, vinegar or sugar is added. However. it is mainly used nowadays in the seedling stage. the succulent hypocotyls being added to salads and as a garnish and decoration for dishes.

The roots, seeds and leaves have been used as a spicy condiment. Columela explains how *oxygala*, a type of curd cheese with herbs, was prepared: 'Some people, after collecting cultivated or even wild garden cress, dry it in the shade and then. after removing the stem, add its leaves to brine. squeezing them and placing them in milk without any other seasoning, and adding the amount of salt they consider sufficient.... Others mix fresh leaves of cultivated cress with sweetened milk in a pot… ".

L latifolium L. stands out for its horticultural interest; although it grows spontaneously on the edges of rivers and lakes, it is also occasionally grown in the same way as *L. sativum*. Its young leaves can be used for salads; the ancient Greeks and Romans used to grow it for this purpose. Its leaves and seeds were also used as a spicy condiment. Several sauces are prepared with its leaves, including in particular the bitter sauce of the paschal lamb of the Jews. The seeds of this species were known in England as the poor people's pepper. The roots have been used on occasion as a substitute for radish.

In the fifteenth century, we know through Alonso de Herrera that garden cress was one of the vegetables most widely eaten in Castile. During the sixteenth century, obstinate attempts were made to introduce it into America. Right up to the beginning of the nineteenth century, its cultivation in Spain continued to be important, since Boutelou and Boutelou (1801) deal specifically with this crop in their *Tratado de la huerta*, commenting on the existence of several cultivars At present, the cultivation of cress is very occasional in countries such as Spain and France. Water cress, in competition with garden cress, has eclipsed the cultivation of the latter. However, this is not the case in other central European countries or the United Kingdom, where its use is normal and the system of cultivation has changed substantially.

Botanical description

Cress is an annual, erect herbaceous plant, growing up to 50 cm. The basal leaves have long petioles and are lyrate-pinnatipartite; the caulinar leaves are laciniate-pinnate while the upper leaves are entire. The inflorescences are in dense racemes. The flowers have white or slightly pink petals, measuring 2 mm. The siliquae measure 5 to 6 x 4 mm, are elliptical, elate from the upper half, and glabrous. Cress flowers in the wild state between March and June.

It is an allogamous plant with self-compatible and self-incompatible forms and with various degrees of tolerance to prolonged autogamy. There are diploid forms, $2n = 2x = 16$, and tetraploid forms, $2n = 4x = 32$. A degree of variability is noted in the character of the basal leaves which are cleft or split to a greater or lesser degree. a character which is controlled by a single incompletely dominant gene.

Ecology and phytogeography

Cress is a plant that is well suited to all soils and climates, although it does not tolerate frosts. In temperate conditions, it has a very rapid growth rate. It grows subspontaneously in areas transformed by humans, close to crops or human settlements. It appears in this way on the Iberian peninsula. mainly in the eastern regions.

Wild cress extends from the Sudan to the Himalayas. Most authors consider it to be a native of western Asia, whence it passed very quickly to Europe and the rest of Asia as a secondary crop, probably associated with cultivars of flax. Vavilov considers its main centre to be Ethiopia, where he found the widest variability: the Near East, central Asia and the Mediterranean are considered secondary centres. It is now naturalized in numerous parts of Europe, including the British Isles.

Genetic diversity

The genus *Lepidium* is made up of about 150 species, distributed throughout almost all temperate and subtropical regions of the world. On the Iberian peninsula and the Balearic Islands, at least 20 species or subspecies exist among the autochthonous and allochthonous taxa, some genetically close to *L. sativum*. Seven of them are exclusively endemic to the peninsula or, at the very most, are common with North Africa. Other close species are *L. campestre* (L.) R. Br. and *L. ruderale* L. which also have edible leaves. The leaves of *L. campestre* are used to prepare excellent sauces for fish.

Common cress (*L. sativum* L.), with regard to the anatomy of the leaf, stem and root, has been divided into three botanical varieties: *vulgare*, *crispum* and *latifolium*. The latter is the most mesomorphic, *crispum* the most xeromorphic and *vulgare* intermediate.

At present, most of the studies on the variability and development of new cultivars are being carried out in liaison with the VIR of St Petersburg, where there is a good collection of material. Of the 350 forms of garden cress studied in the Ukraine, Uzkolistnyti 3 was the best, being highly productive and of good quality. It is being used as the basis of improvement programmes, as it appreciably surpasses the best Soviet varieties in production and quality. Other cultivars well suited to European Russia are Tuikers Grootbladige (broad-leaved) and the lines Mestnyi k137, k106 and k115. Of the types most cultivated in Europe, Early European, Eastern, Dagestan and Entire Leaved stand out, being distinguished by the length and shape of the leaf, earliness and susceptibility to cold. In Western Europe, one broad-leaved type is especially appreciated (Broad Leaved French) as are curly types (Curly Leaved), the latter being used extensively to garnish dishes. In Africa, there are red, white and black varieties.

This crop is also arousing interest in Japan, and collecting expeditions to Nepal have been organized. Some specimens collected during an expedition to Iraq in 1986 are now stored in Abu Ghraib and in Gratersleben, Germany. There are also small collections of *L. sativum* in the PGRC in Addis Ababa (Ethiopia), at the ARARI of Izmir in Turkey and in Bari, Italy. At the Universidad Politécnica de Madrid there are accessions of 20 species of *Lepidium*, while the BGV of the Córdoba Botanical Garden keeps germplasm of the southern Iberian species of the genus.

Cultivation practices

Cress is an easily grown plant with few requirements. It can be broadcast after the winter frosts or throughout the year in temperate climates. However, Boutelou and Boutelou (1801) were already recommending sowing in shallow furrows, which enables surplus plants to be thinned out and facilitates hoeing. Sowing has to be repeated every 15 to 20 days so that there is no shortage of young shoots and new leaves for salads—the leaves of earlier sowings begin to get tough and are no longer usable. The seed sprouts four or six days after sowing, depending on the season, and the leaves are ready for consumption after two or three weeks.

The usual form of cultivation continues to be as described, with 15 to 20 cm between rows and the use of irrigation in the summer, since they are lightly rooted seedlings which can dry up in a few days. Its growth is very rapid and harvesting can begin in the same month as sowing, with yields reaching 6 tonnes per hectare.

Prospects for improvement

Most of the genetic improvement work on garden cress is being carried out in the CIS, with little or no work being done at present in the countries of western Europe. Mainly early cultivars with a prolonged production period and better cold tolerance are being developed.

Cress can be grown and used like white mustard. It geminates more slowly at low temperatures, the emergence period being three or four days longer. Shortening this period is an interesting improvement objective.

However, cress's recovery and its greater presence on markets mainly depends on a modification of cultivation and marketing techniques. In counties such as the United Kingdom, where this vegetable is nominally to be found at the markets. cultivation takes place in greenhouses throughout the year. The whole succulent hypocotyls of the very young seedlings are eaten. The seed is placed on the soil surface on soft, level beds. It is finely sprinkled with water and then covered with sackcloth which has been steam-sterilized and moistened. The latter is frequently wetted to maintain moisture and is removed when the seedlings reach 4 to 5 cm in height (after approximately seven days in spring and autumn and ten days in winter). The yellowish leaves turn green after two to three days.

The cress is harvested when the first pair of cotyledon leaves have developed and it is marketed in small bags or trays, sometimes together with seedlings of white mustard.

Garden cress and white pepper are sometimes sown in the plastic trays or bags in which they will be sold, generally in peat with a nutrient solution.

Purslane

(*Portulaca oleracea*)

Botanical name: *Portulaca oleracea* L.

Family: Portulacaceae

Common names. English: purslane, purslave, pursley, pusley; Spanish and Catalan: verdolaga, verdalaga, buglosa, hierba grasa, porcelana, tarfela, peplide (Spain), colchón de niño (El Salvador), flor de las once (Colombia), flor de un día, lega (Argentina); Portuguese and Galician: beldroega, bredo-femea, baldroaga; Basque: ketozki, ketorki, getozca; French: pourpier, portulache

Origin of the name

The diversity of names and meanings already gives an idea of the age and geographical dispersion of purslane's cultivation or use. On the basis of historical, archaeological and linguistic documentation, De Candolle thought that this species was cultivated more than 4000 years ago. Its common names come from different roots: *lonica* or *louina* (Sanskrit), *koursa* (Hindustani), *kholza* and *perpehen* (Persian), *adrajne* *agria* (Greek), *portulaca* (Latin, which means "little door", because of the way its capsule opens). The Arabs in the Middle Ages called it *baqla hamqa'*, which means "mad" or "crazy vegetable" because of the fact that its branches spread over the ground without any control. The Hispano-Arabs of Al-Andalus (from the tenth to fifteenth century) used the name *riyla*, which means "foot", most certainly because of its dactyliform leaves, and also *furfir*, *farfan, farfag*, *farfagin*, derived from the Persian *perpehen*. They also called it *missita*, which means "mixed", because it is sometimes found growing in gardens and sometimes growing wild. In Spanish, names such as verdilacas, yerba aurato and yerba orate are known (which again mean "crazy herb").

Properties, uses and cultivation

As a medicinal plant, it is considered to have antiscorbutic, diuretic and cooling properties. Being rich in mineral salts and with a high water content (95 percent) and mucilage content, it has emollient and soothing properties for irritations of the bladder and urinary tract. It is also used to regulate the bowels. Dioscorides already recognized its medicinal powers: these were anti-inflammatory (eyes) and analgesic (headache), emollient and soothing, antifebrifuge (in juice) and anthelmintic. He also says that "it reduces the desire to fornicate". In the latter sense, other authors also mention its anaphrodisiac powers (1837 Codex of the Spanish Pharmacopoeia), including this plant among the "four cold seeds", together with chicory, endive and lettuce. The anaphrodisiac effect is perhaps due to the presence of norepinephrin, a precursor of adrenalin, which causes a reduction in the blood flow through constriction of the main arteries. It is also mentioned by Maimonides. In the Middle Ages, the pharmacists of Cairo used to sell purslane seed for various uses, recommending it in particular as a vermifuge. Laguna and Leclerc also recognized its different medicinal properties, especially the anti-inflammatory ones, in mixtures prepared with plantain, violets and gourds. Its magical powers have also been mentioned, as a charm against evil spirits and for dispelling nightmares if placed in the bed.

However, in addition to its medicinal powers, it is also a vegetable, a weed and a food for pigs.

Columela writes in his poem on the garden: "Already the juicy purslane covers the dry beds"; and in *Los doce libros de agricultura*: "Leafy purslane appeases the plot's thirst" (Book X); and in Book XI he gives a recipe for preserving it in vinegar and salt. Paladio refers to it exclusively because of its mucilaginous, medicinal and veterinary properties. Similar references are found in Kastos, taking up the Byzantine tradition. Isidoro de Sevilla mentions it without giving any information on its cultivation. In short, such a summary reference to the Hispano-Roman and Hispano-Visigoth tradition regarding purslane is surprising.

It is the writers of oriental and Arabic treatises who concerned themselves most with this vegetable. Ibn Wahsiyya describes its cultivation in the Near East, presenting it as a summer crop. Most of the Hispano-Arab agronomists deal with this plant. Arib (tenth century) mentions it in his *Calendario agrícola*. Al Zahrawi and Ibn Hayyay (eleventh century) also mention it. Ibn Bassal (eleventh century) deals extensively with its cultivation, already recognizing a certain intraspecific variability (he distinguishes early and late varieties), setting out its temperature and water requirements (summer cultivation and irrigation or vegetable garden), drawing up a sowing calendar which extends from March to August and demonstrating the practice of two basic cultivation periods, depending on whether the aim is to produce seed or to produce for human consumption. Sowing quantities and manuring and irrigation requirements also appear and are dealt with in great detail by the author. Ibn Wafid (Hispano-Arab agronomist of the eleventh and twelfth centuries) mentions it under the names *haqla hamqa'* and *missita*. Ibn al-Awwam, in his *Kitab al-Filaha*, recalls that it is mentioned by almost all the Arab authors and refers to different varieties. He uses the adjectives "mild", "vain" and "blessed".

After the sixteenth century, cultivation of purslane was gradually lost in Spain. Alonso de Herrera (sixteenth century), for example, makes no reference to it while Boutelou and Boutelou (1801) say that "purslane, which is not at all appreciated in Spain, is one of the crops which, in England and other countries further north, need to be cultivated in frames and hotbeds in order to bring forward their vegetation artificially"; and further on: "on this land, it is not usual to cultivate purslane other than using those that have grown at random among other plants cultivated with more care". In spite of Spanish disregard for this plant, it is still valued in many Latin American countries where it was introduced.

Purslane has been eaten as a vegetable, particularly fresh. In England in the seventeenth century. the cooks of Charles II used to add its leaves to all salads, perhaps to satisfy the king's taste or else for its digestive properties. In this recipe, the chopped young leaves were mixed with double the amount of leaves of lettuce, chervil, borage flowers and marigold petals, the mixture being dressed with oil and lemon juice. The recipe resembles that mentioned by Tirso de Molina: "I will have green coriander, garden cress, purslane, borage and mint added to it."

Not only the leaves, but also the stems and rootless plantlets can be eaten raw and fresh. Columela mentions their being eaten pickled with salt and vinegar. Purslane has a pleasant acidic flavour and is very juicy. In Spain, it is usually eaten at a more advanced stage of growth, after cooking. It is also delicious boiled and in omelettes. Sauteed in butter or fried, it is used in soups, broths, salads and sauces. Together with sorrel, it forms part of the French soup *bonne femme*. Recipes are also known for purslane and pea soups.

To complete the range of its applications, one could mention its use as an insecticide, in which case its juice is poured on to anthills, and also its ornamental use in Roman and medieval gardens.

At present in Spain, it is basically a volunteer species (weed) among summer irrigated crops, and its consumption is gradually declining; this is also the case with individuals collected from wild populations.

Botanical description

Purslane is an annual, herbaceous plant, with branched, decumbent or fairly ascending stems of up to 50 cm, and which are reddish, fleshy and glabrous. The leaves measure 0.5 to 3.3 x 0.2 to 1.5 cm, are obovate, entire and fairly papillose. The flowers are yellow and solitary or in axillary groups of two or three. The fruit is in a capsule (pyxidium) of up to 7 mm. The seeds measure 0.6 to 1 mm; they are reniform, black, and maintain their germinating capacity for eight to ten years. Of orthodox behaviour in germination, their viability is maintained much more if they are stored dry at a low temperature.

Ecology and phytogeography

Purslane was one of the most widespread horticultural plants in the Old World since distant times. It was taken to America where it was naturalized, as in Europe, in gardens, among rubble and at waysides. It originates from the region extending from the western Himalayas to southern Russia and Greece. In eastern Asia it does not seem to be spontaneous. In Greece it is spontaneous and cultivated. Vavilov (1951) categorizes it in the Mediterranean countries of the Near East and central Asia as a weed and vegetable.

Nowadays it is distributed over the hot temperate zones of a great part of the world. Together with other species of the genus it occurs as a weed in the majority of tropical and subtropical countries.

It is cultivated in the United Kingdom, the Netherlands and other European countries. It is a popular winter vegetable in northern India. In Spain. it very frequently occurs as a volunteer, but it is very rare as a crop.

Genetic diversity

Little work has been done on the management of purslane's extraspecific variability. Apparently, without any aim at improvement, protoplast fusion of the genera *Portulaca* and *Nicotiana* has been attempted, and heterokaryons and the first division have been observed, but it is not clear whether multiple divisions occurred.

Nevertheless, there is an enormous intrageneric variability. The genus *Portulaca* is cosmopolitan and many species are grown as a vegetable. Thus, *P. afra* Jacq., *P. pilosa* L. and *P. tuberosa* Roxb. in southern Africa and *P. quadrifida* L. in tropical Africa; *P. retusa* Engelm. in North America and *P. pilosa* L. in South America; *P. napiformis* Muell. in Australia; and *P. lutea* Forst in Polynesia. *P. quadrifida* L. is cultivated in many tropical regions.

Within *P. oleracea* and in its wild populations, Danin and Baker distinguish five subspecies (*oleracea, papillato-stellulata, stellata, granulato-stellulata* and *nitida*), on the basis of the seed size and structure of the testa. Recognition of these subspecies is somewhat questionable, especially if we take into account their sympatric character. Generally speaking, the existence of a single *P. oleracea* complex with several varieties is accepted; it includes: var. *oleracea*, which is widespread as a weed; and var. *sativa* (Haw.) Celak, which is cultivated as a vegetable and has a bigger and erect habit.

In a chemotaxonomic study comparing proteins and free amino acids, Prabhakar and Ramayya (1988) found that, within the complex *P. oleracea*, the var. *ophemera* is distinct from the var. *oleracea* and *sativa*.

In the var. *sativa*, it is usual to distinguish two types which can be differentiated by their colouring: green purslane and golden purslane. However, it seems that colour depends basically on exposure to the sun and is more an environmental than a genetic characteristic. Some markets, such as the French market, appreciate red in particular.

In the commercial catalogues of seed firms, cultivars of this horticultural plant are not usually offered.

Girenko (1980) has described the intraspecific diversity and composition of cultivars in various climatic zones of the CIS, along with another set of data of agricultural interest.[1]

Extensive work also has to be done on the recovery and conservation of purslane germplasm. In 1985, as part of a joint project with the IBPGR, a mission of the Agricultural Research Corporation collected indigenous germplasm of *P. oleracea* in the northeastern region of the Sudan. At ARARI in Izmir, Turkey, some accessions of *P. oleracea* are conserved.

[1]This article, published in 1988, has not been translated from Russian.

Cultivation practices

This is a vegetable which develops rapidly in hot environments. Cultivation is very simple, entailing the necessary hoeing and irrigation on light, rich soils which encourage emergence.

It can be grown in greenhouses and may be broadcast or sown by burying the seeds with light pressure. A first and second irrigation are essential and must be carried out either by sprinkler or by hand. In order to ensure moisture during emergence, the plots are sometimes covered with wet sackcloth. The seeds germinate quickly and have to be raised up to accelerate emergence and development. The plantlets are harvested when four or five leaves have formed which, with suitable temperatures, is achieved in about 20 days. It is possible to cover a long production period by staggered sowing.

In temperate areas in central Europe around April, when the frosts are over, cultivation also takes place in the open air with direct broadcasting (10 g per m^2). Moisture must be ensured during emergence. Later, when the seedlings have reached the mid-point in their growth, they tolerate water shortages well. In this type of cultivation, the plant is normally allowed to develop and the stalks are harvested throughout the summer. If the plant is not pulled up, it sprouts again.

The crop's biggest enemies are low temperatures and weeds, which require as many hoeings as necessary. Pests and diseases do not appear to constitute important limitations.

Prospects for improvement

Cultivation does not present any technical difficulty preventing restoration of this vegetable's use. In experimental tests carried out by the authors on the southeastern coast of Spain, uniform production of seedlings of between 6 and 8 cm was obtainable after a month or so during the winter and spring in an unheated polyethylene greenhouse.

This type of cultivation is the one which may be most readily acceptable on western markets, provided clean rootless seedlings are offered, appropriately packaged in trays covered with plastic film. Under these conditions, they keep well at low temperatures for a couple of weeks.

This type of product is practically unknown to the consumer and yet it is the most suitable for salads. If plants or shoots of plants developed under high temperature conditions are used, they may have excessive mucilage and an unpleasant texture. The plantlets have a milder flavour and texture which make them more appetizing.

Where plant material is concerned, practically everything remains to be done, since very little improvement work has been carried out recently.

Borage

(*Borago officinalis*)

Botanical name: *Borago officinalis* L.

Family: Boraginaceae

Common names. English: borage, cool tankard; Spanish: borraja, borraja común, borraga, borracha, bora, corrago, alcohelo, flores cordiales; Catalan: borratja, borraina, pa-i-pexet; Basque: borrai, borroin, murrum, assunasa, porraiña; Portuguese and Galician: borrage, borragem, erva borragem, borraxa

Properties, uses and cultivation

Borage is attributed with sudorific (flowers), diuretic (leaves and petioles) and emollient properties (cataplasms of leaves). It contains substantial mucilage, tannin, potassium and magnesium salts and traces of essence. The seeds contain up to 23 percent linoleic acid.

Pharmacologists in past times used to include borage within the "four pectoral flowers", and it was also strongly recommended in cases of rheumatism, in which case the fresh leaves were applied as a poultice, since they lose their properties when dry. The flowers and seeds had a reputation as euphoriants and were added to wine for this purpose. Some authors think that borage is the plant which the Greeks called *eafrosinon* and which, according to Pliny, "made men joyous and happy". One Greek proverb used to say: "I, borage, always give courage." In sixteenth-century Spain, it was still attributed with this property.

Thus, Alonso de Herrera (1981 [1513]) states that borages "are healthier than any other vegetable and. in truth, it can be said that in many cases they are not appreciated because these powers, which are many, are unknown". He also mentions some of these: "When raw, they engender a very singular blood, and more so when cooked with a good mutton or capons, and for this reason they are very good for old people... and if their seed is drunk in wine, it cheers the heart greatly...". The question arises as to whether the vegetable's virtues might not be due to the other ingredient which accompanied it.

In actual fact, its effects cannot be very obvious. since "in many cases they are not appreciated". The mildness of its action perhaps explains the well-known Spanish expression "it is borage water" to indicate that something has come to nothing. For example, Boutelou and Boutelou (1801) explained: "In ancient times it was very often used in medicine, but nowadays it is practically forgotten since it does not produce the effects for which it was applied in those days."

As a food vegetable, the origin of its cultivation has not been pinpointed. Although it is unclear whether the Greeks and Romans made medicinal use of this plant, it is more certain that they did not cultivate it, since none of the writers of treatises such as Columela or Paladio referred to it, although some authors attribute a Latin etymology to *borago* (derived from *borra* = rigid hair, because of the characteristic hairiness of the whole plant). Other authors support an Arabic etymology, from *abu* = father and *rash* = sweat, because of the sudorific property of its flowers. Some historians even thought that the plant came from Africa during the Middle Ages. However, there is no doubt that the plant is native to Spain and that, around the twelfth century, the Andalusian Muslims were not growing it. Indeed, in his *Kitab al-Filaha*, Ibn al-Awwam makes a single reference to it, treating it as a wild plant which could be used in times of famine. Other Andalusian agronomists and doctors such as Ibn Hayyay (tenth century), Ibn Wafid (eleventh to twelfth centuries) and Maimonides (tenth century) seem to mention it, but there is a degree of confusion regarding its name, *lisan al-lawr* (ox tongue), which may refer to both *Borago officinalis* and *Anchusa officinalis* or *A. italica*.

Consequently, borage must not have been cultivated until after the twelfth century. It is known to have been grown in Castile in the fifteenth century and, in 1539, Alonso de Herrera gave an extensive description of its cultivation and properties. It was one of the first vegetables taken to America by the Spanish; as early as 1494 it was being grown in the gardens of La Isabela, the first city founded on American soil. In the seventeenth century, Cobo (1953 [1662]) also stated that borage had adapted to Latin America. In the eighteenth century, it was frequently grown but had already lost importance.

Borage is grown for its leaves and stalks which are eaten as a vegetable. The young leaves can be eaten raw in salad dressed with olive oil, giving an aroma and flavour similar to cucumber. They should be chopped, since they are not very appealing whole because of their hairiness. They are used cooked in soups, as a garnish for meats and also in olla, a kind of stew. The leaves cooked in batter and served with hot or grated cheese are delicious. Similarly, borage dumplings can be made, while its finely chopped leaves can be cooked with almond milk to make an exquisite soup or used to make an excellent borage omelette.

However, nowadays leaf petioles are the part of the plant most used and lend themselves to most of the uses stated.

The flowers are used to garnish dishes and prepare an exquisite dessert. Genders (1988) suggests a recipe for borage tart. In some regions, a dessert is also prepared by frying the leaves, to which sugar or honey is added, in the same way as the *paparajotes* of Murcia, but using borage instead of lemon leaves. In Majorca, according to Font Quer (1990) the leaves are used to make fritters by preparing a mixture with beaten eggs and wheat flour and then frying the leaves thus coated in hot oil and sprinkling them with sugar and cinnamon.

Borage is also a honey-producing plant, the flowers and roots produce dye, while the active synthesis of linoleic acid—of pharmacological and cosmetic interest—occurs in the ovary, which explains the high content of linoleic acid in the seeds.

Botanical description

Borage is a sturdy, annual herbaceous plant. Almost all the plant is covered with stiff hairs. It has a taproot and erect, sturdy stems which reach 20 to 100 cm and are sometimes branched. It has ovate or lanceolate, petiolate basal leaves in a rosette which grow up to 25 cm. The upper caulinar leaves surrounding the stem are sessile. The flowers are a bright celestial blue on branched tops. Flowering occurs from spring to autumn. The fruit contains four oblongo-ovoid nucules measuring 4 x 2.5 mm.

Borage is an allogamous plant, which has hermaphrodite flowers with exserted stamens. It has a self-incompatibility system controlled by numerous genes. Pollination is predominantly entomophilous (bees).

The plant is propagated from seed. Seed collection is laborious, since the seeds drop easily. Sixty-five seeds weigh 1 g; 1 litre of seeds weighs around 430 g. In commercial storage conditions, germination capacity remains high for eight to ten years. Its behaviour is orthodox in storage.

The seed germinates very quickly, without any dormancy problems. The chromosome pattern is 2n = 2x = 16.

Ecology and phytogeography

In its spontaneous or subspontaneous form, borage grows on uncultivated land, embankments, fallow land, wasteland, garden edges, waysides and among ruins.

It is native to the Mediterranean region but has been naturalized in the hot zones of western, central and eastern Europe, sometimes with unstable escapes northwards. It is also found in Southwest Asia, Macronesia and North America.

Cultivation of borage as a vegetable is limited to certain regions of the Netherlands, France, Spain and Latin America, being unknown in the rest of the world.

In Spain, it is grown mainly in the Ebro valley, in the provinces of Zaragoza, Logroño and Navarra. The total cultivated area in 1987 was 303 ha and production 7818 tonnes.

In recent years, some expansion of cultivation towards Andalusia has been noted, particularly in Almería. Sheltered cultivation is beginning to be carried out, with excellent results.

Genetic diversity

The genus *Borago* has only two Mediterranean species. In humid areas of Corsica and Sardinia, *B. pygmaea* (DC.) Chater & W. Greuter, a perennial with decumbent stems, is found.

Borago officinalis L. is a very variable species. There are varieties characterized by the flower colour. Although they are generally bright blue, there are also types with white and pink flowers. However, these are very heterogeneous populations with a great diversity in habit, vigour and development of the plant, shape, colour and size of the limb and leaf petiole, flowering, etc.

The cultivar Flor Blanca, which is marketed in Spain, has leaves with petioles of 40 to 50 cm in length and 1.5 cm in width. The plant grows to a height of around 50 to 60 cm.

In the gene bank of the SIA at the Diputación General de Aragón (Zaragoza), there is a small collection of accessions of this vegetable.

Cultivation practices

Borage is a very hardy plant which is suited to all types of soil. although it grows best on clayey-muddy soils. It prefers land that is rich in organic matter. It tolerates low temperatures, down to -50°C, and starts to sprout again when the temperature rises.

In Spain, direct sowing is used. The ground should be prepared with a basal dressing using about 50 tonnes of manure per hectare, if it has not been incorporated into the previous crop, and 90 to 120 units per hectare of nitrogen, phosphorus and potassium. The soil must be well broken up with deep ploughing and a couple of harrowings. In Aragon, staggered sowings are carried out in the open air from mid-August to January, in rows or individual drill holes with 25 to 30 cm between plants.

Cultivation presents no particular problems; the plants must be irrigated and, in the event of intensive cultivation, after thinning out top-dressing must be supplemented by 150 units per hectare of easily assimilated nitrogen.

The vegetative cycle takes between 50 and 120 days and harvesting can begin in mid-October, ending in May since, when high temperatures come with spring, the plant goes into flower and loses its value. Harvesting is done by hand. Each plant has two or three rosettes with five to seven leaves each. with a weight of 500 to 1000 g per plant.

Production levels of around 60 to 100 tonnes per hectare are obtained. According to data in the Spanish Government's *Anuario de Estadística Agraria*, average yields are 25 tonnes per hectare in the case of open-air irrigation and 36 tonnes per hectare in sheltered cultivation, Navarra being foremost with yields of 40 tonnes per hectare using both methods of cultivation.

Recently, sheltered cultivation under plastic has been gaining in importance. Under these conditions, much longer and fleshier leaf stalks are obtained and the stalk/plant yield rises to 60 percent, as against the 40 percent obtained with open-air cultivation. Production levels are also usually better.

The crop's main enemies are virus diseases (cucumber mosaic virus), soil fungi (*Fusarium* sp.), soil grubs, caterpillars and aphids.

The plant is usually marketed in 15 to 20 kg "bundles", amounting to 15 to 30 clumps, or in 10 to 12 kg boxes as complete plants, with part of the leaf removed. However, the consumer prefers borage to be completely stripped and packed in trays protected with plastic film.

Borage is subject to the technical regulations on the control and certification of horticultural plant seeds. The requirements for seeds of the basic, certified and standard category are 97 percent specific purity, 65 percent germination of pure seeds, with a maximum tolerance of 0.5 percent of seeds of other species. According to INSPV data, in 1989 2567 kg of borage seed were marketed, 2 489 kg of which were homegrown. Only the white variety was grown.

Another method of cultivation carried out in the Netherlands uses plantlets. After direct sowing, these are allowed to grow to a height of 10 to 15 cm and the complete plantlets are harvested. After washing and root removal, these can be marketed in trays covered with plastic film.

Prospects for improvement

Most improvement work has been carried out using white flower types. Breeding by growers has created forms with more succulent, longer and wider leaf stalks, with little pigmentation and less hair than the wild forms.

One of the main problems of cultivation is its ease of bolting, including the formation of flowers, which lowers the value of production. This process is caused by high temperatures and light intensity and reduced humidity. Breeding for resistance to bolting is a priority improvement objective, and a very high response to breeding is observed.

Although this plant has traditionally been cultivated in the open air, excellent results are now being obtained under plastic, in which case growth improves. A quality product, with long, tender leaf stalks and less hair can be obtained for a good part of the year in a greenhouse. The plant tolerates low winter temperatures and high humidity well. In the area around Zaragoza, borage has been converted into the most profitable crop under plastic.

The expansion of sheltered cultivation may encourage the recovery of this marginalized vegetable. The first tests in this connection have been carried out in Almería. If they prove positive, they would contribute to the diversification of production and to improving the supply in this region. which has great agricultural importance and yet depends on a very small number of crops.

As far as the consumer is concerned, in the case of regions that do not have a tradition of using this plant, borage must be presented stripped and properly packed, so that the work of culinary preparation is reduced. The plant's coarse, hairy appearance may cause some degree of rejection, which is avoided with appropriate cleaning and presentation.

With sights set on possible external markets which are even more demanding than the Spanish market, the high nitrate content of leaves and leaf stalks will need to be reduced. This can be achieved without great difficulty, as breeding to obtain a low nitrate content has been effective in other cases. Breeding to obtain individuals with a low content of lasiocarpine, a pyrrolizidinic alkaloid, would also be advisable, although its content is not excessively high.

As regards the plant's pharmacological use, in vitro cultivation of embryos is being developed; this is a technique whereby the active synthesis of linoleic acid takes place. In vitro propagation techniques of borage have also been developed.

Alexanders

(*Smyrnium olusatrum*)

Botanical name: *Smyrnium olusatrum* L.

Family: Apiaceae = Umbelliferae

Common names. English: alexanders, alisander, maceron; Spanish: apio caballar, apio equino, apio macedónico, perejil macedónico, esmirnio, olosatro, cañarejo; Portuguese and Galician: salsa de cavalo, cegudes, apio dos cavalos, roses de pé de piolho; Catalan: api cavallar, abil de siquia, julivert de moro, cugul, aleixandri

Origin of the name

This is the *hipposelinon* of the Greeks, a word which means parsley or "horse celery". In Arabic, during the Andalusian period, it was called *karafs barri*, one of the various *karafs* (celeries) known by Hispano-Arab agronomists, different from cultivated celery (*Apium graveolens*), aquatic celery (*A. nudiflorum*) and mountain or rock celery (the Greek and Latin *petroselinum* or *oreoselinon*). Alexanders has always been identified as oriental or Macedonian, very possibly as a reference to its geographical origin and its allochthonous character.

Properties, uses and cultivation

Its use as a medicinal plant is very old. The Greek botanist Theophrastus (fourth century BC) made reference to the plant. Dioscorides (first century) also included it in his *Materia medica*, commenting that its roots and leaves were edible. According to this author, its seed, taken with wine, is an emmenagogue. However, Galen said that it was less active than celery. In the Cordoba of the caliphs, Maimonides also spoke of its powers. During the Middle Ages, it was constantly considered as a plant with diuretic, depurative and aperient properties, particularly through its root. However, its most outstanding quality was perhaps as an antiscorbutic because of its high vitamin C content. The fruit has carminative and stomachic properties. In the eighteenth century, it continued to maintain its reputation as a medicinal plant. as the *Flore économique des plantes qui croissent aux environs de Paris* described it in 1799.

The plant, and especially the leaves, have a smell and flavour similar to myrrh. Hence the origin of the word *smyrnion*, its generic name. Columela (first century) refers to the plant as "myrrh of Achaea", because it was grown in Greece. which the Romans called Achaica or Achaea. It is also because of its characteristic flavour and smell that it is used as a condiment; it is used to season food in a similar way to parsley, giving flavour to soups and stews, and to prepare sauces accompanying meat and fish. However. its commonest use has been as a fresh vegetable, with a preference being shown for its leaves, young shoots and leaf stalks, which impart a pleasant flavour similar to celery, although somewhat sharper. It has also been eaten cooked. The Latin word olusatrum, which means "black vegetable". reflects these uses. The roots were used preserved in a sweet-and-sour pickle. The fruit contains an essential oil, cuminal, which is reminiscent of cumin.

The history of its cultivation is surprising. Of all the Umbelliferae used as vegetables, alexanders has been one of the commonest in gardens for many centuries, although in the nineteenth century it was almost completely forgotten. It was probably being gathered before the Neolithic period and was already being grown as early as the Iron Age. It became very popular during the time of Alexander the Great (fourth century BC) and was widely grown by the Romans, who certainly introduced it into western and central Europe, including the British Isles. It is now naturalized in these regions and on the Iberian Peninsula.

Columela elaborates on its cultivation and methods of consumption: "Before alexanders puts out stems, pull up its root in January or February and, after shaking it gently to remove any soil, place it in vinegar and salt; after 30 days, take it out and peel off its skin; otherwise, place its chopped pith into a new glass container or jar and add juice to it as described below. Take some mint, raisins and a small dry onion and grind them together with toasted wheat and a little honey; when all this is well ground, mix with it two parts of syrup and one of vinegar and put it like this into the aforementioned jar and, after covering it with a lid, place a skin over it; later, when you wish to use it, remove the pieces of root with their own juice and add oil to them."

Isidorode Sevilla (sixth century [1982]) seems to attach less importance to alexanders.

In France, it was an important vegetable, and was grown on the estates of the Carolingian kings. Thus, in the *Capitular de Villis*, promulgated by Louis the Pious, son of Charlemagne (around AD 795), alexanders appears among the plants which should be cultivated. In the eighteenth century, in Versailles, it was used blanched to accompany winter salads. In the early nineteenth century, Rozier, in his *Dictionnaire universel d'agriculture pratique*, writes: "The leaves of alexanders can appear among cooking condiments, like parsley. Its roots and young shoots are still eaten in England after blanching in the same way as celery."

There is documentation on its cultivation in Belgium in the fifteenth century and on its abundance in English gardens in the sixteenth century. The Italians also traditionally used this plant. However, by about the eighteenth century its cultivation was only very occasional or had fallen into disuse. In Spain, Font Quer (eighteenth century [1990]) says that its root was eaten in many countries as a salad, raw and cooked, as were the stems and young leaves. By the nineteenth century, Spanish agronomists were no longer making any reference to it. Thus, Boutelou and Boutelou (1801) do not mention it, an omission which contrasts with the 13 pages devoted to celery cultivation.

Alexanders was falling into disuse as from the seventeenth century. in direct competition with the celery of the Italians", an improved form of wild celery (*Apium graveolens*). This is a case of marginalization in which one plant, doubtless widely used since prehistory, is replaced by another one improved later.

Botanical description

Alexanders is a biennial herbaceous plant with a thick elongated root. The stems grow up to 150 cm and hollow on fruiting. It has large, pinnatisect, basal leaves, with ovate to subrhombic terminal segments; the caulinar leaves are pinnatisect. The umbels have seven to 22 rays, with black. didymous fruit measuring 5.5 to 7.5 x 4 to 7.5 mm. Alexanders flowers from April to June and propagates well from seed. Its chromosome structure is $2n = 2x = 22$.

Ecology and phytogeography

Wild populations of alexanders grow abundantly in salt-marshes and uncultivated land near the sea. normally in lime soils. It is also found in hedges. woods and on waysides.

It is spontaneous throughout southern Europe, North Africa (Algeria) and in the Near East. In former times it was very abundant in the area around Alexandria. Vavilov (1951) places this crop in the Mediterranean gene centre.

It also occurs on the Canary Islands and in the rest of the Macronesian region.

Genetic diversity

Perfoliate alexanders (*Smyrnium perfoliatum* L.) has smaller fruit (3.5 mm long) and is distributed through central and southern Europe and southwest Asia. The blanched stems and leaves are used in salads. Its cultivation is documented in the sixteenth century. According to Mathon (1986), this species is of superior quality.

Nowadays it is very difficult to find cultivars of alexanders. However, several cultivated varieties must have existed. For example, in England in 1570, Petrus Pena and Mathius Lobel wrote: "...the cultivated form is far better than the wild plant...". It seems that the plant is still occasionally grown in Great Britain.

Accessions of this species are kept only in the gene bank of the Córdoba Botanical Garden. They are from wild populations in Andalusia.

Cultivation practices

According to Columela, "alexanders must be grown from seed in ground dug out with a *pastino*, particularly close to walls because it likes shade and thrives on any kind of ground: so once you have sown it, if you do not uproot it fully but leave its stems for seed instead, it lasts forever and requires only light hoeing. It is sown from the feast day of Vulcan (August) until the calends of September, but also in January...".

Nowadays, since cultivation has been relegated to a few family gardens, similar practices are frequently seen. The stem is left to seed, and sowing and spontaneous cultivation takes place. Something like this usually occurs with chard: weeds are removed and a little fertilizer is applied.

Modernization of this crop will depend on techniques similar to those used for celery, including blanching, taking into account the fact that alexanders requires less soil and water.

Prospects for improvement

Celery was also known from antiquity but was considered to be an inedible plant of ill omen. The Greeks, who called it *apion*, used it in funeral ceremonies. It appears to have been grown early in our era by the Latins. Columela refers to it: ...after the ides of May, nothing must be put in the earth when summer approaches, except for celery seed, which must nevertheless be watered, since in this way it does very well...". Paladio also mentions it, probably basing himself on the earlier source. Likewise, in the *Capitular de Villis* (eighth century) reference is made to both *apium* and *olisatum*. Throughout this period, cultivation of alexanders seems to be predominant.

Around the seventeenth century, types of celery appeared which were derived through breeding to obtain a better size and improved succulence of the leaf stalks (var. *dulce* (Mill.) Gaud.-Beaup.) or fuller leaf development (var. *secalinum* Mill.) and which were clearly differentiated from the wild plant. These types are actually different vegetables requiring specific cultivation practices. Thus sweet-leaved celery ("celery of the Italians") is well suited to "blanching", which enables a milder, more tender product to be obtained.

The marginalization or disuse of many vegetables used since ancient times in Europe may be connected with the changing tastes in the Western world. The trend has been away from dishes rich in spices and hot ingredients towards milder dishes, which respect the flavour of the food itself or enhance it. This is perhaps the case with celery *vis-à-vis* alexanders. Alexanders is more bitter and pungent and not as tender as sweet celery.

It is significant in this respect that the last agronomic references to the cultivation of alexanders mention the introduction of the blanching technique. It appears thus in the reports by Versailles and Abbot Rozier: "...after they have been blanched in the same way as celery..."; and Barral and Sagnier, in *Diccionario de agricultura* (1889), write: "...in Turkey the cultivation of this plant is still an honour. The leaf is eaten after it has been blanched...". The blanching technique also used to be employed in North America. It is obvious that the smaller plant, celery, had asserted itself and now served as a reference, making it necessary to adopt the same cultivation practice for alexanders, evidently with little success.

While cultivation of alexanders is waning, cultivation of celery is by contrast on the increase, as is its importance in cool subtropical and tropical areas of Latin America and the Far East. Petiolate cultivate with big leaves are chiefly used.

The recovery of alexanders would be achieved via the derivation of plant materials with a specific typology, for specific uses, and the development of associated agronomic techniques; this seems very unlikely.

Scorzonera

(*Scorzonera hispanica*)

Botanical name: *Scorzonera hispanica* L.

Family: Asteraceae

Common names. English: scorzonera, Spanish salsify, black oyster plant, viper's grass; Spanish: escorzonera, escorcionera, escurzo, yerba viperina, salsifí negro, salsifí hispánico, churrimana, tetas de vaca; Catalan: escurçonera; Basque: sendaposei, astobe-harri; Portuguese and Galician: escorcioneira, escorzoneira

Properties, uses and cultivation

Scorzonera has diuretic and depurative properties. The root has restorative and sudorific properties and is an ingredient of many infusions. It is very rich in carbohydrates (18 to 20 percent in fresh weight), with a high proportion of inulin and laevulin, which makes it very suitable for a diabetic diet. It also contains conopherin (glucoside), asparagine, arginine, histidine and choline.

In upper Aragon, the latex is added to milk as a cure for colds. Its ground, fresh leaves are used against viper bites to soothe the pain. Its peeled root, fresh or cooked, acts as a tonic for the stomach and fortifies the body.

It is considered to be an antidote to the bite of poisonous animals, for which reason in Spanish it is called "escorzonera", i.e. herb against *escuerzo* [toad]. The *Diccionario de la lengua española* of the Real Academia Española mentions that the name derives from the Latin "black root" because of its external colour. In Italian, too, *scorza* means "root" and *nera* "black". However, as documented in Mattioli's *Epistolarium medicinalium libri quinque*, published in 1561, the first interpretation seems correct.

Cultivation of this plant is thought to be recent. No Roman or Arab agronomist mentions it. In Spain, its cultivation is not dealt with either by Andalusian agronomists (tenth to fourteenth centuries) or Castilian writers of treatises in the sixteenth century. The same applies in other countries. In France, it is not mentioned in the *Capitular de Villis* of the Carolingian kings, nor does Olivier de Serves, Henry IV's minister, mention it. It was from the sixteenth century onwards that botanists began to concern themselves with this species, describing it as wild, although sometimes introduced into botanical gardens. It is not quoted as a cultivated plant until up to one century later. In time, it was to become fashionable in several countries. Thus Louis XIV of France was very fond of it.

Although scorzonera was perhaps first cultivated in Spain, its cultivation has never been very important in the country. Boutelou and Boutelou (1801) commented: "Scorzonera is usually sown on the edges of unoccupied beds, the empty spaces being profitably used by this tasty root", thereby demonstrating a marginal rather than a main crop.

On the other hand, it is curious that these same authors visualized a greater agricultural importance for white salsify than scorzonera, contrary to what actually happened. Thus, they thought that "...sometimes the roots of scorzonera can begin to be used the first year after sowing, but they are so thin that there is no point in wasting them so young. They require two or sometimes three years for their root to form. Salsify, which has the same taste and properties and which forms in one year, should be preferred because it requires less time in the ground and its product is much more plentiful." The main improvement activity on this crop has enabled some good cultivars to be obtained, with a greater growth rate and better yields than salsify in annual cultivation.

The part of the plant most used is the tender, fleshy root. It is peeled and then cut into pieces and placed in water with lemon to prevent it from turning black. It can then be eaten in a wide variety of exquisite dishes: raw in a salad; dressed with vinaigrette or with other sauces, steamed and served with Béarnaise or Béchamel sauce or with whole milk cream and toast; sautéed in butter with parsley or other herbs; boiled as an accompaniment for meat; grated with cheese; baked with tomato and roast mutton or pork, fried with oil or butter after being lightly cooked and served with lemon; scrambled with eggs or in omelettes; and preserved in sugar.

It is recommended that, once cooked, the roots should be peeled so that they do not lose their flavour.

The leaves can also be eaten, especially the young ones after boiling. The "beards"—young, fresh and tender leaves—can also be eaten raw. The young shoots are used in the same way as asparagus.

The flowers are added to salads as a flavouring. They have an aroma reminiscent of cocoa. For this purpose, the flowers of other species such as *S. mollis* and *S. undulata* are also used. The flower buds can be used too. Recipes exist for scorzonera flower omelette.

Botanical description

Scorzonera is a perennial plant with a long, fragile taproot, which is blackish on the outside and white and milky inside, and which increases in size each year. The stems are solitary or few in number, usually branched on the upper part and between 30 and 120 cm long. The leaves are broad, long, fleshy and spatulate. The yellowish flowers are in capitula at the end of the stems. Flowering is in spring and summer (April-June).

Propagation is from seed. The achenes are 10 to 20 mm long, cylindrical, whitish and rough, with a pappus that has several rows of hairs. The weight of 75 to 90 seeds is I g, the weight of one litre of them is around

580 g. Under ordinary storage conditions they maintain a high germination capacity for two to three years.

It has a diploid chromosome number: 2n = 14. In the var. *crispatula*, some polyploids have been detected: 2n = 4x = 28.

Ecology and phytogeography

Scorzonera grows on dry pasture. rocky areas, in thickets and on limy or marry soils of temperate zones.

It is distributed over central and southern Europe and the south of the CIS, although it is not found in Sicily or Greece or in northwestern Africa or southwest Asia. It probably originates from the Mediterranean region and is native to Spain.

The plant is little cultivated outside Europe. Most cultivation takes place in the gardens of amateurs, with the plant being cultivated in professional gardens on a very small scale. Some estimates put cultivation at only a few dozen hectares. The countries with the biggest cultivated area of scorzonera are Belgium, Poland and members of the CIS.

At present, its cultivation is practically unknown in Spain. Although it is subject to the Technical Regulations on the Control and Certification of Agricultural Seeds and Plants, there is no evidence of the seed being marketed in Spain in recent years.

Genetic diversity

The modern *Scorzonera* genus, which is very close to *Tragopogon*, only includes three sections (*Podospermum*, *Scorzonera* and *Lasiospora*) with some 28 species in Europe. The majority of them are perennial diploid plants with 2n = 2x = 14. Cytotypes also exist with 2n = 2x = 12, x = 6 being derived from the earlier type through translocation.

In Spain, some 13 species are to he found. The majority of them prefer dry soils. This is the case with *S. angustifolia* L., *S. transtagana* Coutinho, *S. hirsuta* L., *S. crispatula* (Boiss.) Boiss. and *S. brevicaulis* Vahl. *S. parviflora* Jacq. is found predominantly on saline soils; *S. laciniata* L. on alkaline soils; *S. aristata* Ramond ex DC. is calcicolous and is found only in meadows and other grassy places of the Pyrenees, the Alps and Apennines; *S. fistulosa* Brot. del W. in Portugal and southwestern Spain. *S. humilis* L., dwarf scorzonera, grows very widely in Europe, while *S. baetica* (Boiss.) Boiss., *S. albicans* Cosson and *S. reverchonii* Deveaux ex Hervier are found only in southern Spain.

Scorzonera (*S. hispanica* L.) is extremely variable, especially in its leaf shape. The botanical varieties recognized are *crispatula* Boiss. (*S. crispatula* (Boiss.) Boiss.), which is very widespread, and *pinnatifida* (Rouy) Díaz de la Guardia & Blanca, which is relatively rare; they are basically distinguishable through their leaf morphology.

Numerous commercial cultivars already exist, and there are generally populations with open pollination:

- **Gigante de Rusia**, with a regular cylindrical, very long and smooth root and a very black skin. Various selections derive from it, such as Gigante negra de Rusia, Gigante anual, Annual Giant Bomba, Russisk Kaempe, etc.
- **Lange Jan**, which is of good quality.
- **Elite Stamm**, which is productive, stable, with a high yield of superior size roots.
- **Schwarze Pfahl**, which is similar to Elite Stamm.
- **Pronora**, which has well-formed roots, a smooth skin and, when canned, a good colour and flavour. It is especially suitable for industrial processing.

- **Vulcan, Duplex** and **Pilotis**, which are suitable for the frozen foods industry.
- **Hoffman 83, Flandria, Nero, Duro** and **Habil** are also good cultivars.

There are collections of local races and old cultivars at the Rijksstation voor Plantenveredling de Merelbeke (Belgium), at the Nordic Gene Bank in Alnarp (Sweden) and at the Vavilov Institute of Industrial Plants, St Petersburg.

Cultivation practices

Scorzonera is a vegetable that resists drought well when the plant has already developed.

It has similar cultivation requirements to white salsify. It is a typically winter vegetable which, although perennial, is grown as an annual.

It is usually sown direct in early spring, in shallow furrows, with 25 to 35 cm x 12 to 15 cm spacing. Care must be taken to provide protection from birds, which are very fond of these seeds.

About 12 kg of seed per hectare is required. Deep, fresh, loose soil is needed; it must be rich in decomposed organic matter and free from stones or gravel, which cause root deformation. The basal dressing recommended is 30 tonnes per hectare of rotted manure, 50 units of N, 100 units of P_2O_5 and 200 to 250 units of K_2O).

Attention must be paid to the first irrigations and hoeings, which can be controlled chemically, both at pre-emergence and post-emergence, with CIPC. It prefers sunny soils and the presence of easily assimilable nitrogen of which an additional 50 units can be applied as a top-dressing.

Harvesting takes place from November to March and requires perhaps more care than the harvesting of white salsify, since the roots are very fragile. This means furrows of about 40 cm have to be opened parallel to the rows of roots. Storage is good, both on the actual cultivation land and in cold stores at between 0 and -1°C, possibly for two to three months, or frozen, with light industrial processing to clean, peel, cut and scald the vegetables to prevent oxidation.

Yields of around 20 to 30 tonnes per hectare have been obtained.

The most important diseases are mycosis, white rust, oidiopsis and strangulation and splitting of the roots, the aetiology of which is unknown.

Prospects for improvement

Although it is thought that this vegetable is very little cultivated in Spain, because it has not been introduced into Iberian cooking, it should be recognized that serious cultivation problems still exist.

Although scorzonera is more productive than salsify and its cultivation more frequent, the two crops have many problems in common:

- a prolonged cultivation cycle, with garden space being occupied for an excessively long time;
- susceptibility to bolting, even during the first year of cultivation—although this does not hollow the root or impair its quality, it does affect yield, making systematic cuts of the flower stems necessary;
- poor seed storage;
- slow emergence and the need for a constant level of moisture;
- very laborious harvesting, since deep trenches have to be opened because the roots are very long and fragile;

- high nitrate content.

Some of these problems have already been tackled or are on the way to being solved. Thus, Schwarze Pfahl is more resistant to bolting than Elite Stamm.

Einjährige Riesen is particularly resistant to bolting and produces a low percentage of roots with cavities. However, it does not attain the yields of the former. Since genetic variability in respect of the character exists within commercial cultivars, rapid progress in improving this cultivar may be expected.

In Belgium, material is being selected which is especially suited to mechanical sowing and harvesting. Lange Jan, Hoffman 83 and Flandria were the ones which contributed the best product qualities among the cultivars tested.

In Poland, work is being done on the development of cultivars suited to industrial processing (both canning and freezing); some cultivars display a good behaviour in this respect.

Insofar as these improvement objectives are achieved. scorzonera may be expected to begin acquiring greater economic importance. It should not be forgotten that it is a vegetable with a very delicate flavour; its glucide composition is rich in inulin, very unlike other tubers and roots rich in carbohydrates, for instance the potato which has a high starch content. This property may be the reason for the increase in demand and price.

Spotted Golden Thistle

(*Scolymus maculatus*)

Botanical name: *Scolymus maculatus* L.

Family: Asteraceae = Compositae

Common names. English: spotted golden thistle; Spanish: tagarnina, diente de porro; Portuguese: escólimo-malhado

Origin of the name and properties

The generic name derives from the Greek, *skolos*, meaning spines, a characteristic shared with many other Compositae. In ancient Greece, a thistle with an edible root was known by the name skolymos. Diuretic and antisudorific properties were attributed to these plants.

Spotted golden thistle has occasionally been cultivated, but generally the wild plant has been used, with harvesting being limited to the leaves only in spring. At present, its cultivation is very restricted and is tending to disappear.

Cervantes did not seem to set great store by this plant: "...1 do not have a stomach made for spotted golden thistle, nor for *piruétanos*, nor for roots of the forests." However, the fleshy parts of the young leaves, like those of Spanish oyster plant, constitute a delicious vegetable which can be used in soups, stews and scrambled eggs or as an accompaniment for meat. Baked au gratin, they make an excellent dish.

Botanical description

Spotted golden thistle is an annual, glabrescent plant with latex. The stems are 20 to 130 cm long, broadly wing-shaped, irregularly dentate and spiny. The leaves, bracts and wings of the stem have a white and continuous cartilaginous edge. The basal leaves are oblong-lanceolate, smooth and pinnatifid, with few spines. The pinnatifid caulinar leaves are sinuate, more or less oval and spiny. The bracts are lanceolate, involucral and are more than five in number. The capitula are golden yellow, solitary or in clusters of two to four and flower from May to June. The achenes are of 3 to 4 mm and without a pappus. The chromosome number is 2n = 2x = 20.

The plant is propagated from seed. Its behaviour is orthodox in storage and its germination capacity is maintained for a long time. Dormancy phenomena are not very pronounced.

Ecology and phytogeography

Spotted golden thistle is found on uncultivated land, in abandoned fields and ditches and along paths and waysides. It prefers clayey soils and temperate climates.

It is distributed through southern Europe, Southeast Asia, North Africa and the Macronesian region. It is a native plant of the Mediterranean region. In Spain, it grows very widely throughout the country, including the Canary Islands.

It is occasionally cultivated in some areas of the Maghreb, southern Italy and Greece. In Spain. cultivation has practically disappeared.

Genetic diversity

The genus *Scolymus* L. includes another two Mediterranean species with a use similar to that of the spotted golden thistle, the Spanish salsify or Spanish oyster plant (*S. hispanicus* L.), with a wide Mediterranean distribution, and *S. grandiflorus* Desf, with a more restricted distribution in the eastern Mediterranean. These are very close species which differ in the leaf margin and wings of the stem and in the involucral bracts. among other characters. Unlike the spotted golden thistle, these Spanish salsify oyster plants are biennial or perennial.

A great morphological variability is observed, but no collections of material are known.

Cultivation practices

The spotted golden thistle is a very hardy plant which prefers clayey soils, although it grows spontaneously in a wide variety of environments. It tolerates cold and drought.

The method of cultivation is similar to that of Spanish salsify, although the latter thrives better on looser soils. Sowing is direct into the soil ready for cultivation, in late winter, with furrows 30 cm apart. After thinning, the plants are spaced 30 cm apart. It is preferable to apply organic fertilizer beforehand. The usual cultivation practices are very simple, being limited to removing weeds.

With hot temperatures, the plant grows very rapidly, with the basal rosette forming quickly, at which time the leaves have to be harvested.

Prospects for improvement

Spotted golden thistles, like Spanish salsify or oyster plants, are practically unknown vegetables on the market. However, they are appreciated in many Spanish regions on account of their very pleasant flavour. As in the case of so many other crops, its revival will have to be accompanied by a marketing system which creates demand. This means publicity campaigns, utilization standards, recipes for traditional dishes, etc., as well as a product of sufficient quality being available on the markets. The fleshy leaf parts would have to be offered peeled and clean and suitably packaged.

From the point of view of improvement, one of the most serious problems of the spotted golden thistle is the ease with which it goes into flower, encouraged by long-day spring conditions and high temperatures. Selection for resistance to this process would increase the cultivation period and make it possible to improve yields of the basal rosette. The plant's general spininess is another problem.

Undoubtedly, the most urgent task is to carry out collecting expeditions in the Mediterranean basin, including the Maghreb, and to characterize the material collected as a starting point for improvement. At the present time it is already very difficult to find traditional cultigens.

This problem is not limited to the spotted golden thistle and Spanish salsify, or even to the genus *Scolymus*, but affects many other Compositae. For example, the tribe *Carduaceae* contains 80 genera with over 2650 species, 227 of which are found in Spain and 150 of which are endemic in the country. Many of these plants have agricultural value and have occasionally been cultivated. In the majority of cases, cultivation is on the decline, even though it is being maintained. The recovery of these genetic resources, the characterization of the materials and the initiation of improvement programmes could contribute towards diversification, both of production and supply, thus helping to make Spanish agriculture more competitive.

Spanish Salsify

(*Scolymus hispanicus*)

Botanical name: *Scolymus hispanicus* L.

Family: Asteraceae = Compositae

Common names. English: Spanish salsify, Spanish oyster plant, common golden thistle; Spanish: cardillo, cardillo de comer, cardillo de olla, cardillo bravío, cardo lechar, cardón lechar, cardón lechal, lechocino, cardo zafranero; Catalan: cardet, cardelina; Basque: kardaberaiakca; Portuguese: cardo de ouro, cangarinha

Properties and uses

The Spanish salsify plant has been recognized as having antisudorific and diuretic properties. The Greeks knew it and it is mentioned by Theophrastus. Pliny makes reference to it and considers it an antiperspirant. However, it is barely mentioned by Andalusian agronomists. The translator of an anonymous Hispano-Arab document of the eleventh and twelfth century interprets that *silyan* and *adaliq*, spiny plants which people collect among wild vegetables, are indeed Spanish salsify, *Scolymus hispanicus*.

Although it has been cultivated occasionally, at present it is clearly in recession. Most of the Spanish salsify that is eaten comes simply from collecting the wild plant.

Several parts of the plant have a fairly delicate flavour. The young basal leaves are eaten as a vegetable in salads, boiled, in soups, stews, omelettes, etc. The most pleasant part of the leaf is the central rib, a white fleshy part which is obtained by peeling the leaf, with a scraping movement with one hand from the base to the apex, while the other hand holds the base. The young stems are used in a similar way. Font Quer (1990) mentioned that this plant is appreciated in almost all of Spain's provinces and "...is used widely in stew during the spring". In the sixteenth century in Salamanca, the washed young plants used to be eaten with their root, either raw or in stews with meat. In soup, its roots are prepared with milk, butter and flour.

Botanical description

Spanish salsify is a biennial or perennial plant, which is erect, contains latex and is very spiny. The stems are between 5 and 250 cm long, branched at the top, with discontinuous spiny, dentate wings. The basal leaves are oblong-lanceolate, smooth, pinnatisect, with few spines, and a long petiole. The caulinar leaves are rigid, coriaceous and spiny. The capitula have one to three golden-yellow, enveloping leaves; they are about 3 cm long, in a lateral or terminal arrangement and surrounded by an involucre of spiny bracts. The achenes are 2 to 3 mm with a pappus that has a short corona. It flowers from May to July. The plant is propagated from seed, which has a very good germination capacity for several years and does not exhibit any marked dormancy phenomena. It is a diploid plant: $2n = 2x = 20$.

Ecology and phytogeography

Spanish salsify is found on waste ground and uncultivated land, among rubble, in ditches and along paths; it is most frequently found in sandy places in temperate zones.

Distributed through southern Europe and North Africa, it extends to northwestern France. Vavilov (1951) pinpoints its origin as the Mediterranean region. In Spain, it grows wild in most of the country but shuns high mountains; it is less common in the north. It is also found in the Canary Islands.

It is occasionally cultivated in Mediterranean countries such as Spain, Greece and the Maghreb; it is practically unknown in the United States.

Genetic diversity

There is considerable variability in the morphological characteristics of Spanish salsify such as hainness, leaf morphology and involucral bracts, receptacular scales, spininess, etc.

No definite cultivars exist; it is still possible to obtain a few cultigens, although there is a serious risk of losing these materials.

There has been no significant activity in collecting or conserving genetic resources of this species.

Cultivation practices

Spanish salsify is a very hardy plant, is resistant to cold and thrives on all kinds of soil, although it prefers light-textured soils that are rich in organic matter. Its cultivation requires very little care.

Sowing is direct and is carried out in late winter or in spring. A light, well-drained, manured soil should be used. It can be sown in furrows, 30 cm apart with a distance of 30 cm between plants after thinning.

The young white shoots can be pulled up when they reach 20 cm or so in height. The fleshy parts of the leaves need the basal rosette to be well formed. The roots are usually harvested around the end of October or during the winter. If the plant is left until the following year, it goes into flower and develops a sturdy stem, while the basal leaves lose their quality because of toughening. Therefore, although the plant can be kept for several years, it should be cultivated as an annual.

There are no serious phytopathological problems.

Prospects for improvement

The considerably spiny nature of the Spanish salsify plant, and especially of the caulinar leaves which have big, tough spines, is a serious drawback to its handling and deters attempts to cultivate it. The breeding of less spiny forms would facilitate the plant's handling.

As far as the most widely used portion is concerned—i.e. the fleshy part of the leaves—forms will need to be bred that have thick, tender and juicy ribs. Wide collections of material must be made, especially of the old cultigens which can still be recovered, so as to characterize and select them. The areas of greatest interest are the Maghreb, southern Greece and non-horticultural Spanish regions.

If the intention is to use the roots, harvesting should be carried out until the end of the winter. Resistance to flowering will enable root yield to be improved by encouraging rapid root growth at the time of hot weather.

Prosopis pallida H.B.K.

Syn.: *Prosopis limensis* Benth.
Mimosaceae
Kiawe (Hawaii), Algarroba

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Very valuable for ornament, shelter in arid conditions, and for timber, fuel, and forage (fruits). Highly esteemed by foresters in Hawaii. Its cultivation might be encouraged in other warm and dry countries (Burkart, 1976). Leaves and pods, fed to cattle, donkeys, and other livestock, are eaten by wildlife. Pods sweeter than those of most other Prosopis species. In its native habitat they are made into a sweet syrup used to prepare various drinks. A potentially important species for plantations in hot, dry regions, especially where salinity makes the cultivation of other species difficult (NAS, 1980a).

Folk Medicine

No data available.

Chemistry

No data available.

Description

Tree (or shrub on sterile soils) 8–20 m high, trunk to 60 cm in diameter, unarmed or spiny, with short axillary, uninodal, geminate, divergent spines less than 4 cm long. Leaves medium to small in size, pallid grayish-green when dry, (1–)2–4 jugate, pubescent, ciliolate to subglabrous; petiole short, with the rachis 0.8–4.5 cm long, pubescent; pinnae 1.5–6 cm long, with a sessile, cuplike gland at their junction; leaflets green or gray when dry, 6 to 15 pairs per pinna, approximate without touching or a little distant, pubescent or at least ciliolate, oblong-elliptic to ovate, obtuse or mucronate, firm, pinnatinerved below, 2.5–8.3 mm long x 1.4–4 mm broad. Racemes spiciform, much (2 to 3 times) longer than the leaves; rachis and the short peduncle pubescent, together 8–15 cm long; florets dense (200 to 250 per raceme), short-pedicelled, greenish-yellow; calyx ciliolate, 0.5–1.5 mm long; petals 2.5–3 mm long, free, villous within; stamens 5–7 mm long; ovary stipitate, villous. Legume straight or subfalcate, very similar to that of *P. juliflora* (Sw.) DC., but thicker, straw-yellow when ripe, with parallel margins, fleshy, sweet, edible, subcompressed, long or short stipitate with rounded base, and acuminate, sometimes nearly subquadrate-rectangular in transection, (6-)10–25 cm long 1.5 cm broad 5–9 mm thick; endocarp segments to 30, broader than long; seeds oblong, brown, 6.5 mm long (Burkart, 1976).

Germplasm

Reported from the South American Center of Diversity, kiawe, or cvs thereof, is reported to tolerate drought, lava, salt, and sand. Shallow-rooted, the species is subject to windthrow. Said to hybridize with *P. juliflora* in Ecuador. The tree may become an invader, forming annoying thickets (Burkart, 1976).

Distribution

Native to Peru, Colombia, and Ecuador in the drier parts and along the Pacific coast. It has been naturalized in Puerto Rico and the Hawaiian Islands, and perhaps elsewhere (Brazil); introduced for cultivation in India and Australia (NAS, 1980a; Burkart, 1976).

Ecology

Probably ranging from Tropical Thorn to Moist through Subtropical Thorn to Moist Forest Life Zones, this species is estimated to tolerate annual precipitation of 2 to 13 dm and annual temperatures of 18 to 26°C. Ranges in soil adaptation from old lava flows to coastal sands.

Cultivation

Seed sown in new locations may require rhizobial inoculation. Can be irrigated with water half as salty as sea water. According to Felker et al (1981), *P. pallida*, *P. articulata*, and *P. tamarugo* grew well on an N-free medium equivalent to 1/2 seawater and grew slightly in full seawater.

Harvesting

No data available.

Yields and Economics

In the 1940's, nearly 181 MT honey were produced annually from the kiawe, once appraised as "the most valuable of all the introduced trees in the Hawaiian Islands. Prior to 1948, ca 500,000 bags of pods were collected annually as fodder in Hawaii (Neal, 1948).

Energy

Largely used for charcoal, the wood has a high calorific value.

Biotic Factors

Apparently attractive to termites and wood boring beetles like *Clytus cornis*. Psyllids feed on the shoots and leaf tips of this species, apparently more than others. Felker et al (1981) review the pest infestations of their *Prosopis* plantings with suggestions for their control.

Prosopis alba Grisebach

Mimosaceae
Algarrobo Blanco, Ibope, Igope, Tacu

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

All information, especially early information, on *Prosopis* spp. is only tentatively assigned to one or the other species of *Prosopis.* Taxonomic identities were extremely confused until Burkart's monograph. Much of the early chemical, ecological, and ethnobotanical data may be masquerading under the wrong name. Burkart (1943) describes several beverages made from the fruits, including a coffee substitute made from toasted pods. A very important tree in arid lands, similar in value to *Prosopis chilensis, P. nigra,* or *P. pallida*. In northeastern Argentina, native people frequently call it "el arbol", the tree, because of its usefulness and abundance. It is cultivated to a limited extent. In the Chaco it furnishes timber of high value for construction, doors, premanufactured houses, etc. Trees with straight trunks 8 to 10 m occur, but these are becoming extremely rare, from being cut in preference to the other shorter ones. Thus a negative, artificial selection is taking place, which should be counteracted by genetic up-building of the best lines in experimental plots (Burkart, 1976). According to NAS (1980a) this valuable food tree is also used for fodder, roadside planting, timber, and windbreaks. Streets of Buenos Aires are lined with these trees in the belief that they subdue vehicular noises (Burkart, 1943). The fruit is milled into a baking flour for human consumption. Though difficult to work, the wood is used for flooring, paving blocks, shoe lasts, and wine casks. Sawdust, like the fruits is used for tanning.

Folk Medicine

Reported to be astringent, lithontriptic, and tonic, the white algarrobo is a folk remedy for ophthalmia.

Chemistry

Per 100 g, the pericarp only (of *P. alba* and *P. velutina*) is reported to contain 4 g H_2O, 10 g protein, 40 g sugar, and 19 g fiber. "Patay" is the sweet floury paste of the pods, ground up and dried, serving as the basis for many popular Argentine dishes. Patay contains 9.6% water, 6.7% ash, 43.9% sugar, 10.4% starch, 5.9% cellulose (we need it), 4.3% protein, 1.2% fats, and 3.5% pentosans. While high in calories, the patay is deficient in certain proteins, vitamin A, C, and D (Burkart, 1943). Like *P. chilensis*, this species contains apigenin 8-glucoside, apigenin 6-glucoside, quercitin 3-glucoside, quercitin 3-rhamnoside, quercitin 3-rutinoside, and traces of myricetin 3-rhamnoside, luteolin, kaempferol-3-OMe quercetin, and quercitin 3-OMe (Simpson, 1977). Pipecolic and 4-hydroxy pipecolic acid also occur in both, but varying concentrations of pipecolic acid and proline are interpreted as reflecting a plastic response to changing environmental conditions. The consistent patterns of flavonoid distributions in several species groups, on the other hand, apparently reflects genetic fixation independent of known environmental factors (Simpson, 1977). Pods contain ca 7–11% protein, 25–28% sugar (Simpson, l977; Burkart, 1943).

Description

Tree 5–15 m tall, in age the short trunk possibly reaching 1 m in diameter; treetop rounded; branchlets drooping; spines scarce and small, only on strong shoots, 2–4 cm long, geminate. Leaves large, uni- to trijugate, glabrous; petiole (including the rachis) 0.5–8 cm long; pinnae 6–14 cm long, with 25 to 50 pairs of leaflets, these linear, acute or subacute, in some forms nearly obtuse, 0.5–1.7 cm long x 1–2 mm broad, scarcely nerved below, approximate, 1.5–6 mm between pairs. Racemes spikelike as in similar species, 7–11 cm long; florets greenish-white to yellowish, small; calyx 1 mm long, puberulous; corolla 3–3.2 mm; stamens 4.5 mm; pistil 5 mm long. Legume falcate to ring-shaped (ring ca 7 cm in diameter), linear, compresses with parallel margins, straw-yellow, stipitate and acuminate, 12–25 cm long x 11–20 mm broad x 4–5 mm thick, with 12 to 30 subquadrate endocarp segments broader than long, ca 0.6 x 1 cm (Burkart, 1976).

Germplasm

Reported from the South American Center of Diversity, white algarrobo, or cvs thereof, is reported to tolerate drought, salt, and sand, but it will withstand only a few hours of mild frost, prolonged cold (-6°C) killing most seedlings. Said to hybridize with *P. flexuosa, P. nigra*, and *P. ruscifolia*. In terms of chromosome number and morphology, there seem to be few genetic or chromosomal barriers to hybridization between various species of *Prosopis*. Sympatry, partial overlap of flowering time, and little specific discrimination by pollinating insects also facilitate hybridization ($2n = 28$) (Simpson, 1977).

Distribution

Plains of subtropical Argentina to Uruguay, Parguay, southern Brazil to Peru (Burkart, 1976).

Ecology

Our computer entries for *Prosopis* spp. are unreliable partly due to past taxonomic confusion. I estimate that the species ranges from Tropical Thorn to Moist through Subtropical Thorn to Moist Forest Life Zones. It will probably tolerate annual precipitation of 1 to 20 dm, annual temperature of 18 to 28°C, and pH of 6 to 8.5. Felker et al. (1981) cite studies suggesting that the annual minimum temperature isotherm of minus 20.5°C defines the northern limit for *Prosopis* distribution generically.

Cultivation

Tree can be seeded directly but is best sown in a nursery and outplanted when 2–3 months old. For quick germination (3–4 days), high temperatures (night 26°C; day 32°C) are best. Running the pods through a coarse sausage grinder both helps to separate and scarify the seed. Felker et al. (1981) found that a coffee mill produced fewer broken seed than the other devices they tested. Felker et al (1981) report water requirements of 478.3 cm /g DM, making this one of the more water efficient species. Felker et al. (1981) report the first successful rootings of mesquite cuttings. Seed need to be inoculated with mesquite rhizobia. Competes well with grasses and shrubs.

Harvesting

This species, like *P. nigra*, has good coppicing qualities. Felker et al (1981) project costs of $23.36 per dry ton (on the stump from tissue cultured seedlings) for the first harvest and only $5.00 per dry ton for subsequent coppice regrowth harvests. Firewood harvested as needed.

Yields and Economics

The three *Prosopis* accessions with greatest potential for woody biomass production in semi-arid southwestern US are *P. alba*, *P. chilensis*, and *P. articulata*. *P. alba* (#0166) had highest biomass production of the three selections, had good coppicing characteristics, and low psyllid insect damage. It has been successfully rooted from cuttings. Thorn free selections have been observed. One tree survives where a 5 mm salt layer covers the ground and a mature tree survived a -9°C (16°F) frost. It may prove more frost hardy than either *P. articulata* (#0016) or *P. chilensis* (#0009). Felker et al (1981) feel that progeny of *Prosopis* alba accessions used for ornamentals are most promising for woody biomass production in arid lands despite impressive biomass production by *Leucaena* and *Parkinsonia*. They report yields of 50 MT DM/ha in 3 years or nearly 17 MT/ha/yr, a yield sufficiently high to make effective use of harvesting and transportation equipment. Felker et al. (1981) give detailed economic projections in their table, *Projected Costs for Mesquite Pod Production.* Perhaps even more important, they talk about total use of the pods, fractionating for mesquite pod gum, protein, and sugar to realize their full economic potential. Galactomannan gums, estimated to constitute 25% of the seeds of some *Prosopis* species have many cosmetic, chemurgic, and food uses. The gum is fairly similar to carob gum, which commanded $0.62–1.11/kg in 1970. Way back in the 40's, the mildly intoxicant beverage, aloja, was made from fruits sold in the market for 30 Argentine centavos/kg. The fermented aloja was further distilled into aguardiente or ethanol. To produce a liter of absolute alcohol requires 1.7 kg fermentable sugar, which constitute about 3/4 of the fruit's weight (Burkart, 1943).

Energy

Burkart (1943) suggests that a ton of fruit could yield 27.2 liters of absolute alcohol. Felker et al (1981) state that the land area required for a small commercial ethanol production plant (1,000 barrels/day) could be contained in a circle with radius of 10.9 km assuming conversion rate of 2.6 gallons ethanol per 55 pounds pods (much higher than Burkart's assumptions) and yields of 4,000 lb/acre. Ca 12% of the land would provide firewood for distillation. Ten year old Argentinean plantations spaced at 2 x 2 m produced 7 m /ha/yr (NAS, 1980a). Felker et al (1981) report yields from 9.8–19.2 MT/ha/yr in the Imperial Valley.

Biotic Factors

Bruchids associated with this species include *Rhipibruchus*, *Pectinibruchus*, and *Scutobruchus*. Spraying cuttings with dithane suspensions has markedly reduced problems with the fungus Alternaria (Felker et al., 1981). Felker et al. (1981) review the pest infestations of their *Prosopis* plantings with suggestions for their control.

Alkali sacaton

Gramineae, Poaceae *Sporobolus airoides* (Torr.) Torr.

Sacaton

***S. wrightii* Munro ex. Scribn.**

Source: Magness et al. 1971

Alkali sacaton is a native bunchgrass found from South Dakota west to Washington and south into Mexico. It is densely-tufted and long-lived, with erect, solid stems about 3 feet tall. Basal foliage is abundant, the leaves being up to 18 inches long and 0.25 inch wide. Roots are fibrous and deep-penetrating. The grass will grow on moist, alkaline soils, hence the name, but also occurs on other soil types. It is palatable while succulent but becomes tough and unpalatable when ripe. Hay is of fair quality if cut early. Propagation is by seed, which is usually harvested from native stands.

Sacaton is a more robust grower than alkali sacaton and is more southern in its range, being native from West Texas to Arizona and south into Mexico. The stems reach to 6 feet and are firm and bard. It is less drought resistant than alkali sacaton. It furnishes useful grazing both while succulent and in winter, and is useful for hay if cut while young. It is rarely planted but is a useful grass in its native range.

Rakkyo

Ch'iao t'ou

Amaryllidaceae *Allium chinense* G. Don

Source: Magness et al. 1971

Rakkyo is an onion relative. It is an important vegetable in the Orient and in this country is grown and used mainly by Orientals. The plants do not produce seeds and are propagated by bulb division. In mild climates, bulbs are planted in late summer, and the crop is harvested in midsummer of the following year. Several small bulbs are obtained from each bulb planted. Rakkyo bulbs are mainly pickled, some are canned. Also, they are used as a cooked vegetable. The leaves have hollow blades. Culture and exposure of plant parts is similar to that of bulb-set onions.

Season, planting to harvest: About 10 months.

Production in U.S.: No data. Grown to limited extent by Oriental gardeners.

Use: Mainly pickles, some canned and some used as fresh cooked vegetable.

Part of plant consumed: Bulbs.

Onion, Welsh

Japanese bunching, Negi, Cibal, Spring onion, Nebuka, Cebollin

Amaryllidaceae *Allium fistulosum* L.

Source: Magness et al. 1971 This is the principal onion of Japan and China, but of limited importance in the U.S. Leaves are rigid and tubular and inflated or swollen in appearance. The bulbs become only slightly enlarged. Plants multiply by tillers from a mother plant, so clusters of plants result from planting a single one. They may also be grown from seed. In the Orient the leaves and leaf bases are often blanched by covering with soil. There, and in the U.S., they are also marketed as green onions. The thick, swollen leaves and leaf bases are harvested.

Season, seed to first harvest: 4 to 5 months for green onions, a year or more for blanched.

Production in U.S.: No separate data. Total green onions 12,071 acres, 1959 census.

Use: As pot herbs, flavoring in culinary cookery, salads.

Part of plant consumed: Thick leaves and leaf bases.

Allspice

Pimento, Jamaica pepper, Pimienta

Myrtaceae *Pimenta dioica* (L.) Merr.

Source: Magness et al. 1971

Allspice is the dried, unripe berries of a large evergreen tree, native to the Caribbean area. The leaves are large and leathery, about 8 inches long by 2 inches wide. The fruits are about 0.33 inch diameter, near globose, produced in clusters of a dozen or more at or near the terminals of branches. The fruit is harvested while immature, as it is then most strongly flavored. It is a drupe, with 1 or 2 seeds. The whole dried fruit is ground to produce the allspice powder of commerce. Both pulp and seeds are aromatic, and contain an oil with qualities similar to clove oil.

Alnus glutinosa (L.) Gaertn.

Betulaceae
European alder, Black alder

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

The wood, elastic and soft, fairly light and easily worked, is used for cigarboxes, pumps, and wooden carvings, shoes and slippers. The bark, used for tanning, imparts a hard red appearance to leather. The wood is also used in making the molds for glass manufacture. The tree provides habitat and food for wildlife, watershed protection, and is used in environmental forestry (Ag. Handbook 450). With little ornamental value, it is recommended only for wet sites.

Folk Medicine

According to Hartwell (1967–1971), the leaves are decocted in folk remedies for cancer of the breast, duodenum, esophagus, face, pylorus, pancreas, rectum, throat, tongue, and uterus. The bark and/or roots are used for cancers and inflammatory tumors of the throat. Reported to be alterative, astringent, detersive, diuretic, sudorific, tonic, and vermifuge, black alder is a folk remedy for cancer, fever, foot ailments, tumors, and worms (Duke and Wain, 1981). The bark decoction is taken as a gargle for angina and pharyngitis, as an enema in hematachezia.

Chemistry

The bark contains up to 20% tannin, a flavone glycoside of the hyperoside type, a reddish dye, emodin (?), alnulin ($C_{30}H_{50}O$), protoalnulin ($C_{30}H_{48}O$) phlobaphene, taraxerol, taraxerone, lupeol, β-sitosterol, glutinone ($C_{30}H_{48}O$), and citrullin. The leaves contain alnusfoliendiolone, 3-β-hydroxyglutin-5-en, Δ-amyrenone, taraxerol, β-sitosterol, wax, and sugars (List and Horhammer, 1969–1979). Gibbs (1974) reports l-ornithine in the roots of this species, l-serine in the genus.

Description

Shrub or small tree to 20 m, the bark initially gray-brown, smooth, lustrous, later dark gray and rougher. Leaves rotund or broadly ovate to ellipsoid or ovate, 4–9 cm long, 3–7 cm wide, basally rounded the petiole 1–2 cm long; stipules obtuse, soon deciduous. Male cones purplish brown in autumn and winter, brown in the spring, 6–12 cm long, in clusters of 3–5. Fruits rounded, the seeds winged. Seeds ca 700,000–750,000/kg, but yielding only ca 20–25,000 plantable seedlings.

Germplasm

Reported from the Eurosiberian Center of Diversity, black alder, or cvs thereof, is reported to tolerate frost, poor soil, and waterlogging. Hortus III lists var. *barbata, denticulata*, and *glutinosa*, as well as several cvs 'Aurea', 'Imperialis', 'Incisa', 'Oxycanthifolial, 'Pyramidatis', 'Quercifolia', 'Rubrinervia', and 'Sorbifolia'. Wyman (1974) mentions 'Laciniata'. *Alnus glutinosa* serves as a rootstock for grafting of other alder species.

Distribution

Throughout the Caucasus, Europe, Siberia, into Asia Minor, Iran, and North Africa. Naturalized locally in eastern Canada and Northeastern U.S.

Ecology

Estimated to range from Warm Temperate Dry to Moist through Cool Temperate Steppe to Wet Forest Life Zones, black alder is estimated to tolerate annual precipitation of 4 to 20 dm, annual temperature of 8 to 14°C, and pH of 6 to 8. Ranging north to Wyman's Zone 3.

Cultivation

Seeds which have remained viable after floating for 12 months, are sown at depths of 3–6 mm, in spring or fall. For blanket bogs in England, spot sowings have been recommended ca 15 seeds per spot fertilized with ca 60 g phosphate. Seeds germinate as well under continuous darkness as with normal day lengths. Air-dried seeds stored at 1–2°C retained their viability for two years. Seeds can however be sown immediately as soon as ripe.

Harvesting

Timber and/or firewood harvested as needed, the shrub apparently coppices readily. In the U.S., it flowers from March to May, the fruits ripening in fall, natural dispersal occurring from late fall to early spring.

Yields and Economics

A 13–18-year-old stand with ca 30,000 trees ha (ca 20% *Alnus glutinosa*, the dominant, with Carpinus and Crataegus et al) in an infertile gley at elevation 265 m had a basal area of 24–40 m^2/ha. The standing biomass was about 59.3 MT/ha wood, bark, and branches, 2.8 MT leaves, and 4.3 MT estimated roots. Leaf litterfall was ca 2.5 MT/ha/yr. A British stand dominated by *A. glutinosa* (ca 1600 trees/ha, 55% *Alnus*, 44% *Betula pendula* and *Acer pseudoplatanus*) had a basal area of ca 25 m^2/ha, a leaf area index of 3.6, and a standing biomass of 109 MT/ha.

Energy

According to the phytomass files, annual productivity is estimated at 6 to 9 MT/ha. The tree has yielded 11.8 MT/ha/yr on pulverized fuel ash (Dennington, et al, 1983). Kestemont (1975) estimated annual productivity at 8.66 MT/ha, with 5.87 MT in wood, bark, and branches, 2.79 MT in foliage. According to Cannell, (1982), Hughes (1971) estimated the aerial productivity at ca 6.7 MT/ha/yr with wood, bark, and branches accounting for 4.26 MT + 0.34 MT litter, 1.78 MT leaf and leaf litter, 0.34 MT fruit and fruit litter. NAS (1980a) recommends the black alder for consideration for firewood plantations in Tropical highlands where unseasonal cold might destroy the red alder. Nitrogen-fixation by trees up to 8 years old has been put at 125 kg/ha/yr, for 20 years at 56–130 kg/ha/yr (NAS, 1979). Related red alder has been estimated to fix as much as 300 kg/ha.

Biotic Factors

Agriculture Handbook 165 lists the following diseases for *Alnus glutinosa*: *Phymatotrichum omnivorum* (root rot), *Polyporus versicolor* (sapwood rot), *Septoria alni* (leaf spot), and *Sphaeropsis alnicola* (on twigs). Like other alders, the cv 'Laciniata' is susceptible to a canker which can kill large parts of the plant quickly (Wyman, 1974). Nematodes include *Longidorus maximus,* and *Pratylenchus penetrans* (Golden, pers. commun. 1984).

Alnus maritima Nutt.

Betulaceae
Seaside Alder

"The alder, whose fat shadow nourisheth
Each plant set neere to him long flourisheth."

William Browne, ca 1613.

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Since in its narrower sense; this species has a very limited distribution (including one transplant in my back yard), there is little economic botany data on this species. Van Steenis has elected to include *Alnus japonica* as a synonym of *Alnus maritime*. He notes that it has been planted for reafforestation purposes on eroded slopes in the Philippines. Amerindians had a wide array of uses for alder, for dyestuffs, insect repellant or insecticide, but mostly for folk medicine. Fernald, Kinsey, and Rollins (1958) relate that "the inner bark is a possible emergency food. The young bark and winter buds are popular nibbles with country boys, not alone for their tolerable flavor, but particularly for the beautiful, olive-brown saliva produced." Bees use the pollen to rear their spring broods. None of these uses were specific to *Alnus maritime*.

Folk Medicine

According to Hartwell (1967–1970), the alders are used in folk remedies for cancers, indurations and/or tumors, especially of the breast, epithelium, duodenum, esophagus, face, lip, pancreas, pylorus, rectum, throat, tongue, and uterus. Reported to be astringent and depurative, closely related *Alnus serrulata* is a folk remedy for bruises, burns, diarrhea, eye, hematuria, malaria, poison ivy, scalds, sores, syphilis, and wounds (Duke and Wain, 1981). Erichsen-Brown (1979) lists many other uses of the alder; e.g. the Potawatomi Indians made a bark tea for flushing the vagina or to shrink hemorrhoids via rectal syringe. None of these are specific to *Alnus maritima*, just generic.

Chemistry

Alnus serrulata is said to contain a sedoheptulose.

Description

Shrub or small tree to 10 m tall; bark light brown to reddish-brown, occasionally mottled with gray, with small orange-colored lenticels on younger branches. Twigs reddish-brown and glabrous in winter; buds ovoid, acute, about 6 mm long, with some pale pubescence. Leaves oblong, ovate, or obovate, 7.5–10 cm long, 3.7–5 cm wide, dark green above, glandular dotted below; margins remotely serrulate; tips acuminate or rounded; bases cuneate; petioles 12–18 mm long. Staminate aments green at first, becoming dark orange-brown, 3.75–6.5 cm long, pistillate catkins peduncled, 3 mm long at first, green tinged with red toward tip, enlarging the following spring, becoming broad-ovoid cones, 1.5–3 cm long; nutlets ovate to obovate, 3–4 mm long; wings narrow (Brown and Brown, 1972).

Germplasm

Reported from the American Center of Diversity, seaside alder, or cvs thereof, is reported to tolerate frost, poor soil, and some salinity and waterlogging. *Alnus maritima* "seems to be more affected by water stress and must be closer to a reliable source of water than *Alnus serrulata* to survive" (Stibolt, 1978). $2n = 28$.

Distribution

In the narrow sense, *Alnus maritima* occurs on the Delmarva Peninsula (four counties in Maryland, one in Delaware), two counties near the Red River in Oklahoma. "Because of its restricted range and susceptibility of the habitat to alteration by man's activities, *Alnus maritima* should be considered as threatened" as proposed in the Report on Endangered and Threatened Plant Species of the United States." (Stibolt, 1978). The peculiar disjunction DelmarvaOklahoma has been postulated by Reed (pers. commun.) to reflect Indian transplant, perhaps of a medicinal species. Perhaps they did not distinguish the species from other alders that they used.

Ecology

Probably ranging from Warm Temperate Dry through Moist Forest Life Zones, seaside alder is reported to tolerate annual precipitation of 9.5 to 40 dm, annual temperature of 13. 5 to 18°C, and pH of 6. 1 to 8. 1. Although the Oklahoma site has the higher annual temperature, it is subject to about the same number of freezes and thaws as the Delmarva sites. Generally restricted to damp or wet soils in sunny areas, most often at the edges of ponds, rivers, or streams. Perhaps due to their N-fixing ability, they can survive on N-poor soils. Mg levels ranged from 75–150 ppm, P_2O_5 from 5–14, K_2O from 38 to 51, NO_3 from 9–23, Ca from 561–1500, and soluble salts from 89–132 ppm. Aspiras (1981) states that it flourishes only in cooler parts of the Philippines, e.g. around Baguio at ca 1500–1800 m, annual precipitation ca 40 dm (164 in.) and annual temperature ca 18.5°C (64.8°F).

Cultivation

No data uncovered.

Harvesting

Can be harvested for fuel as needed.

Yields and Economics

Since this is proposed as a threatened or endangered species, there is little data on its productivity. Perhaps it or its hybrids with other alder species could equal the annual productivity of other alders now being considered for biomass or pulp production.

Energy

According to the phytomass files (Duke, 1981b), annual productivity of other *Alnus* spp. ranges from 5 to 26 MT/ha. Citing literature yields of 58–229 kg N/ha, Aspiras noted that *Casuarina equisetifolia* fixes 1,742 nmoles C2H4/24 hrs/g dry weight, compared to 4,479 for *Casuarina rumphinia*, 4,545 for *Casuarina montana*, 2,267 for *Elaeagnus philippensis*, 225 for *Alnus maritima*, 626 for *Alnus nepalensis*, 7,242 for *Coriaria intermedia*, and only 13 for *Myrica javanica*. According to Stibolt, when the nitrate concentration in the soil reaches a certain level, root nodulation is reduced and no net increase occurs (Stibolt, 1978). "The degree of nitrogen fixation in alder nodules usually exceeds that in legume nodules on a per weight basis." (Stibolt, 1978). Comparing *Alnus serrulata*, Stibolt found its nodules had higher nitrogenase activity, while

Alnus maritima nodules had higher fixation rates some of the time. Twenty-four hours after collection, *Aluns serrulata* activitiy was reduced while that of *Alnus maritima* was retained longer or even increased. In spite of this Stibolt concluded that, overall "*A. serrulata* has some advantage in the ability to fix nitrogen.

Biotic Factors

No data uncovered.

Alnus nepalensis D. Don

Betulaceae
Indian Alder, Nepalese Alder

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Nitrogen-fixing firewood species, the wood of fair quality for use in unexposed situations. It is used to a limited extent in carpentry and house construction and for tea boxes. The timber is rather durable, easily sawed, and seasons well (sp. grav. 0.32–0.37). Locally cultivated by West Java Forest Service to reforest eroded slopes under everwet climate. A fast growing species, suitable for plantation cultivation in tropical uplands (Ramoran and Panot, 1981). The tanniniferous bark is used to deepen the color of *Rubia cordifolia*.

Folk Medicine

The species is cited in the Dictionary of Traditional Chinese Medicine (from which I borrowed the Illustration) as a useful diuretic to reduce swelling of the leg.

Chemistry

Bark reported to contain 7% tannin.

Description

Large tree 8–15 (to 30) m tall, to 1 m DBH with thick silver gray bark. Twigs glabrescent, ribbed, hardly triangular. Leaves alternate, ovate to oblong, acute or short-acuminate, rounded or cuneate at the base, 7–21 x 4–10 cm; nerves 12–16 pairs, puberulous beneath (glabrescent); vein-axils bearded; midrib and nerves sulcate and glabrous above; petiole strong, 1.5–2 cm long. Male catkins to 10 cm by 3–5 mm, in a terminal panicle to 16 cm. Female inflorescences short, axillary, bearing 3–8 oblong, catkins 10–17 by 6–7 mm. peduncles 3–6 mm long. Nuts obtrapezoid, emarginate, incl. the wing 2 mm through, crowned by the style base (van Steenis, 1955–1958).

Germplasm

Reported from the Indonesia-Indochina and Hindustani Center of Diversity, nepalese alder, or cvs' thereof, is reported to tolerate clay, flooding, fog, gravel, sand, shade, slope, waterlogging, and weeds. It is not tolerant of high winds. ($2n = 28$)

Distribution

Native to southeast Asia (Burmese hills, Himalayas, Subtropical China, Indochina). Introduced to Java, India, Hawaii, and the Philippines. I saw a large tree near Kunming in Yunnan China.

Ecology

In its native habitat it ranges from 300–3,000 m, in Hawaii from 300–1,800 m, growing well in areas with more than 500 mm annual precipitation. Van Steenis (1955–1958) suggests it as an afforestation species on eroded slopes under everwet climatic conditions, growing well between 700–1,800 m. Grows best in deep well-drained loams or loamy soils of alluvial soils, but ranges from gravel to sand to clay. I believe it ranges from Subtropical Dry to Wet Forest Life Zones, with annual rainfall estimated at 5–25 dm, annual temperature 19–23°C, and pH 6–8.

Cultivation

Seeds may be sown in nurserys for transplants or direct seeded. In Burma, seed are broadcast during last years of shifting cultivation. It is a fast grower, even capable of outgrowing sugar ratoon crops. Trees coppice well, but regrowth seems to be season dependent. In Hawaii, in aseasonal situations, the trees coppice year round.

Harvesting

In Himachal Pradesh, India, the trees are lopped every other year for fuel (NAS, 1980a).

Yields and Economics

Diameters may increase at the rate of ca 2 cm/yr. In Hawaii, 26 year old trees were 50 cm in diameter.

Energy

According to the phytomass files (Duke, 1981b), annual productivity of other *Alnus* species ranges from 5 to 26 MT/ha. Although used for nitrogen fixation, slope stabilization (both of which help the energy budget of a country), the alder is also used for firewood and might be considered for the generation of electricity. Heat content of *Alnus rubra* is about 4,600 kcal/kg atid it, a temperate species, may yield 10–21 m^3/ha/yr. The wood dries rapidly and burns evenly (Little, 1983).

Biotic Factors

Leaves are sometimes stripped from the tree by coleopterous larvae. Trunk occasionally attacked by borers.

Hazel Alder

Alnus rugosa (DuRoi) Spreng.

Synonym.—*Alnus serrulata* Willd.

Figure 60.—Hazel alder (*Alnus rugosa*)

Other common names.—Tag alder, common alder, red alder, smooth alder, green alder, American alder, speckled alder, swamp-alder, notch-leaved alder.

Habitat and range.—Hazel alder is found in swamps and along the marshy banks of streams from New England south to Florida and Texas and westward to Ohio and Minnesota.

Description.—The hazel alder, although it sometimes attains the height of a tree, is more frequently a shrub from 5 to 20 feet high with smooth, brownish-gray bark. It has somewhat leathery, oval leaves from 2 to 4 1/2 inches long. The flowers, which appear early in the spring before the leaves develop, are reddish green. The male flowers are borne in drooping and the female in erect catkins. The conelike fruit usually remains on the shrub throughout the winter. The bark has a strong, rather aromatic odor and a bitter astringent taste.

Part used.—The bark.

Yautia

Yautia blanca, Yautia amarilla, Coco, Tarrier, Tanier, Eddo, Taya, Tannia,Cuban dasheen, Malanga

Araceae *Xanthosoma* spp.

Source: Magness et al. 1971

This is a tropical plant related to Taro, which see, extensivelycultivated in the West Indies and other tropical countries for the edible cormand cormels. On certain varieties the young leaves and main stems (madre) arealso used as pot herbs. The leaves are large, 1 to 2 feet long, broad-arrow inshape, borne on long petioles radiating from the "mother" or large corm. Thetop of the corm may be at or above ground level. In general exposure of thecorm, the Yautia is similar to turnip. Propagation is by planting small cormelsor the cut off top of the "mother" corm with some of the petioles stillremaining. Yautia blanca corm is white-fleshed and Yautia amarilla isyellow-fleshed. Growing Yautias do not require as much soil moisture as doesDasheen, which see. Yautias are sometimes referred to as *Alocasia* spp.

LEMON VERBENA

Family: Verbenaceae, *Aloysia triphylla* (L'Her.) Britt.

Source: Simon, J.E., A.F. Chadwick and L.E. Craker. 1984. Herbs: An Indexed Bibliography. 1971-1980. The Scientific Literature on Selected Herbs, and Aromatic and Medicinal Plants of the Temperate Zone. Archon Books, 770 pp., Hamden, CT.

Lemon verbena, *Aloysia triphylla* (L'Her.) Britt., is an aromatic shrub native to Argentina and Chile. Also known as herb Louisa and formerly classified as *Aloysia citriodora* (Cav.) Ort., *Lippia citriodora* (Ort.) HBK, *Verbena citriodora* Cav., and *Verbena triphylla* L'Her., the deciduous plant is commonly cultivated in the tropics and Europe. It is produced commercially in France and North Reaching heights of 1 to 3 meters, the plants are characterized by fragrant, lemon-smelling, narrow leaves and small white flowers borne in terminal panicles.

Lemon verbena prefers full sun and a light loam soil. The plant is sensitive to cold and has high water requirements. Either seeds or vegetative cuttings are used for generating new plants. Commercial areas are generally harvested in early summer at full bloom and in the autumn just prior to cold, killing temperatures. Essential oil is extracted by steam distillation as soon as possible to minimize volatilization, because yields of the oil are very low (14.1-11).

The essential oil, known as oil of verbena, contains -citral, -citral, methyl heptenone, carvone, l-limonene, dipentene, linalool, -terpineol, borneol, nerol, geraniol, and other constituents (14.1-11). Because of the its high price, oil of verbena is often adulterated with distillates from other plant material. Extraction of verbena with petroleum ether and alcohol gives the concrete and absolute of verbena (14.1-11).

The leaves and flowering tops of lemon verbena are used in teas and to flavor alcoholic beverages. The plant is also an ingredient in some desserts, fruit salads, and jams. It is used in perfumery, especially in making toilet water and eau de cologne. The plant is often grown as an ornamental, but it needs to be kept indoors during winter months in northern regions.

As a medicinal plant, the leaves and flowers of lemon verbena have been used as an antispasmodic, antipyretic, sedative, and stomachic.

Lemon verbena is generally recognized as safe for human consumption in alcoholic beverages (21 CFR section 172.510 [1982]).

Finn, C. 1999. Temperate berry crops. p. 324–334. In: J. Janick (ed.), Perspectives on new crops and new uses. ASHS Press, Alexandria, VA.

Temperate Berry Crops

Chad Finn

Wherever humans have lived, they have made berries a part of their diet. Most of these have never been developed beyond local markets but some have become economically important crops. In this paper, the berry crops have been divided into four groups based on their current international popularity and potential future value. An overview of the status of development, current production, and future potential for these crops is presented with an American perspective. The discussion is limited to temperate "berry" crops that are produced on a shrub, a perennial herbaceous plant, or a vine, which excludes many of the cherry/plum (*Prunus* sp., Rosaceae) relatives; jujube (*Ziziphus jujuba* Mill., Rhamnaceae); *Cornus* sp. Cornaceae; *Sorbus* sp., Rosaceae; and many other tree fruit.

MAJOR BERRY CROPS

The most economically important and best described berry crops worldwide include strawberry (*Fragaria ×ananassa* Duch., Rosaceae) (Galletta and Bringhurst 1990; Hancock et al. 1996); blueberry (*Vaccinium corymbosum* L., *V. angustifolium* Ait., *V. ashei* Reade, Ericaceae) (Eck et al. 1990; Pritts et al. 1992; Galletta and Ballington 1996); cranberry (*V. macrocarpon* Ait., Ericaceae) (Dana 1990; Eck 1990; Roper and Vorsa 1997); black currant (*Ribes nigrum* L., Grossulariaceae) (Harmat et al. 1990; Brennan 1996); table and wine grapes (*Vitis* spp., Vitaceae) (Ahmedullah and Himelrick 1990); raspberry (*Rubus idaeus* L., Rosaceae) (Jennings 1988; Crandall and Daubeny 1990; Pritts and Handley 1989; Daubeny 1996); and blackberry (*Rubus* sp., Rosaceae) (Pritts and Handley 1989; Hall 1990; Moore and Skirvin 1990; Crandall 1995). These need no further discussion as information is widely available on each.

Other major berry crops have large production areas worldwide but for a variety of reasons have not reached the stature and importance of the above. These include the hybrid berries such as 'Logan' and 'Boysen' (*Rubus* sp., Rosaceae); black raspberry (*R. occidentalis* L., Rosaceae); lingonberry (*Vaccinium vitis-idaea* L., Ericacea); gooseberry (*Ribes uva-crispa* L. Grossulariaceae); and red currant (*Ribes rubrum* L., Grossulariaceae). These will be discussed in turn below.

Hybridberries

'Logan' is a result of cross between red raspberry (*R. idaeus* L.) and a blackberry (*R. ursinus* Cham. & Schldl., Rosaceae derivative) (Logan 1909; Brown 1916; Logan 1955; Jennings 1980). 'Logan' fruit are similar in color and appearance to red raspberry but the torus remains with the fruit like a blackberry and they have a distinctive flavor. The fruit are excellent for processing and are dried, juiced, and canned. In the late 1800s to mid 1900s, 'Logan' was planted on thousands of hectares and accounted for millions of dollars in sales. Today approximately 40 ha remain in commercial production in Oregon. Many factors have led to 'Logan's' decline in popularity including: the difficulty of picking the fruit especially with a mechanical harvester, relatively low yields, and a decline in popularity in a younger generation of consumers.

'Boysen' was discovered on Rudolph Boysen's farm in California. This red raspberry (or 'Logan') × blackberry hybrid was the basis for the initial development of the Knott's Berry Farm fruit and entertainment empire. 'Boysen' has the growth habit of trailing blackberry and the fruit are similar in appearance, larger on average, with larger drupelets, and a purple fruit color. 'Boysen' was widely produced in California, Oregon, and New Zealand into the 1980s. Currently, a few thousand hectares of 'Boysen' are grown in Oregon and New Zealand but California production has largely disappeared. The market for 'Boysen' remains strong.

'Logan' and 'Boysen' can be grown wherever trailing blackberries such as 'Marion' can be grown. Information is available on cultural practices at the Northwest Berry and Grape Infonet (http://osu.orst.edu/dept/infonet/).

Lingonberry

Stang et al. (1990) specifically addressed lingonberries (*Vaccinium vitis-idaea* L., Ericaceae) at the First New Crops Symposium in 1988. Lingonberry continues to be largely a European crop. However, the Pacific Northwest has seen a substantial increase in plantings the last 3 years. Lingonberry is harvested from native stands in northeast China and in some localities a substantial quantity of juice is produced. Lingonberry is found natively on acidic soils in northern temperate zones and can range to near the Arctic Circle, but in many of these northern areas they are protected by snow cover. In addition to Stang et al. (1990), St.-Pierre (1996) has published production information. Since lingonberry is largely a processed crop, either better cultivars or better machines must be developed that will make mechanical harvest viable.

Black Raspberry

Black raspberry (*Rubus occidentalis* L., Rosaceae) production is concentrated in Oregon where 400–600 ha are harvested for processing into juice and jam. Ohio growers are planning on doubling their crop area to 250 ha in the next few years (J. Scheerens, pers. commun.). The juice is valuable as a natural colorant. In other regions, particularly regions of Ohio and Pennsylvania, black raspberry is harvested fresh as a pick-your-own crop. 'Munger' is the most important cultivar worldwide. Black raspberries are relatively easy to grow, however, they are short-lived. Plantings often last only 2–3 harvest seasons due to virus and disease infestation. Poor pollination from rain during bloom can limit the crop. The plants are trellised in the eastern US for fresh harvest but in the western US the plants are "hedged" at about 1 m for mechanical harvesting and processing. The biggest challenge with large-scale production is the fluctuation in fruit price. In 1997, the fruit sold for $US 4.18/kg whereas the price in 1995 had only been $US 1.32/kg (USDA-NASS-ERS 1998). Black raspberries can be established relatively quickly and cheaply so growers are constantly getting into and out of production in response to the fruit price.

Gooseberry and Red Currant

These two members of the *Ribes* have a long history of cultivation. They are widely adapted to temperate regions and many soil types. While they are popular in Europe as a fresh market and processed product, they have had limited success in the US, in part due to white pine blister rust (*Cronartium ribicola* Fisher) restrictions. Both are grown throughout the eastern US primarily as a fresh market crop for local sales. In the Pacific Northwest, they are grown and shipped nationally on the fresh market and Washington has about 40 ha in production. Both of these crops are primarily processed into pies or preserves in the case of gooseberries, and juice or jelly in the case of red currants. Since 1966, when federal legislation was deregulated, 17 states in the US continue to restrict the production of some or all of the *Ribes* species because they are a cohost for white pine blister rust. Some of these states are considering repealing their restrictions so that *Ribes* can be grown. Some *Ribes* genotypes are resistant to this disease and some are immune (Hummer and Finn 1998b). Gooseberry production in the US is often limited by powdery mildew (*Sphaerotheca mors-uvae* [Schwein.] Berk. & Curt), which can regularly cause defoliation in plants. While the primary cultivars grown in the US have been 'Oregon Champion', 'Poorman', and 'Pixwell' due to their reliable production, other cultivars are suitable and are mildew resistant (Hummer and Finn 1998a). The main limitation to these crops appears to be consumer education and acceptance. A number of hybrids between gooseberry and black currant are larger fruited and milder flavored than black currant; 'Josta' is the best known example (Reich 1991). While not widely planted, there are some very small commercial plantings and market development seems to be the biggest drawback to further expansion.

NEGLECTED BERRIES

Neglected berries include those that are regionally important such as elderberry (*Sambucus canadensis* L., Caprifoliaceae); aronia (*Aronia melanocarpa* [Michx.] Elliott, Rosaceae); cloudberry (*R. chamaemorus* L., Rosaceae); arctic raspberry (*R. arcticus* L., *R. stellatus* Sm., and their hybrids, Rosaceae); mora (*R. glaucus* Benth., Rosaceae); alpine strawberry (*F. vesca* L., Rosaceae); muscadine grape (*Vitis rotundifolia* Mich., Vitaceae); Juneberry/saskatoon (*Amelanchier* sp., Rosaceae); hardy kiwi (*Actinidia arguta* [Siebold & Zucc.] Planch. ex Miq., Actinidiaceae); edible honeysuckle (*Lonicera caerulea* L., Caprifoliaceae); sea buckthorn (*Hippophae rhamnoides* L., Elaeagnaceae); and schisandra (*Schisandra chinensis* [Turcz.] Baill., Schisandraceae).

Elderberry

The juice and preserves of *Sambucus canadensis* L., native to eastern North America, and *S. nigra* L., native to Europe, have often been mainstays of rural pantries and Native Americans and early settlers used them as a dried and medicinal crop. Elderberry was seldom cultivated because it was so common in fence rows and along roadsides. While limited, information is available on commercial production (Way 1981; Stang 1990). Selections of superior plants from the wild have traditionally been used locally but high quality cultivars were developed from *S. canadensis* by breeding programs in New York, Pennsylvania, and Nova Scotia (Ritter and McKee 1964; Way 1964; Craig 1966; Darrow 1975). Pennsylvania and Oregon have a few fairly large plantings, Kansas has a small elderberry wine industry and the Austrians have substantial plantings. 'Haschberg', a wild selection of *S. nigra* from near Vienna, is the main European cultivar (R. Wrolstad pers. commun.). The fruit is in demand for processing in preserves, as a natural colorant, and for wine making. In Europe, a company has just released an anthocyanin/flavonoid enriched extract primarily from elderberry for colorant and nutraceutical use. While the crop would benefit from further breeding, it is generally adapted to most locations although viruses can be a problem in the northwestern US. Incorporating the desirable acylated anthocyanin pigments of *S. canadensis* into *S. nigra* and improving pigment stability in processed products (R. Wrolstad pers. commun.) are improvements desired by processors.

Baby Kiwi, Hardy Kiwi, Tara, Wild Fig, Wee-kee

Actinidia arguta (Siebold & Zucc.) Planch. ex Miq., a smooth-skinned, winter tolerant relative of the kiwifruit (*A. chinensis* Planch./ *A. deliciosa* [A. Chev.] C. F. Liang & A. R. Ferguson, Actinidiaceae), has many common names. Recently, it has been developed from a novelty into an economically important crop (Ferguson 1990; Strik and Cahn 1998). The fruit are small, about the size of a large table grape, and are packaged multiply in "clam shell" containers rather than as single fruit. Darrow, in 1937, presented this species as a potential crop but it was not until the 1990s that it has become a small scale commercial crop. As the New Zealanders brought the fuzzy Chinese gooseberry (renamed the kiwifruit) to world attention, homeowner enthusiasts spread the more winter tolerant *A. arguta* across North America. It might have remained in the realm of enthusiasts until Hurst's Berry (Sheridan, Oregon) decided it would fit well in a diverse fresh berry product line. Their interest and development of this crop demonstrate the impact a single company, with good marketing savvy, can have on a relatively obscure crop. While the consistent demand for this crop is undetermined, more than 35 ha of fruit have been planted in Oregon since 1994 and there are a few growers with substantial plantings in Pennsylvania. *Growing Kiwifruit* is an excellent guide to growing *A. arguta* commercially (Strik and Cahn 1998). The major drawbacks to this crop are the expense of establishing a planting and the length of time to the first crop. *Actinidia arguta* requires a substantial trellis system, irrigation, and takes three years until a small crop is produced. Once in production, the biggest problems are frosts that kill newly emerged shoots that would produce the flowers, and abrasion on the fruit surface due to wind. Irrigation and other forms of frost protection reduce this problem. The fruit is harvested and put into storage when it is mature but before it begins to soften. When it is ready to ship it is treated with ethylene to begin the final ripening process. In storage, the pedicels, which do not form an abscission zone with the fruit, dry out and harden which can be of concern to consumers. This problem has yet to be solved but mechanical or genetic solutions may be possible.

Alpine Strawberry

Fragaria vesca L. production seems to have reached its peak prior to the development of *F. ×ananassa* as the primary commercial strawberry. There seems to be a constant interest in producing these small but aromatic fruit (Reich 1991). Bakers like to use these small fruit in products such as muffins where an entire berry is desirable. Homeowners often write passionately about them. They are not likely to have a major commercial impact but could be grown and marketed successfully to niche markets if the labor costs of harvest and low yields can be justified. While the plants are relatively easy to grow and can be raised from seed, they are short-lived where virus pressure is high. In breeding programs, *F. vesca* is often used as in indicator plant for strawberry viruses.

Rubus

Cloudberry (*R. chamaemorus*) and arctic raspberry (*R. arcticus*, *R. stellatus* and their hybrids) in northern Europe and mora (*R. glaucus*) in Andean South America are regionally extremely important and valuable crops. As a group, their perishable nature lends them to processing as juice, preserves, and liqueurs. Rapp et al. (1993) addressed the potential of *R. chamaemorus* at the 1992 New Crops Symposium.

Arctic raspberries are native to the colder regions of the northern hemisphere and are renowned for the strong aromatic character of their fruit. Breeding programs in Finland and Sweden have developed cultivars from these species (Jennings 1988). The cultivars are largely self-sterile so more than a single cultivar must be planted. The cultivars are apparently widely and successfully grown in Scandinavia. Production at this point in time appears to be limited to Scandinavia.

Rubus glaucus is commonly sold in the Andean countries of South America. This crop is typically grown in small, up to 0.5 ha plantings for local sale. Large bottles (2 L) of mora carbonated soda were available in grocery stores suggesting larger scale commercial production is viable. A large fruit processor seriously considered commercial production of this crop in the US in the 1970s but pulled out just before the plantings were to be established. This crop may be similar to the 'Marion' blackberry, which is renowned for its flavor and aroma and excellent processing characteristics. However, as with 'Marion', *R. glaucus* fruit are too perishable for the fresh market. This crop appears to be a developed "land-race;" cultivars have not been developed but the species has commercial qualities. Plants require irrigation on their native volcanic soils and are often trellised (Gaitoni ~1970; Federación Nacional de Cafeteros de Columbia ~1984 [The exact date of these publications is unknown but they are available upon request]). Because the species is native to high elevation near the equator (little change in photoperiod and moderate temperatures year round), widely adapted types must be developed if this crop were to be more widely planted. Commercial production has been reported in Mexico and Central and South America (Gaitoni ~1970; Federación Nacional de Cafeteros de Columbia ~1984; Rincon 1987).

Aronia, Chokeberry

Aronia melanocarpa is native to the eastern US, however, this crop was popularized and is commonly planted in Eastern Europe and the former Soviet Union. Prior to World War II, aronia was primarily used as an ornamental. Seeds were later imported from Germany to the former Soviet Union where cultivars were developed for fruit production (Kask 1987). By 1971, 5400 ha were planted in the former Soviet Union, 4000 of which were in Siberia. The original species is diploid, however, most of the cultivars are tetraploid. The 4*x* cultivars are sometimes designated as *Aronia mitshurinii* Skvorsov et Majjtulina, Rosaceae. The fruit was designated as a "healing plant" in the former Soviet Union. Experimental plantings of cultivars have been established in Czechoslovakia, Scandinavia, and Germany. The fruit is valued for its juice which is very high in anthocyanins, blends well with other fruit juices and is reputed as a source of "phenols, leucoanthocyanins, catachines, flavonoles, and flavones" that are considered to be bioactive in humans. The plants have no special cultural or site requirements. In the Pacific Northwest, the extremely vigorous plants will bear a small crop one year after rooted cuttings are planted. The plants resemble *Amelanchier*, Rosaceae in many respects. Yields of up to 17 kg/bush with 10 kg/bush average are reported in Eastern Europe. The fruit is often hand harvested by cutting the fruit clusters, but they can be mechanically harvested. In Oregon, an unidentified spring rust on the fruit caused some yield loss but its effect appeared to be minimal. Currently, there is interest in establishing commercial production of *Aronia* in the US. (Much of this information is from an unpublished document of an unknown source but is available upon request.)

Muscadine Grape

Vitis rotundifolia, a southeastern US native, seems to primarily have consumer appeal in that region. While evolutionarily related to the "bunch grapes" such as *V. vinifera* L., Vitaceae and *V. labrusca* L., Vitaceae, the muscadines differ in many ways including chromosome number, vine and berry anatomy and morphology, and physical and chemical characteristics of the fruit and juice (Olien 1990). The fruit with its distinctive musky or fruity aroma is eaten fresh but is even more commonly made into juice, wines, pies, jellies, and other processed products. While the fruit has been cultivated by indigenous peoples for more than 400 years, production has been limited to the South. Most of the 1600 ha in production is concentrated in the coastal states from North Carolina to Louisiana (Olien and Hegwood 1990). Traditionally, muscadines have been grown where Pierce's disease has limited the production of American and French-hybrid grapes (Olien 1990). Lack of research on improved cultivars, cultural techniques, and processing methods has also limited commercial expansion of the industry (Olien 1990). Currently, the price for fruit has been good. In 1998, muscadines were being sold at 1.6 times the price of 'Thompson Seedless' on the fresh market (J. Clark, pers. commun.). Although more research is needed, information is available about production practices (Dearing 1947; Hegwood et al. 1983; Olien 1990; Anderson 1996) and breeding of muscadines has been reviewed (Goldy 1992)

Juneberry/Saskatoon

A number of *Amelanchier* sp. have been harvested for their fruit and included in breeding programs (Reich 1991). The Saskatchewan government has developed excellent production guides for saskatoons (St.-Pierre 1997). While this crop has widespread commercial potential, because the purple fruit appear somewhat similar to blueberries (*Vaccinium* sp., Ericaceae), success in the fresh market will probably be limited to areas where blueberry cannot be grown due to extremely cold winter temperatures or alkaline soils (Stang 1990). However, there is certainly the potential to develop processed products that are uniquely different from blueberry. Currently, the industry is concentrated in the Canadian Provinces of Alberta (500 ha), Saskatchewan (200 ha) and Manitoba (80 ha) where growers feel they do not have enough production to meet the demand (Mazza and Davidson 1993; Delidais 1998).

Edible Honeysuckle

Lonicera caerulea (Synonym of *Lonicera caerulea* var. *edulis* Turcz. ex Herder, Caprifoliaceae) is widely harvested in regions of China and northern Eurasia. Superior Russian cultivars have been developed. The cylindrical, blue fruit ripen extremely early in the season on 1–2 m tall bushes. As with *Amelanchier*, its similar appearance to blueberry will make it difficult to establish a marketing foothold. However, it is extremely winter hardy and can grow in regions where blueberry cannot. In trial plantings in the US, it has been extremely susceptible to leaf disease in the Midwest (M. Widrlechner pers. commun.) and, as with apricot, it flowers very quickly given warm temperatures and can be severely damaged by frost. However, the flowers are reported to be able to survive temperatures several degrees below freezing.

Schisandra

A native of northeastern China and the former Soviet Union, *Schisandra chinensis* (Turcz.) Baill. vines produces red fruit that are high in vitamin C. It is harvested from the wild for local consumption and has received a great deal of attention for its reputed medicinal qualities. While it is mentioned as a cure for a large number of maladies, most refereed publications seem to focus on its effects on liver function (Ahumada et al. 1989; Mizoguchi et al. 1991; Ko et al. 1995a,b). Managed plantings would be most comparable to grape production. Currently, most production is from wild harvested fruit and commercial viability is unknown. I could find no references that discussed cultural management. Improved selections from the wild are currently being evaluated in Jilin Province by the Chinese Academy of Agricultural Science (Shen Yugie pers. commun.).

Sea Buckthorn

Hippophae rhamnoides, a native of the colder regions of Eurasia, has been harvested on a large scale in eastern Europe as a vitamin C rich fruit for processing into jellies, juices, and liqueurs. Cultural management (Li and Schroeder 1986; Bernáth and Földesi 1992; Pietilä 1998) and breeding potential (Anderson and Wahlberg 1994) have recently been reviewed for sea buckthorn. This crop could be a valuable crop in North America. Plants can tolerate extremely harsh winters and poor soils. The main limitations are the development of an infrastructure for a processing market. The "Catch-22" with this crop, and others that are only suitable for processing, is that processors are not likely to get interested unless there is a market and conversely, there is not likely to be a market developed unless there are processed products in place.

POTENTIAL NEW BERRIES

Many locally harvested crops from indigenous and introduced fruit could become economically important crops. For example, several companies in the western and northwestern US are hiring pickers to harvest wild fruit for regionally, nationally, and internationally distributed fresh and processed products. In Europe and Asia, native fruit are also commonly harvested to supply a growing nutraceutical industry. Native *Vaccinium* and *Rubus* are the most common examples of these "wild" harvested crops. Potential new crops often follow a natural progression. Interest is first generated in the crop from "wild" harvested plants. When the suppliers run into difficulty with erratic supply, interest in stabilizing the supply of the crop through cultivation follows. If the crop can be adapted to cultivation economically and the market remains in place the crop can become a new crop with commercial potential. In this group I include examples of *Rubus* and *Vaccinium* that are currently harvested form the wild.

Vaccinium "Huckleberries"

"Huckleberry" is a confusing common name. Most accurately huckleberries would describe species in the genus *Gaylussacia* Kunth., Ericaceae. However, in the commerce, this name is often used regionally as a name for the local wild *Vaccinium* species. In late summer and early fall, pickers fan out over the Northwest from the Cascade Mountains as far east as the mountains of Montana to primarily pick *V. membranaceum* Douglas ex Torr. (syn. *V. globulare* Rydb.), Ericaceae as well as *V. ovalifolium* Smith and *V. deliciosum* Piper. The fruit is sold on roadsides and to wholesalers. The restaurant trade is a major consumer of fruit and a company in Montana has become well known nationally for their "chocolate-covered huckleberries." Stark and Baker (1992) present a great deal of information on the biology of the species and propose how they could be raised commercially. While their suggested production practices may be valid they are not practical for large scale production. Recently, our US Dept. of Agriculture laboratory has begun to evaluate populations of these species at a low elevation location using cultural practices that are similar to those used for highbush blueberry (*V. corymbosum*). While the planting is only three years old, it has begun to fruit, and some genotypes appear to be adapted to low elevation production. Whether this crop will prove to be commercially viable in cultivated stands has yet to be determined. In the Northwest, some fruit is also harvested in the Coastal Range from *V. ovatum* Pursh which is more commonly cut as an evergreen "green" for floral arrangements or used as an ornamental plant in the landscape. In the past two years, more than 3 ha have been planted for commercial fruit production. While *V. ovatum* has been grown successfully in the landscape for decades, the fruit are much lower quality, particularly aromatic components to fruit flavor, than the other species discussed.

Mortiño

Vaccinium floribundum Kunth., Ericaceae grows profusely in northern South America (Popenoe 1924). The evergreen nature of this species and its fruit are similar to *V. ovatum* of North America and *V. confertum* Kunth of Mexico and *V. consanguineum* Klotzch of southern Mexico and Central America. In Ecuador, baskets of fruit are commonly available in the market. Mortiño could be more widely grown as it is a popular crop and should be amenable to cultivation. However, if production is expanded it will most likely be successful in a niche market similar to the *Vaccinium* huckleberries of North America. Since, commercial highbush blueberries, which are relatives and produce a somewhat similar fruit, are in such wide production in North America, Chile, and Argentina, it would be difficult for *V. floribundum* to displace this market.

Bilberry

Bilberry (*Vaccinium myrtillus* L., Ericaceae) has a long history in European folk medicine (Morazzoni and Bombardelli 1996) and while the fruit is largely harvested from the wild, commercial production is not unknown (Dierking and Dierking 1993). Recently attention has been focused on bilberry as efforts to determine whether cultivated North American blueberries have similar nutraceutical characteristics to *V. myrtillus* (Kalt and McDonald 1996; Kalt 1997; Prior et al. 1998). These preliminary studies indicate that while *V. myrtillus* has higher levels of antioxidants than the North American commercial blueberries, the commercial blueberries do contain high levels. Although there is potential for commercial production of *V. myrtillus*, Dierking and Dierking (1993) would not recommend it from a horticultural point of view. From a nutraceutical point of view, it would appear that the commercial blueberries, produced in such great abundance and at a relatively low cost, could satisfy this demand.

Bog Bilberry

Millions of hectares of *Vaccinium uliginosum* L., Ericaceae stretch across circumboreal regions of the Northern Hemisphere. In China, we saw these fruit harvested and sold locally and the fruit pressed for juice that was marketed around China and in the Western US. In Scandinavia, the fruit are sold from wild harvested plants and cultivars have been developed for commercial production (Hiirsalmi 1989; Hiirsalmi and Lehmushovi 1993). Unfortunately, this crop has the same niche as North America's commercial blueberry industry. While it would be hard to justify cultivation of this crop if it is to be marketed in competition with the North American blueberries there would seem to be ample justification for improved management of the huge expanses of this species for the processing market.

Trailing Blackberry

Rubus ursinus Cham & Schldl., Rosaceae is an early colonizer of disturbed sites throughout the Northwest. In this era where timber is clear-cut and agriculture has disturbed many sites, the northwest trailing blackberry is very common. As with the *Vaccinium* huckleberries, pickers harvest these fruit from native stands for the restaurant trade and specialty markets. The species is dioecious and the fruit are medium sized, soft, and have a very aromatic flavor. 'Marion' blackberry is remarkable for its flavor and this can be traced to the *R. ursinus* in its pedigree. Trailing species can be grown like the commercial trailing cultivars. However, the only justification for establishing a managed planting of the species as opposed to cultivars is if the "wild" label is critical to marketing. In general, the species is much more susceptible to foliar diseases than the cultivars. Our first generation hybrids between cultivars and this species have yielded disease tolerant, thornless, and early ripening genotypes that retain the species flavor. Whether these are commercially viable will be determined in the future.

Miscellaneous *Rubus*

As you move to different regions, there is often a *Rubus* species that is harvested from the wild for local sales. These species are very similar in their place in the market to the *R. ursinus* just described. Examples worldwide would include the southern dewberries (*Rubus trivialis* Michaux) in the US; *Rubus parvifolius* L. of China and Japan; *R. phoenicolasius* Maxim. in Japan; *R. crataegifolius* Bunge; *R. niveus* Thunb. and *R. coreanus* Miq. in China; and the many blackberry species (*Rubus*) in Europe (Anon. 1912a,b; Card 1915; Williams and Darrow 1940; Sherman and Sharpe 1971; Jennings 1988; Finn et al. 1998). Any of these crops could be developed into a major crop. However, as with mortiño, they will be competing against a well established, productive industry that produces a somewhat similar crop, i.e. red (*R. idaeus*) and black raspberry (*R. occidentalis*), and blackberry (*Rubus* sp.).

POTENTIAL CROPS WITH UNMET POTENTIAL

Finally, many crops that have previously been mentioned in these sorts of forums have not been further developed. Usually, market drives the production, either a large market does not exist or another berry is filling that market niche. A few examples of previously described potential crops in this class include: Nanking cherry (*Prunus tomentosa* Thunb., Rosaceae); cranberry bush (*Viburnum opulus* L., Caprifoliaceae); and buffalo berry *(Shepherdia argentea* Nutt. Elaeagnaceae*)*.

Nanking Cherry/Hansen Bush Cherry

Prunus tomentosa is native throughout temperate regions of eastern Asia and is widely sold in the local markets. At least a century ago, seed lots were brought to the US and breeding programs released a few cultivars in the first half of this century (Darrow 1937; Fogle 1975; Kask 1989). Hansen in South Dakota recognized that the superior cold hardiness of this productive, but small fruited, cherry might be valuable for the northern Great Plains (Kask 1989). While the species has not developed into a commercial crop, it is commonly sold through catalogues to homeowners (Reich 1991). This crop will remain in the realm of homeowners in North America and in local markets of Asia because the fruit are inferior to the commercially available sour cherries (*P. cerasus* L.).

Cranberry Bush

Viburnum opulus (syn. *V. trilobum* Marsh.) is found in northern temperate regions. While popular as an ornamental plant in the landscape, the species has never developed into a commercial fruit crop. The fruit is unpalatable fresh and must be processed into jellies or juice (Card 1915). Cultivars with superior fruit and processing characteristics have been released (Darrow 1975). Cranberry bush may have potential for small scale, local production, or for a unique processed product (Stang 1990) but, in general, the fruit is too similar to cranberry (*Vaccinium macrocarpon*) or red currant (*Ribes rubrum*) as a processed product (Darrow 1975) to justify large scale production.

Buffalo Berry

Shepherdia argentea has been stuck in the "potential" class for nearly two centuries. In 1915, Card wrote, "The buffalo berry has enjoyed the distinction of remaining a new fruit for a very long time.... Yet we are still talking about buffalo berry as a new fruit which ought to be introduced." He cites references back to 1841 that state that buffalo berry was widely grown. This species is native to the Great Plains of the US (Darrow 1975). I think horticulturists continue to return to this crop because the plants are productive, extremely winter hardy, and drought tolerant, the flowers are frost tolerant, and the scarlet fruit are very high in Vitamin C. Despite being dioecious and spiny, it would appear that it might be well adapted for mechanical harvesting and processing as a juice. Buffalo berry is likely to retain its "potential" label until someone aggressively develops the market for the fruit.

CONCLUSION

Berries have been an important part of the diet of indigenous people. The world is now a global market which will have adverse and beneficial effects on crops that have developed from a specific region. Some crops that formerly had only local interest will develop demand worldwide. Other crops may be lost as similar crops from other regions will displace them. These crops will remain regionally important but will not develop worldwide importance.

Blueberry, strawberry, and grape production will continue to expand worldwide. Cranberry production will likely expand rapidly where the proper soil and water requirements can be found or where "wetlands regulations" are not as stringent as they are in the US. Red raspberry, blackberry/hybridberry, lingonberry, and black currant will steadily increase in production. It becomes more difficult to predict the future of "neglected" berries, as there seems to be serious problems with each crop except *Actinidia arguta*. *Actinidia arguta* shows tremendous promise and will see increased production worldwide. Elderberry, aronia, and sea buckthorn production will increase if their unique anthocyanin characteristics are desirable for the colorant and nutraceutical markets. Alpine strawberry, muscadine grape, juneberry, cloudberry, arctic raspberry, and mora will continue to play important roles in regional or niche markets but are not likely to join the lists of major crops worldwide. Similarly, we hope that the "potential new crops" will develop stable crop areas with consistent production as they solidify their standing as important regional or niche market crops. I do not see great potential in Nanking cherry, cranberry bush, or buffalo berry unless someone energetically develops markets for them. The rising interest in the nutraceutical characteristics of foods has carried over to berries. Schisandra and bilberry are two examples of crops primarily harvested for their nutraceutical potential. Whether this is a trend or a fad may impact which new crops will develop a large commercial industry.

Each era has their surprises as to which new crops develop into important crops. In 1915, Card had blueberries listed in the miscellaneous section of his book. By the second half of this century blueberries had become an important crop and today they are one of the major berry crops worldwide. Who would have thought a few years ago that a major chain store in the US would be promoting "Aronia Berry Juice Cocktail?" George Darrow in 1975, gave equal space to *Actinidia arguta* and *Viburnum trilobum* (syn. *V. opulus*) in a chapter on minor temperate fruit. Twenty-five years later, *A. arguta* is on the verge of becoming an important fruit crop while *V. trilobum* remains "only" a beautiful ornamental for the landscape. Let us hope in the future that we continue to be surprised by the neglected or unknown crops.

Galangal

Zingiberaceae *Alpinia officiarum* Hance, *Langras galaga* (L.) Stantz.

Source: Magness et al. 1971

These two species, respectively known as lesser and greater galangal are tropical perennials, cultivated mainly for the underground rhizomes. The plants and rhizomes are similar to ginger. The tuberous rhizomes are the spice used in making vinegar and beer and in liquors, especially in Russia. The spice is also used in curries.

Trifolium species

Fabaceae

Clover, Peavine, Cowgrass

We have clover information from several sources:

Some 250 species of *Trifolium* are recognized throughout the world, with about 50 indigenous in the United States. None of these native species are cultivated although they contribute to grazing and may be an important part of wild hay crops. They contribute nitrogen and thus promote the growth of associated grass. The clovers may be annual or perennial. Leaves are mostly trifoliate, rarely 5 to 7 leaflets. Flower heads are usually short spikes or umbels with numerous small individual flowers in the head. The important agricultural species are described as follows:

Trifolium pratense Handbook of Energy Crops. James A. Duke. 1983. unpublished.

Red Clover Magness, J.R., G.M. Markle, C.C. Compton. 1971. Food and feed Crops of the United States.

Alyce Clover

Leguminosae *Alysicarpus vaginalis* (L.) DC.

Source: Magness et al. 1971

This is a summer annual native to tropical Asia. It was introduced into the United States in 1910 and has proven adapted to areas near the Gulf of Mexico. In thin stands the stems branch, but in thick stands stems reach 3 feet in height with little branching. Leaves are oval, unifoliate, and borne on short petioles along the entire stem. Alyce clover is grown mainly for hay and soil improvement, but also makes good pasturage. The hay appears about equal to other legume hays in feeding value. The crop is seeded in late spring and matures seed the same season. If seed matures and shatters, a volunteer crop is produced in succeeding years. Seed was harvested from about 5000 acres (1954, 1959 censuses), sufficient to plant about 80,000 acres.

Morton, J. 1987. Amazon Tree-Grape. p. 64. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Amazon Tree-Grape

Moraceae

The Amazon tree-grape, *Pourouma cecropiaefolia* Mart., of the family Moraceae, is the best-known of about 50 species of *Pourouma* in Central America and tropical South America. It is known in Brazil generally as *puruma, cucura, imbauba mansa, imbauba-de-vinho, imbauba de cheiro*; in Bahia as *tararanga preta* and in Manaus as *mapati*. In Colombia it is called *puruma, caime, caimaron, caimaron silvestre, uva caimarona, camuirro, cucura, uva, sirpe, hiye* or *joyahiye*. In Peru, it is simply *uvilla*.

The tree resembles *Cecropia* spp., which are called *imbauba* in Brazil. It reaches 23 to 50 ft (7-15 m) in height. The bark is gray and marked with leaf scars. The alternate leaves, on long petioles, are nearly circular but deeply cleft into obovate oblong-lanceolate lobes to 1 ft (30 cm) long. They are green on the upper surface, whitish or bluish-gray and velvety beneath; agreeably aromatic, like wintergreen, when crushed. The unopened inflorescence is reddish-purple, densely coated with fine white hairs. The white male and female flowers are borne on separate trees. Borne in bunches of 20 or more, the fruit is grapelike except for its wintergreen odor. It is round or round-ovate, usually 3/8 to 3/4 in (0.5-1 cm) wide, occasionally to 1 1/2 in (4 cm). The skin is very rough to the touch, inedible but easily peeled; purple when ripe. The pulp is white, mucilaginous, juicy; of subacid, very mild flavor; and encloses 1 conical seed with fibrous, grooved coat.

The tree grows wild in the western part of Amazonas, Brazil, and adjacent areas of Ecuador and Peru. It is especially abundant in the vicinity of Iquitos. It has been cultivated since pre-Hispanic times by the Indians of southwestern Colombia and is grown by Indians and non Indians in Brazil. Patino says that around 1940 propagation was begun at the Estacion Agricola at Palmira, Colombia, and seeds and plants were given to the Estacion at Calima in 1945. Some trees are being grown, too, at the Estacion Agricola de Armero. There is today renewed interest in encouraging cultivation.

The tree grows on high dry land at altitudes below 1,640 ft (500 m). It may be subject to flooding every 4 or 5 years. It cannot stand prolonged drought. The seeds have short-term viability. If planted in time, they may show 86% germination. Cuttings are difficult to grow. Seedlings bear in 1 to 3 years after setting out. There may be 2 crops per year. Some trees that have been at least 3 years in the plantation have yielded 110 lbs (50 kg). The fruit is eaten raw or made into wine.

The wood is light, coarse and non-durable. It is used only for making charcoal.

American Linden

Tilia americana L.

Synonyms.—*Tilia glabra* Vent.; *T. canadensis* Michx.

Figure 6.—American linden (*Tilia americana*)

Other common names.—Basswood, whitewood, bast tree, black lime tree, American lin tree, American lime tree, beetree, daddynut tree, monkeynut tree, whistlewood, white lind, red basswood, yellow basswood, wickup.

Habitat and range.—This native forest tree is found in rich woods, especially along the mountains, from Canada to Georgia and west to Texas and Nebraska.

Description.—The American linden is a large tree attaining a height of from 60 to 125 feet with a trunk diameter of 2 to 5 feet, with spreading branches. The somewhat leathery leaves are pointed at the apex, heart-shaped at the base, with sharply toothed margins and are borne on stems about 1 or 2 inches long. The flowers are produced in great abundance from May to June in drooping clusters composed of from 6 to 20 yellowish, very fragrant flowers. At the base of each cluster and grown to its stalk is a leaflike bract 2 to 4 inches in length. The roundish, grayish-green fruit is dry and woody and contains one or two seeds.

Part used.—The flowers, carefully dried in the shade.

American Mountain-Ash

Sorbus americana Marsh.

Figure 7.—American mountain-ash (*Sorbus americana*)

Synonym.—*Pyrus americana* DC.

Other common names.—Roundwood, round-tree, American rowan tree American servicetree, mountain sumac, dogberry, quickbeam, wild ash, winetree, witchwood, life-of-man, Indian mozemize, missey-moosey, moose-misse.

Habitat and range.—The American mountain-ash occurs in swamps, low woods, or moist ground from Newfoundland south along the mountains to North Carolina and to Michigan. It is most abundant in the northern portion of its range.

Description.—This smooth-barked tree reaches a height of 30 feet with a trunk 18 inches in diameter. The leaves resemble those of the sumac, consisting of from 11 to 17 lance-shaped, pointed leaflets about 1 1/4 to 4 inches long. When young they are slightly hairy, both sides soon becoming smooth. The white flowers are borne from May to June in dense clusters measuring from 3 to 6 inches across. The flowers are followed later in the season by large, dense, showy clusters of bright-red berries about the size of peas, which give the tree a brilliant appearance.

Part used.—The bark with the outer layer removed.

Beachgrasses

Gramineae

American beachgrass *Ammophila breviligulata* Fern.
European beachgrass *A. arenaria* (L.) Link

Source: Magness et al. 1971

These grasses are tough, coarse perennials with extensively creeping rhizomes. They produce good growth on sands of low fertility, and are used primarily for erosion control in sandy areas. For this purpose, dividing and transplanting clumps of the grasses is the most effective method of establishing stands. If planted not more than 3 feet apart, spaces between plants are rapidly filled in. These grasses are resistant to the cutting effect of blowing sand. They are of little value except for stabilization of sandy soils.

Last update February 18, 1999 by ch

Cardamom

Zingiberaceae *Elettaria cardamomum* (L.) Maton.

***Amomum cardamomum* L.**

Source: Magness et al. 1971

Both the above related species of tropical plants produce the cardamom seeds of commerce. Both are tropical, perennial herbs, the tops growing each year from underground rhizomes. *E. cardamomum* reaches 5 to 10 feet, with lanceolate leaves up to 2 feet long. The capsules are oblong to globular, ribbed and indehiscent. These dried capsules are the principal cardamoms of commerce. The seeds and plant of *A. cardamomum* are very similar to "grains of paradise" These seeds are also sold as cardamom.

Index | Search | Home

Bothriochloa pertusa (L.) A. Camus

Syn.: *Amphilophis pertusa* (L.) Stapf
Andropogon pertusus (L.) Willd.
Holcus pertusus L.
Poaceae
Hurricane grass, Seymour grass, Barbados sourgrass, Pitted bluestem, Comagceyana

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Much valued as a good fodder grass, both for grazing and for stacking. Satisfactory for lawns, as it sends out numerous creeping shoots which root at the nodes. Although valued by some for pasture, others consider it a weed. In the Virgin Islands, e.g., some forms are difficult to eradicate and replace with better pasture grasses (Bogdan, 1977).

Folk Medicine

No data uncovered.

Chemistry

On a zero moisture basis the early-bloom grass (34.7% DM) contains 5.7% CP, 34.9% CF, 11.7% ash, 1.0% EE, 46.7% NFE (Venezuela); the mature grass (India) contains 3.9% CP, 37.9% CF, 10.0% ash, 2.3% EE, 45.9% NFE; the hay (94.3% DM) contains 5.7% CP, 34.9% CF, 11.7% ash, 1.0% EE, 46.7% NFE (India) (Gohl, 1981).

Description

Stoloniferous or tufted perennial grass; culms ascending, branching, sometimes long running, rooting at the nodes, about 30 cm tall, much taller when cultivated; sheaths rounded; leaf-blades flat; panicle axis shorter than the lower branches, purplish, emitting an aromatic odor when crushed; racemes few to several, sparsely villous; first glumes of sessile spikelets always pitted; awn of sessile spikelet geniculate, 10–15 mm long; pedicellate spikelet about as long and broad as the sessile ones. $2n = 60$. Fl. summer-fall.

Germplasm

Reported from the Africa, Mediterranean, and Near East Centers of Diversity, comagueyana or cvs thereof is reported to tolerate drought, grazing, and slope. Both apomictic and sexual reproduction have been observed in India, the latter predomina.tly. ($2n = 40, 60$)

Distribution

Widely distributed in Old World Tropics, from Arabia and Tropical Africa to Southeast Asia, India, Sri Lanka, and Indonesia. Considered one of the better pasture grasses in the West Indies, Uganda and India. Sparingly introduced in southern United States on experimental basis.

Ecology

Ranging from Warm Temperate Moist through Tropical Very Dry to Wet Forest Life Zones, comagueyana is reported to tolerate annual precipitation of 5 to 40 dm (mean of 7 cases = 13.9), annual temperature of 17 to 27°C (mean of 7 cases = 23.3), and pH of 5.0 to 7.8 (mean of 7 cases = 6.9) (Duke, 1978,1979). Bogdan (1977) suggests that it occurs where rainfall is 500–900 mm, mainly on well drained soil. Rather common in disturbed as well as undisturbed areas, along roadsides, and in rather dry areas. Can withstand moderate periods of drought. Thrives on a wide range of soils in tropical climates. Does not tolerate frost.

Cultivation

Cultivated mainly in pasture mixtures. Also seeded along roadside embankments in warmer regions. Germinated quickly and established readily.

Harvesting

Mature plants stand repeated cutting, continuous grazing and trampling. Because of its ability to withstand being trampled and its habit to send out rooting shoots, it is used for lawns. Moisture-free grass contains 8.8% protein, 33% fiber, 46.1% N-free extract and 1.7% fat.

Yields and Economics

Said to be low yielding (Gohl, l981), but yield figures approach 15 MT DM/ha. An excellent pasture grass in many tropical areas of the world, as West Indies, East Africa, India, in the last where it is suggested for reseeding degraded grassland. Used to some extent in warmer parts of the United States along roadsides.

Energy

According to the phytomass files (Duke, 1981b), annual productivity ranges to 15 MT/ha.

Biotic Factors

Following fungi have been reported on this grass: *Balansia sclerotica, Claviceps purpurea, Physoderma bothriochloae, Puccinia cesatii, P. duthiae, P. erythroaeensis, P. pusilla, Sphacelotheca tenuis, Ustilago bothrioch- loae, Uromyces andropogonis-annulati.*

Bhuinimb or Kalmegh (*Andrographis paniculata* Nees.)

Contributor: Pankaj Oudhia

Copyright (c) 2002. All Rights Reserved. Quotation from this document should cite and acknowledge the contributor.

English Name: Creat , Green Chirayta, King of bitters.

Common (Indian) Name:

Hindi: Kalmegh, Kiryat, Mahatit,
Gujrati: Kiriyata, Olikiriyat
Marathi: Olen Kirayat,
Canarese: Nelabevu gida
Sanskrit: Bhuinimb, Kirata, Mahateet
Malyalam: Nilaveppu, Kiriyatta,
Telugu: Nela Vemu
Tamil: Nilavempui

Family: Acanthaceae

Distribution: Kalmegh is an annual herb found through India, specially in dense forests.It is under cultivation in many states of India.

Botany: It is an erect branched annual, 0.3-0.9 meters high, branches sharply quadrangular winged in the upper part; leave - lanceolate, acute, undulate, pale beneath; Flowers small, solitary distant, in axillary or terminal racemes or panicles, bracts lanceolate; Corolla - 2 lipped, upper lip 2-toothed, lower 2 lobed, rose coloured; Flowers - Capsule, linear - oblong, acute at both ends; Seeds many, rugosely pitted, yellowish brown. Flowering time in India is November - December.

Useful parts: Whole plant.

Medicinal Properties: According to Ayurveda the plant is bitter, acrid, cooling, laxative, vulnerary, antipyretic, antiperiodic, anti-inflammatory, expectorant, depurative, soporific, anthelmintic, digestive and useful in hyperdispsia, buring sensation, wounds, ulcers, chronic fever, malarial and intermittent fevers, inflammations, cough, bronchitis, skin diseases, leprosy, colic, flatulence, diarrhoea, dysentery, haemorrhoids etc. Kalmegh is also a reputed Homoeopathic drug. In Bengal (India), household medicine known as "Alui" is prepared from fresh leaves and is given to children suffering from stomach complaints. Recent experimental finding indicated that Kalmegh is having antityphoid and antibiotic properties. It has been proved to be hepatopratective drug.

Chemical Constituents: Kalmegh contains bitter principles andrographolide, a bicyclic diterpenoid lactone and Kalmeghin (upto 2.5%). The leaves contain the maximum active principle content while in the stem it is in lesser amount.

Cultivation: In India, it is cultivated as rainy season (Kharif) crop. Any soil having fair amount of organic matter is suitable for commercial cultivation of this crop. About 400 gms. seed are sufficient for one hectare. The spacing is maintained 30 × 15 cm. No major insect and disease infestation has been reported. The plants at flowering stage (90–120 days after sowing) is cut at the base leaving 10–15 cm stem for plant regeneration. About 50–60 days after first harvest, final harvest is performed. In Indian condition, the yield varies between 2000–2500 Kg dry herb per hectare.

Andropogon gayanus Kunth

Poaceae
Gamba grass

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Considered one of the best grazing grasses in northern Nigeria and northern Ghana. Makes valuable hay and green fodder grass in central and northeastern Brazil. In Africa, this grass grows in large tufts up to 2 m tall. Young shoots are preferred, but cattle will eat it up to time of flowering. Stems, flattened, are used for coarse matting (weaving grass mats and thatching). Plants are useful for planting on banks for erosion control.

Folk Medicine

No data uncovered.

Chemistry

On a zero moisture basis, fresh Ghanan grass (19.9% DM) contains 12.9% CP, 25.6% CF, and 8.5% ash; the same (24 weeks old) (59.4% DM) contains 5.4% CP, 29.9% CF, and 5.5 % ash. Nigerian hay (88.5% DM) contains 6.1% CP, 35.1% CF, 7.9% ash, 1.7% EE, and 49.2% NFE, while silage (DM 25.0%) contains 5.8% CP, 37.4% CF, 7.4% ash, 1.9% EE, and 47.5% NFE (Gohl, 1981).

Description

Tall annual or perennial, tussock grass; culms erect, up to 3 m tall, more or less stout, about 0.6 cm in diameter, glabrous, many-noded, producing flowering branches from the third node upward; leaves glabrous or softly pubescent, rarely villous or tomentose; sheath tight, striate; ligule short, rounded or truncate, glabrous or somewhat hairy on back, rarely exceeding 0.2 cm long; lamina linear to lanceolate-linear in the lower leaves, usually from a much attenuated base and there often forming a terete petiole, tapering to a fine point, over 30 cm long, up to 1.6 cm broad, glaucescent or reddish, margin scabrous; inflorescence in panicles up to 6 or more primary mixed 2 to many rayed tiers, the inner ray of lower or lowest tiers often up to 30 cm long (sometimes up to 60 cm long), with 2–4 secondary few-rayed tiers; spatheoles pale green, herbaceous, lanceolate-oblong, 6.5–7.5 cm long, at length more or less tightly enrolled and turning red; racemes in pairs, 3.5–6.5 cm long, one sessile, the other with a bare base about 0.4 cm long, joints stout, cuneate-clubshaped; sessile spikelets greenish or tipped brown or red, about 0.8 cm long including the obtuse callus; scantily bearded at base; glumes equal; awn 1.3–2.2 cm long, twisted well below middle, column brown, bristle pale; pedicellate spikelets male and glabrous. Fl. April–June in tropical Africa.

Germplasm

Several varieties are recognized: var. *gayaunus* with pedicelled spikelets glabrous, the joints and pedicles ciliate on one margin only; var. *squamulatus*, with pedicelled spikelets scaberulous, the joints and pedicels ciliate on both margins; var. *argyophoeus*, with pedicelled spikelets plumosely villous, basal leaves villous; var. *bisquamulatus*, with pedicelled spikelets not so hairy, basal leaves not villous. *Squamulatus* and *bisquamulatus* are "dry ground" varieties which grow best on well-drained sandy clays of medium to high fertility (Bowden, 1963). Reported from the Africa Center of Diversity, gamba grass or cvs thereof is reported to tolerate drought, fire, frost, high pH, heavy soil, low pH, poor soil, savanna, slope, and waterlogging. Var. *gayanus* is more likely to tolerate waterlogging and frosts than the "dry-land" varieties (Duke, 1978). ($2n$ = 20, 40, 44)

Distribution

Native and widely distributed in tropical Africa, north and south of Equator; introduced to other tropical areas, as tropical Queensland, Brazil, India, and western Australia.

Ecology

Ranging from Warm Temperate Moist through Tropical Dry to Wet Forest Life Zones, gamba grass is reported to tolerate annual, precipitation of 8 to 27 dm (mean of 9 cases = 12.2), annual temperature of 15 to 32°C (mean of 9 cases 21.4), and pH of 4.3 to 8.3 (mean of 5 cases = 6.1). In grassy places, damp places, low-lying meadows, edge of thickets; often forming large areas. Also thrives in areas with long dry season up to 7 months long. Adapted to a wide range of soil types, with different ecotypes adapted to various soils varying from sandy to heavy black cracking clays. Very drought resistant and not to susceptible to frost.

Cultivation

Propagated by seed. Caryopses germinate better with chaff removed and covered over by soil or sand. Clean seedbed required, but sowing should not be delayed more than 2 months after beginning of rains (in India). It is often under-sown in corn, sesame or millet. Seeding rate varies: in Brazil, 5 kg/ha; in Nigeria, 35–70 kg/ha, of uncleaned seed. Seed production is often very low. Sometimes grown in mixture with *Clitoria ternatea* in tropical Australia. May also be propagated by splints, those from mature woody stumps doing best (Bowden, 1963). Highest return of dry matter per unit N (14.4 kg DM/kg N) occurred at 28 kg N/ha; CP content increased only modestly as N was increased, reaching a maximum 10.5% with the highest N level. At higher levels of N, *A. gayanus* was replaced by less desirable grasses (Haggar, 1974). Bogdan (1977) reports trebling of yields with 100 kg N/ha and double to treble with 20 MT fym/ha.

Harvesting

Plants persist well under grazing, but are only palatable before flowering. The flowering stems, which are produced in quantity, are hard and should be removed by mowing or burning. Frequent burning tends to suppress this grass and allows it to be replaced by less useful species. In one experiment (Bowden, 1963) over three years, plots were cut only when grass reached 6, 9, 12 and 15 dm, necessitating 12, 9, 8 and 7 cuts respectively. The taller the grass when cut, the higher the annual DM yield. Plants grown in rows gave more DM, CP and soluble carbohydrate than plants grown in swards.

Yields and Economics

Haggar (1974) reported yields of 2–7 MT in 1964, 10–12 in 1965, and 6–12 in 1966, at 0 to ca 200 kg/N/ha respectively. According to Bogdan (1977), this is one of the high yielding grasses of West Africa, being outyielded by *Melinis minutiflora*, *Panicum maximum* and/or *Pennisetum purpureum*. Fresh fodder yield of 57 MT are recorded from India, 76 from Mali. From the Cameroons, DM yields of 7.1–7.8 MT/ha, 4 MT/DM from Australia, and 2.4–8.6 MT elsewhere (Bogdan, 1977). Seed yields up to 30 kg/ha per cut with 3 cuts per year have been recorded in Brazil. In pure stands in Ghana, dry matter yields per harvest from March 12 to November 12 (in 5 harvests) averages 7,478 kg/ha, with total harvest being 37,391.35 kg/ha. In

Andropogon-Desmodium stands 34,334 kg/ha; in Andropogon-Centrosema, 30,397.45 kg/ha (Tetteh, 1972). Widely cultivated and used grass used in tropical Africa (Nigeria and Ghana), Brazil, India, and Australia for fodder, grazing, hay and to some extent for erosion control.

Energy

According to the phytomass files (Duke, 1981b), annual productivity ranges from 4 to 25 MT/ha. According to Gohl, the ME (metabolizable energy) for cattle ranges from 1.71 megacalories/kg DM in silage to 1.65 in hay, 2.02 in mature forage and 2.33 in early vegetative forage.

Biotic Factors

Following fungi have been reported on this grass: *Fusarium moniliforme* (on seed), *Phyllachora assimilis, Puccinia erythraeensis, P. versicolor, Sphacelotheca andropogonis, S. ischaemicola*. Nematodes isolated from this grass include: *Criconemella* sp., *Helicotylenchus cavenessi, R. pseudorobustus, Memicriconemoides cocophilus, Hemicycliophora oostenbrinki, Scutellonema clathricaudatum, Tylenchorhynchus annulatus, Xiphinema ebriense*, and *X. nigeriense*.

Big bluestem

Gramineae *Andropogon gerardii* Vitm.

Source: Magness et al. 1971

This is a vigorous, rather coarse bunchgrass, native over most of the United States; but of major importance in the Central States and the eastern edge of the Great Plains. The stems, which may reach to 6 feet, are solid between nodes. The leaves reach 12 inches or more in length, and are 0.5 inch or less in width and hairy near the base. Growth starts late in the spring and continues throughout the summer, providing good grazing for all kinds of livestock. Good quality hay is produced if mowed before seed heads have formed. Roots penetrate deeply; but the grass thrives best on moist, well drained soils of good quality. Propagation is by seeds.

Last update February 18, 1999 by ch

Sand bluestem

Gramineae, Poaceae *Andropogon hallii* Hack.

Source: Magness et al. 1971

This is a sod-forming grass native from North Dakota and Montana south to Texas and Arizona. It generally resembles big bluestem but differs in having a hairy panicle (the seed head) and more vigorous rhizomes, resulting in more rapid and extensive lateral spread. Stems reach up to 7 feet under the best conditions. It is found mainly on deep, sandy soils and is a valuable range grass on such soil.

Last update June 28, 1996 bha

Broomsedge

Gramineae *Andropogon virginicus* L.

Source: Magness et al. 1971

Broomsedge is a native bunchgrass, widely distributed over the United States, closely related to big and little bluestem grasses. The palatability of broomsedge is poor, so it ranks low as livestock feed. However, it thrives on soils of low fertility and is often the dominant growth on worn out, unproductive soils, affording protection from erosion and some forage. Because of its low palatability it is not used in seeded pastures.

Purplestem Angelica

Angelica atropurpurea L.

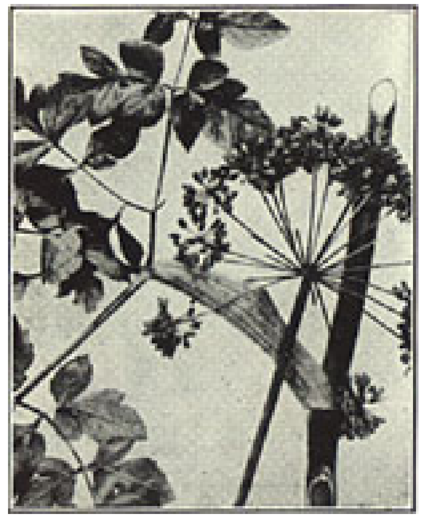

Figure 89.—Purplestem angelica (*Angelica atropurpurea*)

Synonym.—*Archangelica atropurpurea* Hoffm.

Other common names.—American angelica, great angelica, high angelica, purple angelica, masterwort.

Habitat and range.—Purplestem angelica is a native herb, common in swamps and damp places from Newfoundland to Delaware and west to Minnesota.

Description.—This strong-scented, tall, stout perennial reaches a height of from 4 to 6 feet. It has a smooth, dark purple, hollow stem 1 to 2 inches in diameter. The leaves are divided into three parts, each of which is again divided, with many broad leaflets. The lower leaves are sometimes 2 feet in width, but the upper ones are smaller, and all have very broad stalks. From June to July the greenish-white flowers are produced in somewhat roundish heads, which sometimes are 8 to 10 inches in diameter. The root is branched, from 3 to 6 inches long, and less than an inch in diameter. It has an aromatic odor, and the taste at first is sweetish and spicy, afterwards bitter. The fresh root is said to be poisonous.

Part used.—The root, dug in autumn. It must be carefully dried and preserved, because it is very subject to the attacks of insects.

Wild Custard Apple

Annona chrysophylla

A noteworthy, useful African member of the Annonaceae is the wild custard apple, *Annona chrysophylla* Boj. (syn. *A. senegalensis* Auct. non Pers., often cited erroneously as *A. senegalensis* Pers.). The tree is so popular in its native land that it has acquired a wealth of vernacular names: wild soursop, in several localities; *mavulu, mugosa, mbokwe, makulo, mlamote*, etc., in Kenya; *mtopetope* and *mchekwa* in Zanzibar and Pemba; *mabengeya, elipo, obwolo, ovolo*, etc., in Uganda; *aboboma, batanz; bangoora, bullimbuga*, etc., in Ghana; *mposa, muroro* and *mponjela* in former Nyasaland; *dilolo, iolo*, and *malolo* in Angola; *sougni; mete*, d*angan, sounsoun, tangasou, dougour, ianouri*; *ndong, anigli* in former French West Africa.

Description

This is a sprawling shrub or a tree to 20 ft (6 m) high with smooth, silvery bark. The leaves are aromatic, deciduous, alternate, blue-green, broad-elliptic or broadovate, 3 to 7 in (7.5-17.5 cm) long, 1 1/2 to 4 in (4-10 cm) wide, rounded at apex and base, blue-green above, downy, prominently veined beneath. The flowers, borne singly or in pairs in the leaf axils on stalks 1 to 1 1/2 in (2.5-4 cm) long, are clasped by a 3-parted calyx and have 3 triangular, thick, waxy, velvety, whitish outer petals, 3 pale-yellow inner petals, and numerous stamens. Typically compound, the pineapple-scented fruit is smooth but with the carpers distinctly outlined on the surface; yellow or orange when ripe; rounded oval; 1 to 4 in (2.5-10 cm) long; fleshy; seedy.

Origin and Distribution

This species is native and common in savannas throughout tropical Africa from the Cape Verde Islands and the Nile and Upper Guinea to the Transvaal and Zululand. It is little-known outside its natural range. It was long ago introduced by the United States Department of Agriculture into Florida as a potential rootstock for related species, and into Puerto Rico in 1924 and again in 1925 and grown at the Insular Experiment Station, Rio Piedras. According to G.L. Cruz (1979), verbatim from his 1965 publication (see Bibliography), it has become well established as *araticum da areia* in Brazil, especially around Minas Gerais, Bahia and Espirito Santo, but he describes the fruit as rough-surfaced and 8 to 12 in (20-30 cm) in diameter, so he must have it confused with some other species unless there is great variation among seedlings.

Varieties

The botanical variety, *deltoides*, with elliptic to oblongelliptic leaves, rounded to broadly deltoid at the base, is the most common form in Ghana. Eggeling mentions a variety *porpetac* in Uganda with oblong-elliptic, ovalelliptic or elliptic leaves, rounded-obtuse or broadly cuneate at the base. There is reportedly a dwarf form, the fruits of which are borne so low they touch the ground, and are of better quality than those of taller types.

Climate

The wild custard apple is limited to tropical areas up to an elevation of 5,000 ft (1,500 m) and thrives best where its roots can reach water. It remains leafless for several months in the dry season.

Food Uses

The fruit pulp is edible and said to have an apricot-like flavor. Williamson quotes an unidentified source as saying that it is one of the best of the indigenous fruits in parts of tropical Africa. It is much appreciated in the wild by shepherds. According to Irvine, the unopened flower buds are used in soup and to season native dishes; and the leaves are eaten.

Food Value

The dried leaves contain 8.2% protein.

Other Uses

Fruit: The green fruit, because of its high tannin content, is made into ink.

Leaves: Fresh leaves are employed as fodder for domestic animals. Boiled leaves serve as native perfume, and dried leaves are used as filling for mattresses.

Wood: The soft, grayish wood is fashioned into hoe handles and employed in building huts.

Ashes: The wood ashes are used in making soap and native snuff.

Bark and roots: The bark yields a yellow or brown dye. It is pounded in water and the liquid is then used as a hair dressing. A poor-quality fiber derived from the bark is made into rope for tying fences. A combination of the bark and roots serves as an insecticide, and the root has been used for homicidal purposes. The irritant, gummy sap of the bark is an adhesive for arrow poison. There are many superstitious uses of the various parts of the plant.

Medicinal Uses: Fresh fruits in quantity and dried fruits are applied on Guinea worm sores. The parched green fruits are taken to relieve diarrhea and dysentery. A tea of the young leafy twigs or of the roots is taken to alleviate pulmonary complaints. An infusion of the leaves is a popular eye lotion. Dried, powdered leaves are regarded as purgative and as a remedy for mucous diarrhea. With quantities of water, the pulverized leaves are given to horses to expel worms. Combined with the roots and bark and other materials, they are said to be effective in treating yaws in horses. The leaves also enter into a tonic for horses. Venereal diseases and intestinal disorders are treated with preparations of the roots. The bark is chewed to relieve stomachache. It is an emetic and a vermifuge and is given to overcome convulsions in children. The bark infusion, held in the mouth, relieves toothache. In the Upper Volta, an ointment made from the bark is applied on burns. Bark and roots together will halt dysentery, expel worms, and are part of a remedy for sleeping sickness. The root infusion is employed as eye drops. Charcoal of the burned roots is applied on twitching eyelids. The root bark is considered an antidote for snakebite and is used by Nigerian medicine men as a cancer remedy. Investigations have revealed antitumor activity against sarcoma 180 ascites, and antibiotic activity. The trunk bark contains alkaloids, including 0.02% anonaine, also tannins and saponins. The leaves contain rutin, quercetin and quercetrin.

Related Species

The mountain soursop, *A. montana* Macf. (syns. *A. Marcgravii* Mart.; *A. sphaerocarpa* Splitg.; *A. Pisonis* Mart.) is also called wild soursop, *guanabana cimarrona, guanabana de perro, guanabana de loma, corossol zombi; corossolier batard, boszuurzak, araticum-ponhe* and *araticum de paca*. It grows wild from sea-level to 2, 000 ft (650 m) throughout the West Indies and southward into Peru and Brazil, and is cultivated in the Philippines and rarely in Florida.

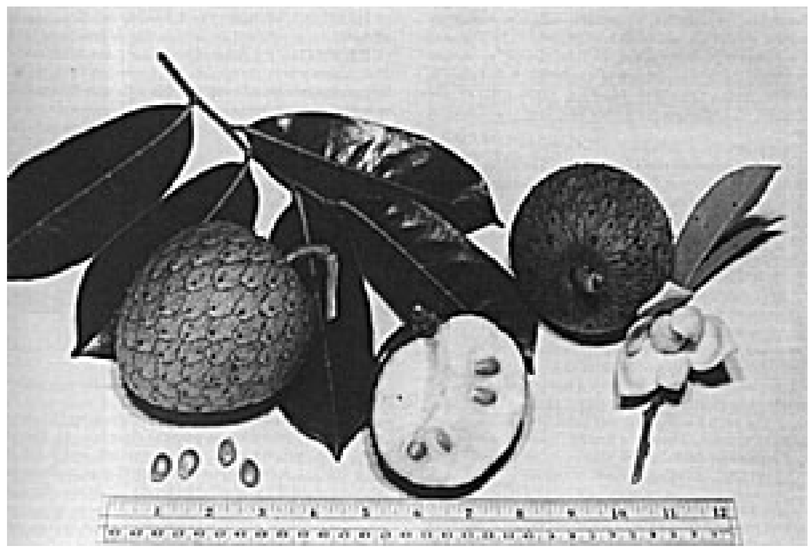

Fig. 25: The scarcely-edible mountain soursop (*Annona montana*).

The tree somewhat resembles that of the soursop but has a more spreading crown and very glossy leaves. It is slightly hardier and bears more or less continuously. The fruit is nearly round or broad-ovoid, to 6 in (15 cm) long. Its dark-green skin is studded with numerous short, fleshy ";spines";. It becomes very soft and falls when ripe. The pulp is yellow, peculiarly aromatic, sour to subacid and bitter, fibrous, and contains many light-brown, plump seeds. The quality is variable but generally very poor. The fruit is generally regarded as inedible but is referred to as ";edible but mediocre"; in Brazil. There, the firm core attached to the base of the peduncle is pulled out and eaten as a tidbit. In southern Florida, exotic parrots eat the fruits and scatter the seeds, and a few trees are consequently occurring as escapes. The tree is of minor interest to horticulturists as an ornamental and rootstock. The wood is soft, fibrous and useful only as fuel.

The pond apple, *A. glabra* L. (syn. *A. palustris* L.), is also called alligator apple, monkey apple, custard apple, corkwood, *mamon de perro, cayur, cayuda*, and various other colloquial names. It grows wild in the Florida Everglades and in coastal swamps and marshes of the Bahamas and throughout the West Indies, in southern Mexico, Central America, and southward into Peru and Argentine; also on the coast of West Tropical Africa. It is occasionally planted in southern Florida and has been introduced into Malaya and the Philippines.

The tree may reach 45 ft (13.5 m), is rather open and spreading; may become very thick at the base; has glossy, leathery, deciduous leaves. The fruit is oval or heartshaped, to 5 in (12.5 cm) long with thin, faintly reticulated, glossy yellow skin and salmon-colored, resinous, subacid, dryish pulp containing many light-brown, flattened-oval, longitudinally-winged seeds that float on water. When fully ripe and soft, the pulp is edible and some specimens are of fair quality and have been made into jelly or wine. The pond apple is of value as a ";survival"; food in extremity and of great importance as fare for wild creatures. Fishermen fashion the light, corklike wood into floats. The leaf decoction is a common, multipurpose folk remedy in the Netherlands Antilles, Mexico and South America. Seedlings are useful as rootstock for other Annona species in wet soils.

Soncoya

Annona purpurea

Among lesser species of the family Annonaceae, the soncoya, *Annona purpurea* Moc. & Sesse (syns. *A. manirote* HBK. *A. involucrata* Baill., *A. prestoli* Hemsl.) is called *cabeza de negro, cabeza de ilama, chincua, ilama*, or *ilama de Tehuantepec* in Mexico; *anona sincuya, chincuya, cabeza de muerto, sencuya, suncuyo, soncolla*, or *matacuy* in Guatemala; *guanabano torete* or *toreta* in Panama; *gallina gorda, guanabano pun*, or *matimba* in Colombia; *castiguire, manire, manirote, tiragua*, or *tucuria* in Venezuela.

Description

The tree is small to medium, to 20 or even 33 ft (6-10 m) high, with short trunk to 1 1/2 ft (45 cm) in diameter, and spreading branches, which are rusty woolly when young. The deciduous leaves are alternate, short-petioled, undulate, oblong-elliptic or oblong-lanceolate to oblongobovate, 8 to 12 in (20-30 cm) long and 4 to 5 1/2 in (1014 cm) wide, acuminate at the apex, brown-hairy on both surfaces and with prominent veins beneath. Strongscented flowers, which emerge with the new leaves, are solitary, fleshy, large, conical, usually enclosed at first by a pair of bracts; are held at the base by a rusty-hairy, 3 parted calyx, and have 3 very thick outer petals, brownhairy outside, yellowish and purple mottled within, and 3 smaller, thinner inner petals, creamy white outside, purple inside. The fruit, thick stalked, is ovoid or nearly round, 6 to 8 in (15-20 cm) wide, set with hard, somewhat 4-sided, conical protuberances, each tipped with a curved hook, and is coated overall with a brown felt. The pulp is agreeably aromatic, suggesting the mango; abundant, yellow or orange, soft, fibrous, of mild, agreeable flavor. Seeds are numerous, obovate, 1 to 1 3/16 in (2.5-3 cm) long, dark-brown, and each is enclosed in a thin, closefitting membrane. The fruit carpers separate easily when ripe.

Origin and Distribution

The soncoya is native and common in coastal lowlands from southern Mexico to Panama, Colombia and Venezuela. It is grown in dooryards and the fruit is sold in local markets, though it is of mediocre quality and not popular because it is outwardly so hard. The tree was introduced into the Philippines in the early 1900's, grew well and flowered at Lamao but apparently did not set fruit for several years. It was planted at the Federal Experiment Station at Mayaguez, Puerto Rico, in 1918 and in St. Croix in 1930. Several trees have grown well and borne poorly at the Lancetilla Experimental Garden, Tela, Honduras.

Climate

The soncoya requires a hot, humid climate and it never occurs at an altitude higher than 4,000 ft (1,200 m).

Season

The fruits ripen in August in Yucatan; generally in the fall in Central America.

Food Uses

In Colombia, the pulp is eaten raw or is strained for juice, drunk as a beverage or folk remedy.

Toxicity

The seed extract destroys fleas. In Guatemala and Costa Rica, rural people believe the fruit to be unwholesome.

Medicinal Uses

In Mexico, soncoya juice is regarded as a remedy for fever and chills. Elsewhere it is given to relieve jaundice (probably because of its color). The bark decoction is effective against dysentery and a tea of the inner bark is administered in cases of edema.

Annona reticulata L.

Annonaceae

Custard Apple

We have information from several sources:

Custard Apple—Julia Morton, Fruits of warm climates

Annona reticulata —Neglected Crops : 1492 from a Different Perspective. 1994. J.E. Hernándo Bermejo and J. León (eds.). Plant Production and Protection Series No. 26. FAO, Rome, Italy. p. 85-92.

Last update Thursday, January 28, 1999, by ch

Neglected Crops : 1492 from a Different Perspective. 1994. J.E. Hernándo Bermejo and J. León (eds.). Plant Production and Protection Series No. 26. FAO, Rome, Italy. p. 85-92.

Custard apples

(*Annona* spp.)

The author of this chapter is H. Mahdeem (Boynton Beach, Florida, USA).

There are an estimated 2200 species of Annonaceae in the world. These include numerous fruit-trees, especially of the genera *Annona and Rollinia;* the majority of *Annona* species and all the *Rollinia* species originate from the New World.

Many of these species were carefully cultivated by indigenous peoples in Mesoamerica, the inter-Andean valleys, the Amazon region and other areas. Other Annonaceous fruits of the New World include species of *Asimina, Duguetia, Fusaea* and *Porcelia.* These fruit-trees have a considerable diversity and degree of adaptation to different environments and are valuable material for hybridization, selection and vegetative propagation studies. The high nutritional value of the fruit, its very distinct flavours and aromas and its attractive shapes and colours justify these efforts.

There are three species, *Annona cherimola, A. muricata* and *A. squamosa,* which are marginal in several regions of tropical America; in other regions, the technology for producing and handling the product has been developed to such a degree that they cannot really be included in this category. The known techniques and selected cultivars can be extended to regions where cultivation is still underdeveloped. Another three, *A. diversifolia, A. reticulata* and *A. scleroderma,* however, have been marginalized in spite of their intrinsic value and potential as fruit-trees.

The fruit of the Annonaceae must not be seen solely as a luxury item for rich consumers, but also as part of the diet of indigenous populations. This fruit is not only special because of its good flavour; it is also highly nutritional. Its food value varies considerably, but most forms have an abundance of carbohydrates, proteins, calcium, phosphorus, iron, thiamine, niacin and riboflavin, while some are rich in magnesium, ascorbic acid and carotene. If they were plentiful and sold at reasonable prices, they would considerably improve the nutrition of many people.

Annona cherimola Miller, the cherimoya, is thought to originate from cold but frost-free valleys of the Andes at an altitude of between 700 and 2400 m.

Excellent cultivars are known, all produced by vegetative propagation, which are planted on a commercial scale in Spain, Chile, Australia, Israel, the United States (California, Florida) and the island of Madeira. The fruit is sold in the supermarkets of many countries and is highly regarded.

The commercial cultivars include Bay Ott, Chaffey, Dr White, Libby, Nata, Orton and Spain.

In the regions where the cherimoya is still a marginal crop, new methods must be applied: artificial pollination, grafting of superior cultivars either on to stock of the same species or on to stock of *A. squamosa* or *A. glahra;* the control of anthracnosis and seed-boring insects; the control of green leaflhoppers; and fruit handling and packaging.

A. muricata L. (English. soursop; Spanish: guanábana; Portuguese: graviola) is possibly native to the Antilles and to the northern part of South America. It grows between 0 and 1000 m altitude. Its commercial production has been developed in Brazil, Venezuela, Costa Rica and other countries for local consumption and export. Cultivation practices have been established in the production areas mentioned; they include the control of insects and diseases and protection of the fruit in plastic bags. There is a great deal of variation in fruit size and sugar content. Trees of higher quality or resistance must be grafted on to stocks of the same species of *A. purpurea* and *A. montana* or, with great difficulty, on *A. glabra*.

A. squamosa L. (English: sugar apple, sweetsop, custard apple; *Spanish:* sarumuyo, anón; Portuguese: ata, pinha) seems to be native to southeastern Mexico, in dry areas and between 0 and 1000 m, although it grows well in regions of medium humidity. It has spread throughout the tropics and displays great variability in India. It is propagated by seed with satisfactory results; however. commercial cultivars are grafted. Of these. Red Sugar, with a red skin and white flesh, is recommended. The main problems are seedboring insects, the green leaflhopper, the tendency towards mummification of the fruit and harvesting and packaging difficulties caused by the fruit's lack of firmness.

The name "atemoyas", derived from "ata" (in Portuguese) and "cherimoya", is given to hybrids between these two species. Several cultivars are known which are sown commercially in the United States (Florida) and Australia. The best atemoyas combine adaptation to low altitudes and hot climate and the high productivity and good flavour of *A. squamosa* with the firm skin, low flesh/seed ratio and the flavour and aroma of *A. cherimola so* that, from the standpoint of quality and packaging, the product is comparable to the best cherimoyas, although it has a higher sugar content. At present, crosses are being made between cultivars of cherimoya and *A. squamosa* Red Sugar and M-2, with the aim of obtaining atemoyas with red- or pink-skinned fruit, which is more attractive than the green fruit of those currently available. The most famous green cultivars are Gefner in Israel and the United States and African Pride in Australia.

Annona diversifolia

Botanical name: *Annona diversifolia* Saff.

Family: Annonaceae

Common names. English: llama; Spanish: anona blanca; other: llama, ilamatzapotl, izlama, papausa

This fruit-tree, which is very highly regarded in its area of origin, has not been developed as it deserves, since it is virtually planted exclusively by indigenous peoples. Although it is greatly esteemed and fetches a good price on the markets of Guatemala, its cultivation does not attract other agricultural owners, nor do the latter obtain bank credit for this tree, whereas they do obtain it for exotic fruit-trees. Other factors that add to its neglect are: the tree's low productivity; the difficulty of seed germination (although methods to encourage germination artificially are already known); and the short shelf-life of the fruit at the markets (two to three days at ambient temperature). If it is left to ripen on the tree, the fruit splits, but if it is picked in this state and stored at normal temperature, the splits scar over. In Guatemala, it is customary to pick the fruit split in this way and to ripen them subsequently in crates or other closed places.

Botanical description

A. diversifolia is distinguished from other species of *Annona* in that it has two classes of leaf: the usual obovate, glabrous leaves with a petiole; and leaves in the form of round, deciduous bracts without a petiole, which grow on the base of the small branches. The undersides of the leaves, small branches and fruit have a powdery, whitish appearance, which is more noticeable in the white-fleshed varieties.

The flowers have three outer petals that are 2 to 5 cm long, and three minute inner petals; the colour is a varietal characteristic and ranges from pink to purplish red.

The fruit, which is about 12 cm long, has white, pink or reddish flesh, with a typical aroma and a sweet, exquisite flavour which, according to most people, is superior to that of the cherimoya. The fruit is very resistant and sometimes completely immune to attack from seed-boring insects.

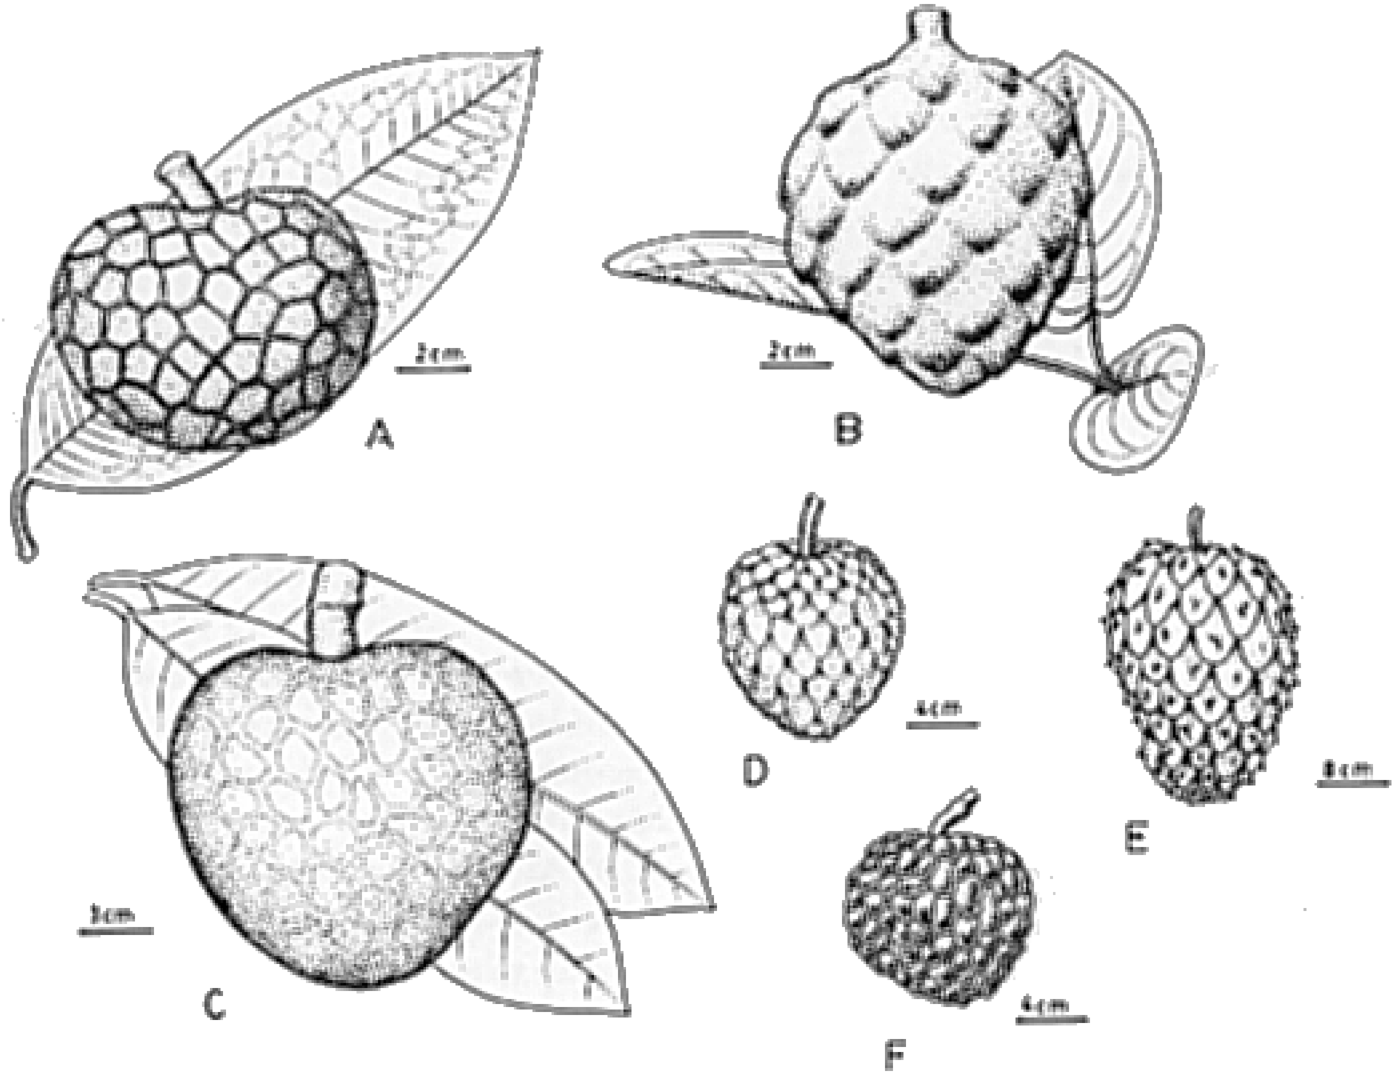

Figure 7. Custard apples: A) *Annona scleroderma*; B) *A. diversifolia*; C) *A. reticulate*; D) *A. cherimola*; E) *A. muricata*; F) *A. squamosa*

Ecology and phytogeography

The llama grows between 0 and 1800 m on the Pacific slope from central Mexico to El Salvador, but it is sown more intensively between 200 and 600 m in southwestern Guatemala. This region has a pronounced dry season (December to March), with an annual rainfall of between 1000 and 1400 mm and very fertile volcanic soils.

Genetic diversity

A. diversifolia is grown alone in vegetable gardens with few trees, and a wide variability is noted. This is particularly expressed in the characteristics of its fruit: its colour (see list of cultivars): its texture, which can range from slightly pasty to juicy, soft or with concentrations of harder grain; and its sweet taste, with a typical aroma. Following is a list of A. *diversifolia* cultivars:

- **Fairchild, Rosendo Pérez, Guillermo** and **Gramajo** have a thick-skinned, greyish green fruit with prominent round areoles and pink flesh. Rosendo Peréz and Gramajo have big fruit. (These cultivars have been bred for Florida.)

- **Imery** (bred in El Salvador) has big fruit that has a thinner skin, low prominences, is pinkish green (greyish brown when ripe) and has pink flesh with bolder spots.
- **Pajapita** has a soft, pink surface (brown when ripe) and bright-pink flesh.
- **Nilito** has a slightly irregular surface, which is bluish green, and red flesh.
- **Roman** has smaller fruit with a hard skin, which is bluish green with pink spots, and purple flesh.
- **Genova white** has a smooth, thin, whitish green skin, and white flesh.
- **Efrain** has up to 200 fruits per tree.

Guatemalan markets sell an llama that has bluish green fruit, with swirling marks such as those in a Van Gogh painting, and delicious bright-red flesh which is easily separated from the seeds. The trees from which this fruit comes have not yet been studied.

The only region to be evaluated as regards genetic erosion is southwestern Guatemala, where the problem does not seem to be serious. There are no gene banks, nor are any preservation techniques known other than live collections. The most promising areas for future exploration are southwestern Guatemala and the state of Chiapas in Mexico.

Cultivation practices

The llama is only grown together with other fruit trees, on the patios of houses or on smallholdings belonging to indigenous peoples. It is always propagated by seed with a long dormancy period which is difficult to interrupt. The seeds should not be sown without being pretreated to interrupt dormancy, such as soaking them in a solution of gibberellic acid, exposing them to the sun, immersing them in hot water or storing them for two to three months.

Prospects for improvement In the case of *A. diversifolia*, urgent work is needed in the following areas:

- vegetative propagation, by grafting, of the best varieties, using various stocks and grafting methods;
- effective interruption of seed dormancy;
- picking and commercial handling of the fruit;
- increasing the production period (July-August) by selecting early and late varieties;
- the establishment of gene banks, at least in localities of the Pacific area of Central America and Mexico;
- stepping up exploration of the species' production areas in Mexico, Guatemala and El Salvador;
- hybridization with other species of *Annona* for the production of more adaptable varieties;
- research on stock of the related wild species *A. macroprophyllata*, from Guatemala and El Salvador;
- research into the possibility that the absence of mycorrhizae or other soil factors are responsible for the growth of this species in other regions of Mesoamerica with favourable climate and soils, and into the possible use of grafting in these cases.

Annona reticulata

Botanical name: *Annona reticulata* L.

Family: Annonaceae

Common names. English: bullock's heart, custard apple, sugar apple; Spanish. anona, anona colorada, anona rosada, corazón; Portuguese: coração de boi; other: cahuex, pox, qualtzapotl, tzumuy

Althosugh it is said that *A. reticulata* is a native of the Antilles. the presence in Guatemala and Belize of a wild variety, *A. reticulata* var. *primigenia*, and also of a very wide variability of cultivars suggests that this zone is the species' area of origin. It has been introduced in other regions of the American tropics and Southeast Asia, without achieving a level of importance comparable to that of *A. cherimola* or *A. squamosa*.

Of the causes of *A. reticulata's* current marginalization, two seem to be the most notable: reproduction by seed, which results in many trees producing much smaller fruit; and the attack of the seed weevil which lays its eggs in the young fruit. When the adult insect develops, it bores tunnels through the flesh, causing mycotic infections and a consequent deterioration of the fruit.

The most attractive aspects of this species are: its pleasant-tasting fruit, which is generally sweet and creamy; the relatively small volume taken up by the skin and seed; and the plant's modest soil requirements.

Botanical description

A. reticulata is a low tree with an open, irregular crown and slender, glabrous leaves which in some varieties are long and narrow, 10 to 20 x 2 to 7 cm, straight and pointed at the apex; and in other varieties wrinkled and up to 10 cm wide. The flowers are generally in groups of three or four, with three long outer petals and three very small inner ones. The fruit is heart-shaped or spherical and 8 to 15 cm in diameter; according to the cultivar, the flesh varies from juicy and very aromatic to hard with a repulsive taste. There is a wide variability in the presence of groups of hard cells that are similar to grains of sand. Both the outside and inside colour varies according to the cultivar.

Ecology and phytogeography

A. reticulata grows between 0 and 1500 m in the areas of Central America that have alternating seasons, and has spread to South America. However, it is in the former region that the varieties previously classified as species are to be found: *primigenia,* already mentioned; and *lutescens.* the yellow custard apple which grows from Mexico to Costa Rica.

Genetic diversity

In Florida (United States) superior cultivars have been selected. especially from Belize and Guatemala. They differ in the characteristics of their fruit and even in their compatibility with stocks.

- **Tikal** is of excellent quality and medium yield; its flesh is bright-red, except in the white areas surrounding the seeds.
- **Canul** has a medium fruit with a waxy, shiny dark-red surface and purplish red flesh; it is very aromatic and deliciously sweet with few concretions of hard cells.
- **Sartenaya** has a medium fruit with a waxy, shiny red surface and pink flesh with a magnificent taste and texture. Although the fruit is not as attractive in appearance as that of the previous two cultivars. the tree is sturdier.
- **San Pablo** has a long, large fruit with an opaque, light-red surface. The flesh is dark-pink with a good aroma and taste. It is a vigorous, productive cultivar.
- **Benque** has a big conical fruit with a dark-red surface and very tasty dark-pink flesh.
- **Caledonia** has a small fruit with a dark surface: it is very attractive to cochineal insects (*Philophaedra* sp.), which are not very common in other varieties. The flesh is pink and has an excellent taste.
- **Chonox** has a medium fruit with a red skin and juicy. very tasty pink flesh; it is very productive and, for this reason, often has low-quality fruit. It produces abundant flowers in groups of up to 16.

No selections have been made from yellow custard apple and there are apparently no great risks of genetic erosion. It is possible that more intensive exploration in Belize, Guatemala and El Salvador might allow new cultivars to be found.

Cultivation practices

A. reticulata is generally propagated by seed, the germination rate of which ranges from low to medium. Grafting is usually done on stock of the same species. The fruit is harvested after its colour changes patterns although in some cultivars this does not occur and ripeness is determined by feel. The skin is very thin and the fruit must therefore be handled carefully. Most fruit is produced for family consumption and it is not commonly found on the markets outside Guatemala. The commercial future of this species depends on two factors: the establishment of grafted trees of high-yielding cultivars with fruit of a high quality and good appearance; and the adoption of control practices such as using protective bags or eradicating seed-boring insects.

Annona scleroderma

Botanical name: *Annona scleroderma* Saff.

Family: Annonaceae

Common names. English: poshte; Spanish. chirimoya, anona del monte; other: cawesh, cahuex, poshté

A. scleroderma is one of the least-known fruit trees of the genus; it is grown mainly in southwestern Guatemala and is notable for the structure of its fruit which, unlike the other cultivated species, has a very tough skin, allowing it to be handled much more easily and making it resistant to insect attack. The fruit may be cut and the flesh removed with a spoon. Its potential value is in its high-quality flesh, hard skin and high yield. It could become an export item and a product for wide local consumption.

However, the height of the tree (which does not facilitate fruit harvesting), the fact that the fruit is attacked by birds and the defoliation caused by wind are an obstacle to exploitation of this species.

Botanical description

A. *scleroderma* is a tall tree which reaches 15 to 20 m and has tough, lanceolate leaves measuring 10 to 25 x 5 to 8 cm. They are shiny on the upper side, slightly pubescent on the underside and have fragile, 3 cm long petioles. The flowers are greenish yellow, the outer petals have a longitudinal prominence which arises in the small branches or in groups in the old part of the thick branches. The fruit occurs in compact spherical groups, is 5 to 10 cm in diameter and generally falls off when ripe, without a noticeable colour change. The cream-coloured flesh has a bittersweet flavour and a soft texture.

Ecology and phytogeography

This species apparently grows wild on the Atlantic slope from Campeche to Honduras but is only grown in southwestern Guatemala between 300 and 1000 m on the Pacific slope. In this area. which is called the Bocacosta and has very fertile volcanic soils, there is a short dry season and an annual rainfall of around 4000 mm. The plant fruits between late December and April, with a maximum yield around the beginning of February.

Genetic diversity

The most visible characteristic of variability is in the fruit's surface. The areoles are generally marked by raised edges which form a hexagon. In some varieties, the edges are reduced to a crisscross of brown lines on a smooth, green surface; in other varieties, there is a central prominence on each areole; in some varieties there are well developed edges and prominences, while still others have an irregular, corrugated surface. The fruit also seems to vary in the thickness of its skin, which is on average 3 mm, but slightly thicker and tougher in the smooth-skinned varieties. The Pacific varieties are green or green with brown spots, while those from the Atlantic side have a thicker, reddish green skin.

No cultivars are known to be established by vegetative propagation. Genetic erosion is evident, since it is a crop with a restricted area in a highly populated region where land is required for building or cultivating coffee. Trees which were sown on coffee plantations have been destroyed or deformed because they produce too much shade or because they were damaged by children picking their fruit.

Genetic erosion is very pronounced in *A. scleroderma*; there are no gene banks and a few plants have been introduced into Australia and the United States (Florida). For this reason, material urgently needs to be collected in southwestern Guatemala (from San Felipe, San Andrés Villa Seca, San Sebastián, Colomba, El Tumbador, etc.).

Cultivation practices

Fresh seeds take about a month to germinate. whether they are collected and dried on the same day or stored in bags for a week or two. They do not need to be soaked or treated in any other way. Seeds that have been stored for two to three months need about six months to germinate. In Australia, *A. scleroderma* grows well when grafted on to stocks of *A. muricata* and *Rollinia mucosa*. When grafted material is planted. it must be borne in mind that the trees should be pruned so that a wide crown remains to facilitate fruit harvesting. This also reduces exposure to wind and bird damage.

The shade requirements of young plants—shade seems to promote growth—need to be studied. However, trees located in sunny positions would have a lower, more compact habit. Trees grown from seed begin to produce at around tour years when they reach a height of 4 to 6 m.

Prospects for improvement

The advantages of *A. scleroderma* as a fruit for local consumption and export are its high productivity and the fact that the flavour and aroma of its flesh are not as strong as in other *Annona* species, but are different and pleasant. The abundant, cream-coloured or creamy grey flesh separates easily from the seeds and it does not have sandy grains or fibres that adhere to the seed membrane. The thick, leathery skin does not split and is very resistant to insect attack and ordinary packaging and transport.

Activities that merit close attention regarding *A. scleroderma* are:

- the collection and evaluation of genetic material;
- propagation through grafting on to stock of the same species or related species to obtain low trees with an open crown, which facilitate fruit harvesting;
- running small market gardens or interplanted crops;
- marketing, since it is a "new" fruit even for Guatemalan markets;
- packaging and transport technology to prolong the good condition of the fruit and its acceptance on the market.

Bignay

Antidesma bunius Spreng.

When Corner referred to this member of the Euphorbiaceae as a "shady, rather gloomy tree", he could not have been viewing it in fruit, a spectacle that has always aroused enthusiasm. The colorful bignay, *Antidesma bunius* Spreng., is called *bignai* in the Philippines; *buni* or *berunai* in Malaya; *wooni* or *hooni*, in Indonesia; *ma mao luang* in Thailand; *kho lien tu* in Laos; *choi moi* in Vietnam; *moi-kin* and *chunka* by the aborigines in Queensland. Among English names are Chinese laurel, currant tree, nigger's cord, and salamander tree.

Description

The tree may be shrubby, 10 to 26 ft (3-8 m) high, or may reach up to 50 or even 100 ft (15-30 m). It has wide-spreading branches forming a dense crown. The evergreen, alternate leaves are oblong, pointed, 4 to 9 in (10-22.5 cm) long, 2 to 3 in (5-7.5 cm) wide, dark-green, glossy, leathery, with very short petioles. The tiny, odorous, reddish male and female flowers are produced on separate trees, the male in axillary or terminal spikes, the female in terminal racemes 3 to 8 in (7.5-20 cm) long. The round or ovoid fruits, up to 1/3 in (8 mm) across, are borne in grapelike, pendent clusters (often paired) which are extremely showy because the berries ripen unevenly, the pale yellowish-green, white, bright-red and nearly black stages present at the same time. The skin is thin and tough but yields an abundance of bright-red juice which leaves a purple stain on fabrics, while the pulp, only 1/8 in (3 mm) thick is white with colorless juice. Whole fruits are very acid, much like cranberries, when unripe; are subacid, slightly sweet, when fully ripe. Some tasters detect a bitter principle or "unpleasant aftertaste" which is unnoticeable to others. There is a single, straw-colored stone, an irregular, flattened oval, ridged or fluted, very hard, 3/8 in (1 cm) long, 1/4 in (6 mm) wide.

Plate XXVI: BIGNAY, *Antidesma bunius*

P.J. Wester mentions a "very distinct and superior variety" as reliably reported from the Mountain Province, Philippines.

Origin and Distribution

The bignay is native and common in the wild from the lower Himalayas in India, Ceylon, and southeast Asia (but not Malaya) to the Philippines and northern Australia. It is an abundant and invasive species in the Philippines; occasionally cultivated in Malaya; grown in every village in Indonesia where the fruits are marketed in clusters.

The United States Department of Agriculture received seeds from the Philippines in 1905 (S.P.I. #18393); twice in 1913 (S.P.I. #36088 and #34691), and again in 1918 (S.P.I. #46704). Quite a few trees have been planted in southern Florida in the past and the fruits were formerly appreciated as a source of juice for jelly, commercialized in a limited way, but are rarely so used today. There are specimens in experimental stations in Cuba, Puerto Rico, Honduras and Hawaii.

Climate

The tree is not strictly tropical for it has proved to be hardy up to central Florida. It thrives in Java from sea-level to 4,000 ft (1,200 m). It grows well and flowers but does not set fruit in Israel.

Propagation

Many seeds are non-viable in Florida, perhaps because of inadequate pollination. Since seedlings may turn out to be male, and female seedlings may not bear for a number of years, vegetative propagation is preferred. The tree is readily multiplied by cuttings, grafting or air-layering. The air-layers have borne fruit in 3 years after transplanting to the field. Ochse recommends grafting in the wet season because scions will remain dormant in dry weather. Most female trees will bear some fruit without the presence of a male because many of the flowers are perfect.

Culture

The trees should be spaced 40 to 45 ft (12-14 m) apart, each way. And one male tree should be planted for every 10 to 12 females to provide cross-pollination. Wind-protection is desirable when the trees are small. Otherwise they require very little cultural attention.

Yield

Yield varies greatly from tree to tree if they are grown from seed. A mature tree in Florida has produced 15 bushels of fruit in a season. One very old tree at the home of Dr. David Fairchild produced 22 bushels yielding 72 gals (273 liters) of juice.

Season

In Indonesia, the trees flower in September and October and the fruits mature in February and March. The fruiting season is July to September in North Vietnam. In Florida it extends from late summer through fall and winter because some trees bloom much later than others.

Pests and Diseases

The tree is attacked by termites in Southeast Asia. In Florida, the leaves may be heavily attacked by mealybugs and by scale insects and sooty mold develops on their excretions. Here, also, the foliage is subject to green scurf and algal leaf spot caused by *Cephaleuros tirescens.*

Food Uses

In Malaya, the fruits are eaten mostly by children. Indonesians cook the fruits with fish. Elsewhere the fruits (unripe and ripe together) are made into jam and jelly though the juice is difficult to jell and pectin must be added. Some cooks add lemon juice as well. If the extracted bignay juice is kept under refrigeration for a day or so, there will be a settling of somewhat astringent sediment which can be discarded, thus improving the flavor. For several years, the richly-colored jelly was produced on a small commercial scale in southern Florida. The juice makes an excellent sirup and has been successfully fermented into wine and brandy.

In Indonesia and the Philippines, the leaves are eaten raw or stewed with rice. They are often combined with other vegetables as flavoring.

Food Value Per 100 g of Edible Portion*	
Moisture	91.11-94.80 g
Protein	0.75 g
Ash	0.57-0.78 g
Calcium	0.12 mg
Phosphorus	0.04 mg
Iron	0.001 mg
Thiamine	0.031 mg
Riboflavin	0.072 mg
Niacin	0.53 mg

*According to analyses made in Florida and the Philippines.

Toxicity

The bark contains a toxic alkaloid. The heavy fragrance of the flowers, especially the male, is very obnoxious to some individuals.

Other Uses

Bark: The bark yields a strong fiber for rope and cordage.

Wood: The timber is reddish and hard. If soaked in water, it becomes heavy and, according to Drury, "black as iron". It has been experimentally pulped for making cardboard.

Medicinal Uses: The leaves are sudorific and employed in treating snakebite, in Asia.

Related Species

The **Herbert River cherry,** *A. dallachyanum* Baill., is a bushy tree, seldom over 25 ft (7.5 m) in height. The young shoots are slightly hairy. Mature leaves, almost hairless, are ovate to lanceolate-elliptical, 2 to 6 in (5-15 cm) long; deep-green above, bright-green beneath; thick and leathery. The odoriferous male flower spikes are hairy, generally in panicles in the leaf axils, occasionally solitary, more or less interrupted. The greenish female flowers are borne in racemes. The fruits, single or in clusters of 4 to 30, are round to obovoid, up to 3/4 in (2 cm) wide, rich-red when unripe, dark purple-red (nearly black) when ripe and very acid. They ripen fairly evenly in the cluster.

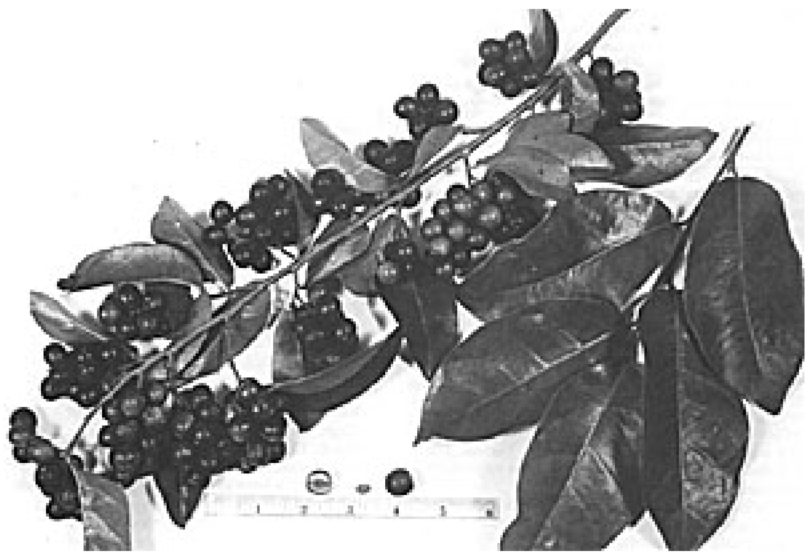

Fig. 55: The Herbert River Cherry of Australia *(Antidesma dallachyanum)* is less showy than the bignay but the fruits have more flesh.

The tree is native to coastal North Queensland, growing on the borders of rain forests and on the banks of streams and lagoons. Seeds were imported by the University of Florida Agricultural Research and Education Center, Homestead, Florida, in 1941 and the seedlings grew and bore well. The seeds germinate readily and seedlings begin to fruit at about 6 years of age when they may be 8 ft (2.4 m) tall. Multiplication may also be by cuttings, air-layering or grafting. One nursery in Florida offered grafted plants for sale but they did not become popular and the species is still rare.

In Australia, the trees bloom from December to February and again in September and the fruits mature in their fall and winter months. In Florida, blooming takes place from April to June and the fruit is in season in September and October.

The extracted juice is very dark-red, nearly black, but it yields, with the addition of pectin, a deep-red jelly.

The tree, like that of the bignay, is prone to infestation by mealybugs and scale insects and associated sooty mold.

The **black currant tree,** *A. ghaesembilla* Gaertn. (syn. *A. pubescens* Roxb.), called *dang kiep kdam* in Cambodia, *chop moi, choi moi, chua moi* or *chum moi* in Vietnam, is a deciduous shrub or bushy tree up to 26 or, at most, 40 ft (8-12 m), with short, russet hairs on the young branches, rosy new foliage and inflorescences. The mature leaves are broad-ovate or nearly circular, 1 1/2 to 3 in (4-7.5 cm) long, glossy on the upper surface. Male flower spikes, purplish or light-yellow with pollen, are dense, 1 to 2 in (2.5-5 cm) long; the erect female shorter and not as compact. Both types occur in terminal panicles or rarely solitary. Some trees bear both male and female flowers but on separate branches. The trees flower off and on during the year but mostly March to May in Asia.

The fruit is velvety, dark-red or very dark-purple, obliquely ovoid with one seed or occasionally double with 2 seeds. The seed kernels are sharply angular. When fully ripe the fruit is subacid to somewhat sweet.

This species has a wide natural range: in tropical Africa, and from the moist tropical lower Himalayas in northern India through Ceylon, southern China, Southeast Asia and Malaysia to the Walsh River region of Queensland. Generally the fruits are eaten mainly by children, but they are appreciated as thirst-quenchers by forest people of Thailand. They were made into jam by early settlers in Australia. In Malaya and Indonesia, they are made into a kind of relish, and the very young leaves are added as acid flavoring to various foods.

The wood is red, hard, close-grained, smooth and used for light rafters in huts, but for little else. Small branches are lopped twice a year for fuel. In India, the leaves are used to treat fever, headache and swollen abdomens. In Cambodia, various parts of the tree are valued in native medicine. The bark, combined with tobacco, is applied on wounds of animals. Combined with the bark of other species, it is boiled and the decoction given to halt diarrhea. The leaves and wood are similarly employed. A decoction of young branches and papaya roots is considered an effective emmenagogue. Crushed leaves are applied on the head of a newborn infant.

Hemp Dogbane

Apocynum cannabinum L.

Other common names.—Black hemp, black Indian hemp, Canadian hemp, American hemp, amy-root, bowmans root, bitterroot, Indian-physic, rheumatism weed, milkweed, wild cotton, Choctaw-root.

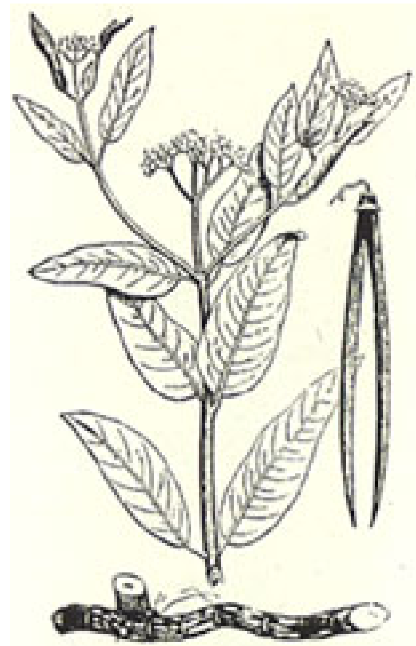

Figure 62.—Hemp dogbane (*Apocynum cannabinum*)

Habitat and range.—Hemp dogbane is a native of this country and may be found in thickets and along the borders of odd fields throughout the United States.

Description.—Hemp dogbane is from 2 to 4 feet high, with erect branches and sharp-pointed, short-stalked leaves from 2 to 6 inches long. The small greenish white flowers which appear from June to August are borne in dense heads followed later by the slender, pointed pods which are about 4 inches in length. The plant contains a milky juice.

Other species.—The roots of a closely related species, *Apocynum androsaemifolium* L., are also collected. The branches of this plant are diverging and forked and the flower heads loose and spreading. It also contains a milky juice. There are several well-recognized forms which formerly were recognized as varieties of *A. cannabinum* and *A. androsaemifolium*, but which are now considered distinct species. The roots of all these species possess somewhat similar properties, but they are not all acceptable to the trade.

Part used.—The root, collected in autumn.

Apricot kernel oil

Rosaceae *Prunus armeniaca* L.

Source: Magness et al. 1971

Fairly large tonnages of apricot seeds are available from fruits dried or canned. The kernels constitute about 20 percent of the pit weight and contain 40 to 45 percent of a semi-drying oil. To obtain the oil the pits are cracked, shells and kernels separated by flotation in brine, and the oil expressed. The oil is used for edible purposes as well as in cosmetics and some pharmaceuticals.

Udo

Araliaceae *Aralia cordata* Thunb.

Source: Magness et al. 1971

Udo is a vegetable grown for its tender, etiolated spring shoots, somewhat like asparagus. It is grown in Japan and to a limited extent by Oriental gardeners in the U.S. The plant is a strong growing perennial, producing the edible shoots from the roots each spring. The summer growth reaches 4 to 8 feet in height, with large, compound pinnate leaves. In culture, the roots are established in beds or rows, like asparagus. As the young shoots start in spring, they are kept covered woth soil for complete blanching. The shoots harvested are up to 18 inches long and 1.5 inches diameter at the base. Prior to use, shoots are boiled in salt water, or are sliced and held in cold water, to remove a turpentine like resin. They are then eaten raw as a salad or cooked.

Season, from growth start in spring to harvest: 2 to 4 weeks.

Production in the U.S.: No data, very limited.

Use: As raw salad or cooked vegetable.

Part consumed: Young etiolated stems only.

Wild-Sarsaparilla

Aralia nudicaulis L.

Other common names.—False sarsaparilla Virginian sarsaparilla, American sarsaparilla, small spikenard, rabbitroot, shotbush, wild licorice.

Figure 119.—Wild-sarsaparilla (*Aralia nudicaulis*)

Habitat and range.—Wild-sarsaparilla grows in rich, moist woods from Newfoundland west to Manitoba and south to North Carolina and Missouri.

Description.—This plant produces a single, long-stalked leaf and flowering stalk from a very short stem. The leafstalk is about 12 inches long and is divided at the top into three parts each bearing about five leaflets from 2 to 5 inches long. The flowering stalk produces in May to June three flower clusters consisting of from 12 to 30 small greenish flowers followed later in the season by round purplish black berries. The rootstock is rather long, creeping, somewhat twisted, and possesses a very fragrant, aromatic odor and a warm, aromatic taste.

Other species.—The American spikenard (*Aralia racemosa* L.), known also as spignet, spiceberry, Indian root, petty-morrel, life-of-man, and old-man's root, is used for the same purpose as *A. nudicaulis*. It is distinguished from this by its taller form, its much-branched stem from 3 to 6 feet high, and very large leaves. The flowers are arranged in numerous clusters instead of only three, as in *A. nudicaulis*, and they appear several months later. The range of this species extends as far south as Georgia.

Part used.—The root, collected in autumn.

Iwu, M.W., A.R. Duncan, and C.O. Okunji. 1999. New antimicrobials of plant origin. p. 457–462. In: J. Janick (ed.), Perspectives on new crops and new uses. ASHS Press, Alexandria, VA.

New Antimicrobials of Plant Origin

Maurice M. Iwu, Angela R. Duncan, and Chris O. Okunji

Infectious diseases account for approximately one-half of all deaths in tropical countries. In industrialized nations, despite the progress made in the understanding of microbiology and their control, incidents of epidemics due to drug resistant microorganisms and the emergence of hitherto unknown disease-causing microbes, pose enormous public health concerns. Historically, plants have provided a good source of antiinfective agents; emetine, quinine, and berberine remain highly effective instruments in the fight against microbial infections. Phytomedicines derived from plants have shown great promise in the treatment of intractable infectious diseases including opportunistic AIDS infections. Plants containing protoberberines and related alkaloids, picralima-type indole alkaloids and garcinia biflavonones used in traditional African system of medicine, have been found to be active against a wide variety of micro-organisms. The profile of known drugs like *Hydrastis canadensis* (goldenseal), *Garcinia kola* (bitter kola), *Polygonum* sp., *Aframomum melegueta* (grains of paradise) will be used to illustrate the enormous potential of antiinfective agents from higher plants. Newer drugs such as *Xylopia aethiopica*, *Araliopsis tabouensis*, *Cryptolepis sanguinolenta*, *Chasmanthera dependens* and *Nauclea* species will be reviewed.

INFECTIOUS DISEASE

World wide, infectious disease is the number one cause of death accounting for approximately one-half of all deaths in tropical countries. Perhaps it is not surprising to see these statistics in developing nations, but what may be remarkable is that infectious disease mortality rates are actually increasing in developed countries, such as the United States. Death from infectious disease, ranked 5th in 1981, has become the 3rd leading cause of death in 1992, an increase of 58% (Pinner et al. 1996). It is estimated that infectious disease is the underlying cause of death in 8% of the deaths occurring in the US (Pinner et al. 1996). This is alarming given that it was once believed that we would eliminate infectious disease by the end of the millenium. The increases are attributed to increases in respiratory tract infections and HIV/AIDS. Other contributing factors are an increase in antibiotic resistance in nosicomial and community acquired infections. Furthermore, the most dramatic increases are occurring in the 25–44 year old age group (Pinner et al. 1996).

These negative health trends call for a renewed interest in infectious disease in the medical and public health communities and renewed strategies on treatment and prevention. Proposed solutions are outlined by the CDC as a multi-pronged approach that includes: prevention, (such as vaccination); improved monitoring; and the development of new treatments. It is this last solution that would encompass the development of new antimicrobials (Fauci 1998).

Historic Use of Plants as Antimicrobials

Historically, plants have provided a source of inspiration for novel drug compounds, as plant derived medicines have made large contributions to human health and well-being. Their role is two fold in the development of new drugs: (1) they may become the base for the development of a medicine, a natural blueprint for the development of new drugs, or; (2) a phytomedicine to be used for the treatment of disease. There are numerous illustrations of plant derived drugs. Some selected examples, including those classified as antiinfective, are presented below.

The isoquinoline alkaloid emetine obtained from the underground part of *Cephaelis ipecacuanha*, and related species, has been used for many years as and amoebicidal drug as well as for the treatment of abscesses due to the spread of *Escherichia histolytica* infections. Another important drug of plant origin with a long history of use, is quinine. This alkaloid occurs naturally in the bark of *Cinchona* tree. Apart from its continued usefulness in the treatment of malaria, it can be also used to relieve nocturnal leg cramps. Currently, the widely prescribed drugs are analogs of quinine such as chloroquine. Some strains of malarial parasites have become resistant to the quinines, therefore antimalarial drugs with novel mode of action are required.

Similarly, higher plants have made important contributions in the areas beyond antiinfectives, such as cancer therapies. Early examples include the antileukaemic alkaloids, vinblatine and vincristine, which were both obtained from the Madagascan periwinkle (*Catharanthus roseus* syn. *Vinca roseus*) (Nelson 1982). Other cancer therapeutic agents include taxol, homoharringtonine and several derivatives of camptothein. For example, a well-known benzylisoquinoline alkaliod, papaverine, has been shown to have a potent inhibitory effect on the replication of several viruses including cytomegalovirus, measles and HIV (Turano et al. 1989). Most recently, three new atropisomeric naphthylisoquinoline alkaloid dimers, michellamines A, B, and C were isolated from a newly described species tropical liana *Ancistrocladus korupensis* from the rainforest of Cameroon. The three compounds showed potential anti-HIV with michellamine B being the most potent and abundant member of the series. These compounds were capable of complete inhibition of the cytopathic effects of HIV-1 and HIV-2 on human lymphoblastoid target cell in vitro (Boyd et al. 1994).

The Development of Phytomedicines and the Ethnomedicinal Approach

The first generation of plant drugs were usually simple botanicals employed in more or less their crude form. Several effective medicines used in their natural state such as cinchona, opium, belladonna and aloe were selected as therapeutics agents based on empirical evidence of their clinical application by traditional societies from different parts of the world. Following the industrial revolution, a second generation of plant based drugs emerged based on scientific processing of the plant extracts to isolate "their active constituents." The second-generation phytopharmaceutical agents were pure molecules and some of the compounds were even more pharmacologically active than their synthetic counterparts. Notable examples were quinine from *Cinchona*, reserpine from *Rauvolfia*, and more recently taxol from *Taxus* species. These compounds differed from the synthetic therapeutic agents only in their origin. They followed the same method of development and evaluation as other pharmaceutical agents.

The sequence for development of pharmaceuticals usually begins with the identification of active lead molecules, detailed biological assays, and formulation of dosage forms in that order, and followed by several phases of clinical studies designed to established safety, efficacy and pharmacokinetic profile of the new drug. Possible interaction with food and other medications may be discerned from the clinical trials.

In the development of "Third Generation" phytotherapeutic agents a top-bottom approach is usually adopted. This consists of first conducting a clinical evaluation of the treatment modalities and therapy as administered by traditional doctors or as used by the community as folk medicine. This evaluation is then followed by acute and chronic toxicity studies in animals. Studies should, when applicable, include cytotoxicity studies. It is only if the substance has an acceptable safety index would it be necessary to conduct detailed pharmacological/ biochemical studies.

Formulation and trial production of the dosage forms are structured to mimic the traditional use of the herb. The stability of the finished product is given careful attention during the formulation of the final dosage form. This is a unique blend of the empiricism of the earlier first *generation* botanicals with the experimental research used to prove the efficacy and safety of second *generation* isolated pure compounds. Several pharmaceuticals companies are engaged in the development of natural product drugs through the isolation of the so-called active molecules from plant extracts.

PRESENT USE OF PLANTS AS ANTIMICROBIALS

It is estimated that today, plant materials are present in, or have provided the models for 50% Western drugs (Robbers 1996). Many commercially proven drugs used in modern medicine were initially used in crude form in traditional or folk healing practices, or for other purposes that suggested potentially useful biological activity. The primary benefits of using plant derived medicines are that they are relatively safer than synthetic alternatives, offering profound therapeutic benefits and more affordable treatment.

Therapeutic Benefit

Much of the exploration and utilization of natural products as antimicrobials arise from microbial sources. It was the discovery of penicillin that led to later discoveries of antibiotics such as streptomycin, aureomycin and chloromycetin. (Trease 1972). Though most of the clinically used antibiotics are produced by soil micro-organisms or fungi, higher plants have also been a source of antibiotics (Trease 1972). Examples of these are the bacteriostatic and antifugicidal properties of *Lichens*, the antibiotic action of allinine in *Allium sativum* (garlic), or the antimicrobial action berberines in goldenseal (*Hydrastis canadensis*) (Trease 1972). Plant based antimicrobials represent a vast untapped source for medicines. Continued and further exploration of plant antimicrobials needs to occur. Plants based antimicrobials have enormous therapeutic potential. They are effective in the treatment of infectious diseases while simultaneously mitigating many of the side effects that are often associated with synthetic antimicrobials. They are effective, yet gentle. Many plants have tropisms to specific organs or systems in the body. Phytomedicines usually have multiple effects on the body. Their actions often act beyond the symptomatic treatment of disease. An example of this is *Hydrastis canadensis*. *Hydrastis* not only has antimicrobial activity, but also increases blood supply to the spleen promoting optimal activity of the spleen to release mediating compounds (Murray 1995).

Economic Benefit

World wide, there has been a renewed interest in natural products. This interest is a result of factors such as: consumer's belief that natural products are superior; consumer's dissatisfaction with conventional medicines; changes in laws allowing structure-function claims which results in more liberal advertising; aging baby boomers; national concerns for health care cost.

Sales of products in this market have increased dramatically in the last decade. Sales of botanical products in the United States have reached $3.1 billion of the $10.4 billion dollar dietary supplement industry 1996 (NBJ June 1998). The industry anticipates growth on the order of 15–20% into the new millenium (Herbalgram 1996). This growth rate will be maintained in an industry that is still considered to be in its infancy. Many plants that were previously wildcrafted will need to be grown domestically to meet the demands of the consumer. This represents many opportunities for the cultivation of crops for this industry.

A market based illustration of the need for plant based antimicrobials is demonstrated by the dissection of the herbal products market. In reviewing the top botanicals used as antiinfectives, the primary botanical used as an antimicrobial is *Hydrastis* with sales of 4.7% in 1995 (Gruenwald 1997). While antiinfectives agents make up 24 % of the pharmaceutical market (1992 Census of Manufactures 1994).

A similar, analysis of *Hypericum* (St. John's wort), demonstrates the value of such an evaluation. Though *Hypericum* is an antiviral, it is primarily used for its antidepressant activity. In 1995 it was not among the top selling herbs (Gruenwald 1997). However, by 1997, it had become an overnight success, with sales increasing over 20,000% in the mass market sector (Aarts 1998). The meteoric increase in the sales of *Hypericum* is multifactorial, but one factor in its in popularity was the existence of an unexploited market opportunity. In 1994 21% of pharmaceuticals sold were for the conditions affecting the central nervous system (1992 Census of Manufactures). Most of the drugs sold in this category are for depression. During this period of time, none of the top selling herbs sold had a primary indication for depression. This market hole, coupled with the media exposure produced a market success.

Many market holes exist. When using the same strategy to look at antimicrobial agents there is a similar gap. If the market dissection for antiinfectives is viewed in the same light as the *Hypericum analogy,* then perhaps this market is prime for receiving new plant based antimicrobials.

The potential for developing antimicrobials into medicines appears rewarding, from both the perspective of drug development and the perspective of phytomedicines. The immediate source of financial benefit from plants based antimicrobials is from the herbal products market. This market offers many opportunities for those cultivating new crops, as many of the plants that are wildcrafted today must be cultivated to match the demands of this market. Again *Hydrastis,* one of the top selling antimicrobials in the US herbal market, represents an example of a herb that has undergone domestication. Originally this plant, native to eastern North America, was wild crafted. *Hydrastis,* has been used by Native Americans for many conditions, including as an antimicrobial for infections. Efforts to cultivate this plant were undertaken in order to supply the demands of the herbal products market and to battle it's threatened extinction.

It is vital to be in the position to capitalize on the phytomedicine market, providing environmentally responsible solutions to public health concerns presented by new trends in infectious disease. In order to be prepared, the industry must be able to sustainably harvest and supply the herbal market. That means we must be able to anticipate the market needs and develop products to satisfy this market.

PLANTS WITH PROMISING ANTIINFECTIVE ACTIVITY

In our organizations, our major emphasis has been on drug discovery from ethnomedicinal information using the "Third Generation Approach." This method differs in that the clinical evaluation in humans takes place before the precise active constituents are known but the chemical composition and safety of the extracts are determined before formulation into dosage forms.

Plants containing protoberberines and related biflavones used in traditional African system of medicine have been found to be active against a wide variety of micro-organisms. Many medicinal plants of Africa have been investigated for their chemical components and some of the isolated compounds have been shown to posses interesting biological activity. Some of these plants are discussed below.

Garcinia kola, bitter kola (Guttiferae)

Garcinia kola, is found in moist forest and grows as a medium size tree, up to 12 m high. It is cultivated and distributed throughout west and central Africa. Medicinal uses include, purgative, antiparasitic, antimicrobial. The seeds are used in the treatment of bronchitis and throat infections. They are also used to prevent and relieve colic, cure head or chest colds and relieve cough. Also the plant is used for the treatment of liver disorders and as a chewing stick (Iwu 1993).

The constituents include—biflavonoids, xanthones and benzophenones. The antimicrobial properties of this plant are attributed to the benzophenone, flavanones. This plant has shown both anti-inflammatory, antimicrobial and antiviral properties. Studies show very good antimicrobial and antiviral properties. In addition, the plant possesses antidiabetic, and antihepatotoxic activities (Iwu 1993).

Aframomum melegueta (Zingiberaceae) Grains of Paradise

This is a spicy edible fruit that is cultivated and occurs throughout the tropics. It is a perennial herb. The medicinal uses of *Aframomum* include aphrodisiac, measles, and leprosy, taken for excessive lactation and post partem hemorrhage, purgative, galactogogue and anthelmintic, and hemostatic agent (Iwu 1993). The constituents are essential oils—such as gingerol, shagaol, paradol. Studies show antimicrobial and antifungal activity and effective against schistosomes (Iwu1993).

Xylopia aethiopica, Ethiopian Pepper (Abbibacceae)

An evergreen, aromatic tree growing up to 20 m high with peppery fruit. It is native to the lowland rainforest and moist fringe forest in the savanna zones of in Africa. Largely located in West, Central and Southern Africa. Medicinal uses of the plant are, as a carminative, as a cough remedy, and as a post partum tonic and lactation aid. Other uses are stomachache, bronchitis, biliousness and dysentery. It is also used externally as a poultice for headache and neuralgia. It is used with lemon grass for female hygiene. It is high in copper, manganese, and zinc (Smith 1996).

Key constituents are diterpenic and xylopic acid. In studies, the fruit as an extracts has been shown to be active as an antimicrobial against gram positive and negative bacteria. Though it has not been shown to be effective against *E. coli* (Iwu 1993). Xylopic acid has also demonstrated activity against *Candida albicans* (Boakye-Yiadom 1977).

Cryptolepis sanguinolenta Lindl. Schltr. (Periplocaceae)

A shrub that grows in the rainforest and the deciduous belt forest, found in the west coast of Africa. Related species appear in the east and southern regions of the continent. Its main medicinal use is for the treatment of fevers. It is used for urinary tract infections, especially *Candida*. Other uses are inflammatory conditions, malaria, hypertension, microbial infections and inflammatory conditions, stomach aches colic (Iwu 1993).

Active principals identified are indo quinoline alkaloids. Studies show inhibition against gram negative bacteria and yeast (Silva 1996). Additionally studies have shown this plant to have bactericidal activity. Clinical studies have shown extracts of the plant were effective in parasitemia. Recent in vitro study shows activity against bacteria specifically, enteric pathogens, most notably *E. coli* (but also staphylococcus, *C. coli*, *C. jejuni*, pseudomonous, salmonella, shigella, streptococcus, and vibrio) and some activity against *candida* (Sawer 1995). It has shown histamine antagonism, hypotensive, and vasodilatory activities (Iwu 1993). In addition it has demonstrative antihyperglcyemic properties (Brierer 1998).

Chasmanthera dependens Hoschst (Menispermaceae)

A woody climber that grows wild in forest margins and savanna. The plant is cultivated. It is used medicinally for venereal disease, topically on sprained joints and bruises and as a general tonic for physical and nervous debilities. The constituents include berberine type alkaloids, palmatine, colombamine, and jateorhizine. Studies show that the berberine sulfate in the plant inhibits lieshmania.

Nauclea latifolia Smith (Rubiaceae)

It is a shrub or small spreading tree that is a widely distributed savanna plant. It is found in the forest and fringe tropical forest. Medicinal uses are as a tonic and fever medicine, chewing stick, toothaches, dental caries, septic mouth and malaria., diarrhea and dysentery (Lamidi 1995).

Key constituents are indole-quinolizidine alkaloids and glycoalkaloids and sapponins. There are studies showing the root has antibacterial activity against gram positive and negative bacteria and antifungal activity (Iwu 1993). It is most effective against Corynebacterium *diphtheriae*, *Streptobacillis* sp., *Streptococcus* sp., *Neisseria* sp., *Pseudomonas aeruginosa*, *Salmonella* sp. (Deeni 1991).

Araliopsis tabouensis (Rutaceae)

It is a large evergreen tree found throughout west tropical Africa. Its medicinal use is for the treatment of sexually transmitted diseases. The bark infusion is drunk for gonorrhea in the Ivory Coast (Irvine 1961). Its major constituents are alkaloids. Seven alkaloids have been isolated from the root and stem bark (Fish 1976).

CONCLUSION

Thomas Jefferson wrote that "The greatest service which can be rendered any country is to add a useful plant to it's culture." Plants have forever been a catalyst for our healing. In order to halt the trend of increased emerging and resistant infectious disease, it will require a multi-pronged approach that includes the development of new drugs. Using plants as the inspiration for new drugs provides an infusion of novel compounds or substances for healing disease. Evaluating plants from the traditional African system of medicine, provides us with clues as to how these plants can be used in the treatment of disease. Many of the plants presented here show very promising activity in the area of antimicrobial agents, warranting further investigation.

Burdock, Edible

Gobo, Harlock, Clotbur

Source: Magness et al. 1971

Compositae *Arctium lappa* L.

Burdock plants are rather coarse perennials which are weeds in many temperate areas, including the U.S. Tops die down in winter. New sprouts rising from roots in spring are peeled and eaten raw or after cooking. Roots are also eaten in Japan. Sparingly grown as a vegetable in Japan and possibly other countries.

Season, start of growth from old roots to harvest of sprouts: 2 to 4 weeks.

Production in U.S.: 100 acres, 1959 census; 187 tons, 1968 census.

Use: Sprouts as salad or pot herb. Roots cooked.

Part of plant consumed: Tender spring sprouts, roots.

Burdock

Arctium minus (Hill) Bernh.

Synonym.—*Lappa major* Gaertn.

Other common names.—Cockle button, cuckold dock, beggar's-buttons, hurr-burr, stick-button, hardock, bardane.

Figure 28.—Burdock (*Arctium minus*)

Habitat and range.—Burdock, one of our most common weeds, was introduced from the Old World. It grows along roadsides and in fields, pastures, and waste places, being very abundant in the Eastern and Central States and in some scattered localities in the West.

Description.—Burdock is a coarse, unsightly weed. During the first year it produces only a rosette of large leaves from a long tapering root. In the second year the plant grows to a large size, measuring from 3 to 7 feet in height. The stem is round, fleshy, and much branched and bears very large leaves, the lower ones frequently measuring 18 inches in length. The flowers are not produced until the second year, appearing from July until frost. They are purple and are borne in small clustered heads armed with hooked spines, and the spiny burs thus formed are a great pest, attaching themselves to clothing and to the wool and hair of animals. The plant has a large fleshy taproot. When dry this root is much wrinkled lengthwise.

Part used.—The roots, collected from plants of the first year's Growth. As they are large and fleshy they are likely to become moldy, and it is best to slice them lengthwise, so that drying may proceed more rapidly. The roots of other species of Arctium are also used.

Bearberry

Arctostaphylos uva-ursi (L.) Spreng.

Figure 14.—Bearberry (*Arctostaphylos uva-ursi*)

Other common names.—Uva-ursi, red bearberry, bear's-grape, bear's bilberry, bear's whortleberry, foxberry, upland cranberry, mountain cranberry, crowberry, mealberry, rockberry, mountain box, kinnikinnic, killikinnic, universe vine, brawling, burren myrtle, creashak, sagachomi, rapper dandies (fruit).

Habitat and range.—Bearberry, also commonly known in the trade as uva-ursi is a native of this country, growing in dry sandy or rocky soil from the middle Atlantic States north to Labrador and westward to California and Alaska.

Description.—The bearberry is a low, much-branched shrub trailing over the ground and having numerous leathery evergreen leaves about 1 inch in length. The waxy flowers, which appear in May, are few and are borne in short, drooping clusters at the ends of the branches. They are white with a pinkish tinge, 5-lobed, and somewhat bell-shaped in form. Smooth, red, globular fruits containing five nutlets follow the flowers.

Part used.—The leaves, collected in autumn.

Mizrahi, Y. and A. Nerd. 1996. New crops as a possible solution for the troubled Israeli export market. p.37-45. In: J. Janick (ed.), Progress in new crops. ASHS Press, Alexandria, VA.

New Crops as a Possible Solution for the Troubled Israeli Export Market

Y. Mizrahi and A. Nerd

In stimulating articles, Noel Vietmeyer (1986, 1990) pointed out that relatively few plant species, most of which were domesticated thousands of years ago, serve as food for humans and animals, as medicinal plants, and as industrial crops. As a result of atmospheric CO_2 increase and global warming, dryer conditions are expected in the future and many existing crop species will unable to survive. Many undeveloped and neglected species could be the new crops of the future, which will tolerate these changing climatic conditions. Research and Development on the development of tolerant crops should be initiated world wide to meet these challenges. New crops should have the potential to thrive in marginal, infertile, dry lands where common crops fail to provide the diversification required to enable sustainable agricultural systems in the future and offer viable commercial opportunities.

Israel is small country (~5 million people and 22,000 km^2) that is self sufficient in agricultural production. The local market is tiny and is subject to dramatic fluctuations in supply and demand. When extra few tonnes of fresh fruits and/or vegetables are dumped onto the local markets, prices plummet and farmers cannot make a living. In contrast the export market, mainly Europe, with hundreds of millions of consumers is unlimited from an Israeli point of view. Thus, Israel is basically an export oriented producer. At its peak, the export volume of fresh agriculture produce (mainly fruits, vegetables, and flowers) from Israel was valued around US$1 billion/year. In the 1960s the fruit export industry (mainly citrus, with the famous `Jaffa' orange being the main product) constituted one of the main sources of foreign currency (out of a total export market of US$211 million agricultural produce comprised about US$64 million, i.e., 30.3% of the total!). Today, Israel is an industrial exporting country with total annual export value of US$14 billion while exports of agricultural fresh produce amount to US$547 million, a mere 3.9% of the total (Statistical Abstracts 1994). It is obvious that a small country such as Israel has to compete in world markets in terms of quality rather than quantity. As a result, millions of R&D dollars have been invested in the past two decades to enable Israel to compete in the world markets with the best possible products giving the highest possible return to the growers. Despite the huge input of R&D in the agricultural sector, the production of the citrus is diminishing (Fig. 1) due to lack of profitability (Fig. 2) and farmers are complaining. Citrus sales have diminished by 30.6% from 1990 to 1993 and profitability in terms of revenue's buying power has declined to 57.3% when inflation is taken into account (Fig. 2; Statistical Abstracts 1994; BDO 1995). The Israeli tomato export industry has stagnated at 8,000 t annually for the past few years, despite the enormous R&D efforts that have produced the world's finest quality (Statistical Abstracts 1994). Israel has additional cost limitations on its competitiveness. Water is a major limiting factor and its actual price is very high (US$0.22 per m^3) and the alternative price is even higher. Labor is very expensive, since farmers are in the upper middle class strata. More than 90% of the agricultural community in Israel is either a kibbutz (community farm) or a moshav (family farm) with minimum hired labor, where most of the work is performed by the farm owners and their families. Gross income below US$100 and even 150 US$/day is considered very low. Israel's competitors in the world markets pay to agricultural workers 10% and less of this sum! Finally, energy is expensive, since almost all the country's energy is imported.

These problems have led many experts in Israel to raise the possibility of giving up agricultural production, even for the local markets, and purchasing all the country's agricultural needs abroad, as do Singapore and Hong Kong. We subscribe to a totally different approach. We believe that supplying the new crops niche in the world markets will serve as a remedy for the troubled Israeli agricultural export industry.

PRODUCT PROFIT CYCLE

In a free market every product is following the profit cycle, as described in Fig. 3. When a totally new crop is first marketed, no profit is expected, since the market has yet to accustom itself to the product. At this stage, low prices are set to attract consumers. In many cases, the market does not respond to the new product, and it simply vanishes without being noticed by most consumers. But if the market likes the new product (perhaps as a result of good marketing strategy), profits will rise as a result of increasing demand and improved production efficiency (Fletcher et al. 1995). Maximum profitability will be achieved by the first producer as long as he is the only suplier in the market. Competition will then start, first with the most efficient and aware producers and from many others. As a result, profitability will decline, and as with all common crops, it will fall to a maginal level. At this stage, only the big and efficient producers can survive. It is thus evident that Israel cannot compete in the market for common crops. A good example of the scenario described above is the "iceberg lettuce episode." In the late 1970s, Marks and Spencer (from the UK) approached the Negev R&D Organization to test the feasibility of growing iceberg lettuce in the Israeli Negev Desert for their chain. Farmers in the Arava valley (Moshav Ein Yahav and Hatzeva) produced the best iceberg lettuce that Marks and Spencer had ever received. The company, which was ready to pay these farmes higher prices than those given their American counterparts in California, was mystified by the refusal of the Israeli farmers to accept the contract. The buyers from Marks & Spencer simply did not understand that these farmers consisted of very small farms (4 ha!), expensive water, and very high energy, and labor costs. In no way, could they compete with the large American producers.

On the other hand, when we start with totally new product, the high profits obtained for small quantities of exotic fruits and vegetables, creates a natural niche for Israeli farmers. These farmers, being highly educated, can easily adopt new crops and new technologies. Israel is also blessed with research institutions and extension services capable of carrying an efficient R&D programs, which are essential for the introduction of new crops. In addition, Israel has a single efficient marketing arm of agricultural products (AGREXCO), which can easily adapt to such programs.

Unfortunately, such a strategy has not yet been adopted by the Israeli R&D authorities. The main objection to such R&D programs is the fact that the market size and the prices of the new products are unknown. Our feeling is that such a niche does exist, and the only way to confirm its existence is to test it. Even the return from R&D is expected to be higher when dealing with new crops. We may ask the question: how much can new R&D increase the profitability of well-established crop at the edge of their profit cycle? We claim that such an effort can yield much more when new crops are investigated.

Unfortunately, in Israel as in most other countries, most agricultural R&D is conducted with money raised as levies from sales. Thus apple growers for example, would like to see their money invested back into R&D on apples. The bigger the crop and the greater the body of knowledge about its biological and agricultural aspects, more R&D is applied. As a result, money is allocated mainly to the "good old crops," while the new crops of the future are neglected. A change in policy is needed to promote more research in the direction of new crops.

NEW CROPS INITIATIVE

In the light of the dilemma discussed above, we initiated in 1984 an R&D project for the "Introduction and domestication of rare and wild fruit and nut trees as new crops to the Israeli Negev Desert" (Nerd et al 1990; 1993). This project includes about 40 different fruit tree species (Table 1) from all over the world that are considered to be potential new export crops. For the project, four sites were selected in the Negev Desert and one location in the Judean Desert, each site differing from the others in terms of climate, soil, and water (Nerd et al. 1990, 1993). The first stage, which lasted about 10 years, was devoted to assessing the survival, growth, phenology, yields, and quality of seedlings of the investigated species. For all the species we preferred to start with seedlings, which provide wide base of genetic backgrounds, rather than to concentrate on a very narrow base of vegetatively propagated preselected genotypes. Many species did not survive, and others are still at various stages of R&D, far away from any onsiderations of economic potential. Four types of fruit have already been moved to the second stage of this program, which will enable us to provide economic evaluation, such as the cost of various inputs per unit area and the output during the years up to the time that the orchards will reach the full production stage. In this second stage of the project, vegetatively propagated specimens are also being tested in a cultivar trial. The expected small quantities that will be produced at this stage (20-30 t/year/crop) will also enable us to evaluate the marketing and find solutions to post-harvest problems. The market figures will enable farmers to take decisions whether or not to enter into the arena of these new crops.

The species that are currently in the second stage of the project include: (1) climbing trellised cacti growing in net houses--*Selenicereus megalanthus* and three species of *Hylocereus*; (2) the outdoor-grown cactus *Cereus peruvianus*, also known as apple cactus; (3) white sapote (*Casimiroa edulis*); and (4) Ber (*Ziziphus mauritiana*) also known as "desert apple," a species introduced from India. Two more species are under consideration for moving to the second R&D stage: (5) marula (*Sclerocarya birrea* subsp. *caffra*), for which 10 clones are currently being propagated and will be ready for planting next year, and (6) argan (*Argania spinosa*), a wild oil tree from Morocco, which will be promoted to the second stage after the selection of the current fruiting year.

Crawling Cacti

These species which are native to Central and north South America, climb on tree trunks in the tropics and may be epiphytic (Gibson and Nobel 1986). Their fruits have various sizes, tastes, shapes, and colors. Some have spines that abscise upon ripening and others have scales of various shapes and colors. The pulp also varies in color from white to various hues of red and purple, while the abundant seeds may be soft and edible (Mizrahi et al. 1996). The reproductive biology of these species is described in a review by Nerd and Mizrahi (1996). Five genotypes are already growing in an area of 2 ha, mainly in net houses since they require shade (Nerd et al. 1990; Raveh et al. 1993; Mizrahi et al. 1996). One clone of *Selenicereus megalanthus*, also known as yellow pitaya, is being cultivated (Weiss et al. 1995). Yellow pitaya is already an established crop that is being exported worldwide from Colombia (Arcadio 1986; Cacioppo 1990; Mizrahi et al. 1996). Other clones include one of *Hylocereus polyrhizus*, one of *H. undatus* and two of *Hylocereus* sp. (Barbeau 1990), all our selections. These clones have been planted in two plantations, each of 0.5 ha. Each clone was planted in a different row to allow cross pollination from the neighboring rows (Weiss et al. 1994b). All were planted in the late summer of 1993 as rooted cuttings removed from the same mother plants, and all started to fruit in 1994. In these plantations two net houses were planted, one with 50% shade in the Arava valley, having a hot climate and saline water (EC 4 dS/m), and the other with both 30% and 60% shade sections in the Besor area, which is characterized by good quality water (EC 1 dS/m) and moderate temperatures with only rare frosts (Nerd et al. 1993). The second hectare was planted in the Yad Mordekhay area, with sub-freezing temperatures as low as -4deg.C; here, plastic houses were planted to accommodate selected and non-selected plants. All started to fruit one year after planting.

Cactus Apple

Of many columnar cacti tested by us as potential new crops, one species--*Cereus peruvianus*--grew the fastest. It started to flower and fruit four years after seeding (Nerd et al. 1993; Weiss et al. 1993). Rooted cuttings of seven clones of this cactus, selected from over 300 seedlings, were planted in the Arava valley and the Besor, with a total area of 2 ha. All cuttings were planted as a mixture of clones, since this species demonstrates self-incompatibility (Weiss et al 1994a). The reproductive biology of this cactus is also described in the review of Nerd and Mizrahi (1996). All clones started to flower and fruit two years after planting. Over 1,000 seedlings have been planted for further selection.

White Sapote

White sapote (*Casimiroa edulis*, Rutaceae) is an evergreen medium-size tree native to the highlands of Mexico and Central America. The fruits are green-yellow, with a thin skin and a creamy white-yellow sweet flesh (Morton 1987). Selected clones are available, mainly in Southern California (Chambers 1984; Morton 1987), and some effort has been made to introduce the species into New Zealand and Australia (Dawes and Martin 1988; George et al. 1988). A small commercial plantation (16 hectares) with selected cultivars is being grown in Carpenteria near Santa Barbara, California and the fruits can be found as an exotic item in the United States and Australia. Early tests in the Israeli Negev Desert demonstrated partial tolerance to salinity (Nerd et al. 1992). In autumn 1992 and spring of 1993, 21 grafted clones were planted in Qetura and Besor; 16 were introduced as bud-wood from Fallbrook, Southern California (from R.R. Chambers orchard), while the remaining five were propagated as grafted bud-wood from our own selections. Nine replications from each clone were planted in three blocks at each location. In 1995 some clones started to flower and set fruits in these two locations.

Desert Apple

Desert apple (*Ziziphus mauritiana*, Rahmnaceae), also known as ber or Indian jujube, is an evergreen, medium-size, thorny tree believed to be of African origin (Alexander, 1979). The fruits can reach plum size, turning yellow from green as ripening starts, and becomes sweet and sour in taste, both the flesh texture and taste being reminiscent of apples. The fruit has a unique aroma, similar to that of carob, which becomes too strong for "Western" tasters when fully ripe, at which stage the color turns brown. The fruit can be consumed dry, similar to its relative the "Chinese date" *Z. jujube*. Ber is grown commercially as a desert crop (hence the name desert apple) in India. Seedlings and introduced cultivars from India developed and yielded very well (over 100 kg/tree annually) in all our introduction orchards, including areas with frequent sub-freezing temperatures and highly saline water (Nerd et al. 1990). Three Indian cultivars were planted at Neot Hakikar, the lowest point on earth -400 m below sea level with 3,960 mm evaporation/year and saline water (EC 4 dS/m) with Na and Cl as the major ions (Nerd et al. 1993). Most of our introduced fruit tree species did not survive under these conditions, but ber has fruited heavily from very early ages. A semi-commercial plantation was planted by a farmer in 1993, and the first yield was sold in 1995 in the local market, mainly to immigrants from India who are familiar with the fruit.

Marula

Marula (*Sclerocarya birrea* subsp. *caffra*, Anacardiaceae) is a large, dioecious, deciduous tree, which grows wild in southern Africa. Female trees bear plum-sized fruits with a thick yellow peel and a translucent, white, highly aromatic sweet-sour fruit, which is eaten fresh, like a small mango, or used to prepare juices, jams, conserves, dry fruit rolls, and alcoholic beverages. The seeds, which are eaten as a delicate nut, are highly appreciated by the locals and hence the name "the kings nut." The nut has high nutritive value and a high oil content (56%) with very good dietetic ratio of saturated to unsaturated fatty acids (Weinert et al. 1990). Trees were established very well at introduction sites in the Negev Desert and produced abundant fruits from early ages, mainly when grown in a hot area with saline water (Qetura) (Nerd and Mizrahi 1993). Trees were badly damaged after a spell of sub-freezing temperatures of -6° and -7°C; all recovered but never set fruits, and thus this species is not recommended for areas with such low temperatures. At Qetura, some pistillate trees are bearing well, over 400 kg/tree annually, and we have moved the species to the second stage of our R&D program to test selected clones on a semi-commercial basis. Ten selected clones are being propagated and will be ready for planting in 1996.

Argan

Argan (*Argania spinosa*, also known as *A. sideroxylon*, Sapotaceae) is a medium, thorny, evergreen tree native to south western Morocco. The tree bears plum-sized fruits, which are eaten by goats which often climb the trees. The fruits have a bitter pericarp around a stone-like structure, containing one to three kernels with a high oil content (over 50%). The oil has high dietetic value, total unsaturated fatty acids/total saturated fatty acids being around 4.5, a ratio similar to that of olive oil (Morton and Voss 1987; Prendergast and Walker 1992). The oil has a unique aroma and is considered as the best culinary oil by Moroccans, who are the only people familiar with the oil. In Israel, where 600,000 immigrants from Morocco reside, imported argan oil is sold for US$43/liter in comparison with $4/liter for olive oil. Attempts to domesticate this wild tree in Israel started about 10 years ago. The species demonstrated adaptability to the hot hostile environment of the Arava valley when irrigated with brackish water; yields of oil per tree at Qetura were double those at Ramat Negev, which has much milder environmental conditions (Nerd et al. 1994). The oil yield of best specimens was around 1 kg/tree annually. Some seedlings died as a result of infection with *Fusarium oxysporum*. Until tolerant rootstocks can be found, we decided to plant grafted trees from the best yielding ones and to plant additional seedlings from various habitats in Morocco. Even though this species is not in as advanced stage of introduction as the marula, we consider it to be a high-priority species because of its rarity and the high demand in Israel for its oil.

CONCLUSIONS

It is interesting to note that in our earliest publication (Nerd et al. 1990), we mentioned six species as promising, an evaluation based on their early development and growth. These species included white sapote and ber, which are still considered promising, and marula, which has been moved to the second stage of the R&D, but they also include yehib (*Cordeauxia edulis*), mongongo (*Ricinodendron rautanenii*), and pitaya agria (*Stenocereus gummosus*), which did not meet our early optimistic expectations. The latter three species proved to be late yielders (pitaya agria); or exhibited sensitivity to the desert conditions of our introduction sites, such as salinity or sub-freezing temperatures; or were not as abundant in fruiting as the promising species described in this presentation. Other promising species emerged, such as *C. peruvianus*, with its adaptability to a spectrum of conditions, including slight salinity and sub-freezing temperatures. The species produces early and heavily, giving good-quality, tasty fruits. The most surprising successes were the various crawling cacti (*Hylocereus* species and *S. megalanthus*), which did not survive the outdoor Negev Desert conditions (Nerd et al. 1990), but once trellised and protected from high radiation by net houses, started yielding precociously and early to give some of the most beautiful fruits on earth.

Of the six promising species from the first R&D stage, three were moved into the second stage (white sapote, ber, and marula), while others, the apple cactus and the crawling cacti, emerged as promising and already planted as vegetative clones (moved to second stage). This evaluation was based on fruiting (both as yields and fruit quality) and early selection of good-performing specimens.

We anticipate that at least some of these newly introduced species will become export items with profit levels that will be sufficiently high to revive the fruit export industry and replace the old "dying-out" export crops. The high profitability of new fruit crops was demonstrated for kiwi fruit by New Zealand in the world market and for avocado by Israel in the European market. There is no reason why such new exotic fruits will not be the commodities of the future. We should not forget that no crop can stay at its peak forever, and low profits always loom in the future. Mr. Dan Rymon (pers. commun.), found that it took 17 years from the first sales of flower crops in the European markets until Israel was chased out by its competitors. With fruit trees, it may be much much longer, as was the case with the kiwi fruit from New Zealand (47 years) and the `Shamuti' (`Jaffa') orange from Israel (80 years).

We should conclude with an evaluation of the benefits of our program to the world as a whole. Any species that can produce good yields in the Arava valley--the location of both Qetura and Neot Hakikar--can serve as a future crop species that can tolerate extremely high temperatures and salinity. Because of the unique situation in the Negev Desert of short distances between agriculturally different ecozones, we recommend that this area be used as a global laboratory for the introduction and acclimation of new desert crops. In 1994 the International Program for Arid Land Agricultural Crops (IPALAC) was initiated under the auspices of UNESCO. This program is aimed at R&D similar to that described in this paper, to be executed with all kinds of agricultural crops in representative desert areas around the globe.

Table 1. List of candidate species.

Family Botanical name	Common name	Distribution
Apocynaceae		
Carissa grandiflora A. DC.	Carrisa	Southern America
Anacardiaceae		
Sclerocarya birrea subsp. *caffra* Sounder	Marula (Morula)	Southern Africa
Spondias cytherea (*Spondias dulcis*) Forst	Ambarella	Polynesia
Bombacaeae		
Bombax glabra	Malabar nut	Central America
Cactaceae		
Acanthocereus tetragonus (L.) Humlk.	Acanthocereus	Mexico
Cereus peruvianus (L.) Miller	Apple cactus (Pitaya)	North South America
Escontria chiotilla (Weber) Britt & Rose	Pitaya (Jiotilla)	Mexico
Hylocereus costaricensis (Weber) Br. & R.	Pitahaya	Central America
Hylocereus paolyrhi (Weber) Br. & R.	Pitahaya	Central America
Hylocereus polyrhizus (Weber) Br. & R.	Pitahaya	Central America
Hylocereus purpusii (Weber) Br. & R.	Pitahaya	Central America
Hylocereus undatus (Weber) Br. & R.	Pitahaya	Central America
Myrtilloactus geometrizans (Mart.) Cons.	Pitaya	Mexico
Nopalea cochenillifera (L.) Salm-Dyck	Nopalito, Nopalea	Mexico
Opuntia ficus-indica (L.) Miller	Prickly pear	Tropical America
Opuntia streptacantha Lem.	Prickly pear	Tropical America

Pachycereus pringlei (Berger) Britt & Rose	Cardon pelon	Sonoran Desert
Selenicereus megalanthus (Schum.) Br. & R.	Pitaya	Columbia
Stenocereus griseus (Haw.) Buxb.	Pitaya	Oaxaca Mexico
Stenocereus gummosus (Engelm.) Gilbs.	Pitaya agria	Sonoran Desert
Stenocereus stellatus (Pfeiff.) Riccob.	Pitaya	Mexico
Stenocereus thurberi (Engelm.) Buxb.	Pitaya dulce	Sonoran Desert
Stenocereus thurberi var. *litoralis* (E.) B.	Pitaya dulce	Sonoran Desert
Caesalpiniaceae		
Cordeauxia edulis Hemsl.	Yehib	Northeast Africa
Ebenaceae		
Diospyros digyna Jacq.	Black sapote	South America
Diospyros discolor Willd.	Mabolo (Velvet apple)	Philline Islands
Diospyros mespiliformis Hocht.	Mmilo namibia	South Africa
Euphorbiaceae		
Ricinodendron rautanenii Schinz	Mongongo	Southern Africa
Guttiferae		
Rheedia madruno Triana & Planch.	Madrono	Central America
Flacourtiaceae		
Dovyalis caffra Warb.	Kei apple	Southern Africa
Leguminosae		
Tamarindus indica L.	Tamarind	Tropical Africa
Loganiaceae		
Strychnos cocculoides Backer	Monkey orange	Southern Africa
Strychnos spinosa Lam.	Monkey orange	Southern Africa
Strychnos pungens Solereder	Monkey orange	Southern Africa
Mimosaceae		
Inga spp.	Ice cream bean	South America
Moraceae		
Artocarpus heterophyllus Lam.	Jackfruit	Asia
Rhamnaceae		
Ziziphus mauritiana Lank.	Ber	Old World Tropics
Rosaceae		
Prunus salicifolia H BK.	Capulin cherry	Mexico

Rubiaceae		
Vangueria infausta Burch.	Mmilo	Southern Africa
Rutaceae		
Casimiroa edulis Llave & Lex.	White sapote	Mexico, Central America
Santalaceae		
Santalum acuminatum (R. Br.) A. DC.	Quandong	Australia
Sapotaceae		
Argania spinosa L.	Argan	Morroco
Chrysophyllum cainito L.	Star apple	Central America
Manilkara zapota van Royen	Sapodilla	India, Africa, Central America
Mimusops angel Engler	Angel	Somalia
Mimusops zeyheri Sond.	Mmupudu	Southern Africa
Pouteria sapota (Jacq.) Merr.	Mammey sapote	Central America

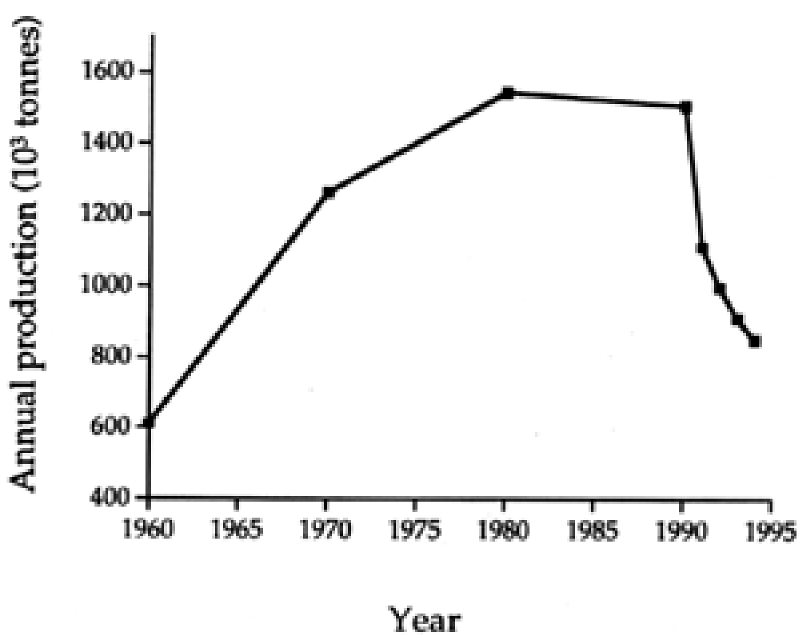

Fig. 1. Changes in annual citrus production in Israel 1960-1994. (Statistical Abstracts of Israel 1994).

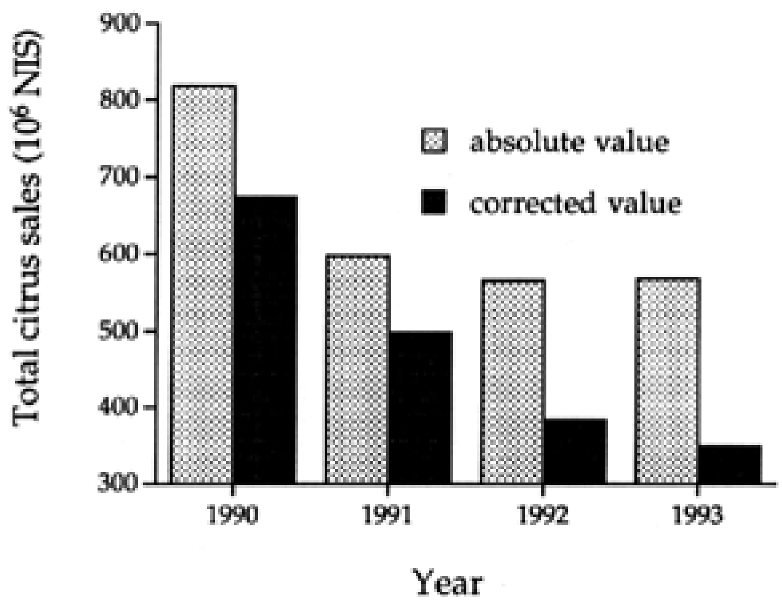

Fig. 2. Changes in sales volume and in buying power of citrus exporters in Israel 1990-1993. Data are taken from the Statistical Abstracts of Israel (1994). Production during this period decreased and prices increased but well below the consumer price index. The inflation rates were 17.6%, 18.6%, 9.4%, and 11.2% for 1990, 1991, 1992, and 1993, respectively (BDO Bavly Milner & Co. 1995). By the time farmers received their money, its value had been eroded due to inflation. The corrected value of their income is calculated from the actual value and the inflation rate.

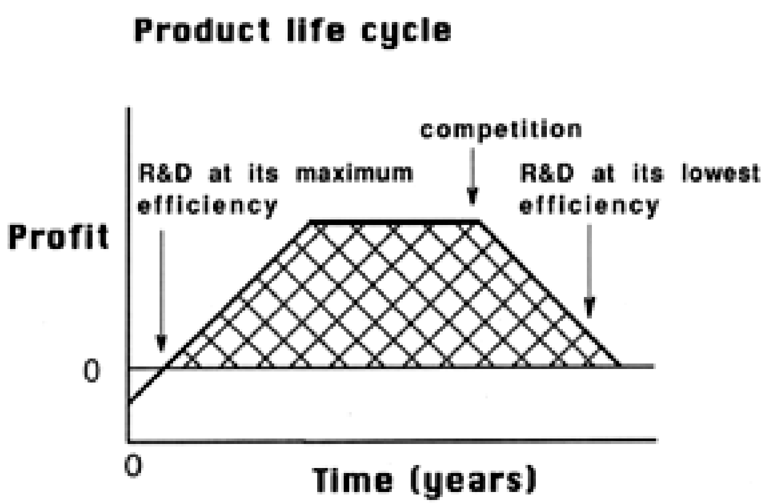

Fig. 3. Hypothetical product life cycle in a free market. For cut flowers exported from Israel to Europe the span is 17 years (D. Rymon, Agricultural Research Organisation, pers. commun.).

Medicinal weed Satyanashi (*Argemone mexicana* Linn)

Contributor: Pankaj Oudhia

Copyright (c) 2002. All Rights Reserved. Quotation from this document should cite and acknowledge the contributor.

English name: Mexican prickly poppy

Common (Indian) names

Hindi: Shialkanta, Satyanashi
Gujrati: Darudi
Danarese: Balurakkisa, Datturi, Pirangi, datturi
Marathi: Daruri, Firangi-kote-pavola, dhotara.
Sanskrit: Brahmadandi, Pitopushpa, Srigalkanta, Svarnakshiri.
Malyalam: Ponnummattu, Kantankattiri
Tamil: Kutiyotti, Ponnummuttai
Telugu: Brahmadandicettu

Family: Papaveraceae

Habitat: In India it is introducd and naturalised and occur as wasteland weed in almost every part of India. In many parts it is repoorted as crop weed also.

Related species: It is native of Tropcal America. The genus Argemone includes 12 species. Some major species are: *A. alba* Lestib. (used medicinally in North America), *A. platyceras* Link. & Otto., *A. grandiflora* Sweet.

Botany: It is a prickly, glabrous, branching herb with yellow juice and showy yellow flowers, The Sanskrit name svarnakshiri is given because of the yellow juice (Svarna - Gold; Kshiri - Juice). The height of this plant varies between 0.3 to 0.12 meters, Leaves are thistlelike. Stem clasping, Oblong, sinuately pinnatifid, spinous and viens are white. Flowers are terminal, yellow and of 2.5–5.0 cm diameter. Fruits are capsule. Prickly and oblong ovoid. Seeds numerous, globose, netted and brownish black. Flowering time is all round the year in Indian conditions. The plants is toxic to animals and cattle avoid grazing this plant. Harmful allelopathic effects of Argemone mexicana on germination and seedling vigour of wheat, mustard, fenugreek, sorghum, fingermillet, tomato, cucumber etc. (important crops in India) have been reported. The allelochemicals cinnamic and benzoic acid are identified as harmful chemicals responsible for inhibition of germination and seedling vigor.

Useful Parts: Roots, leaves, seeds and yellow juice.

Medicinal Properties and Uses: According to Ayurveda the plant is diuretic. purgative and destroys worms. It cures lepsory, skin-diseases, inflammations and bilious fevers. Roots are anthelmintic. Juice is used to cure ophthalmia and opacity of cornea. Seeds are purgative and sedative. Seeds resemble mustard seeds and in India it is used to adulterate mustard seed. Seed yield non edible toxic oil and causes lethal dropsy when used with mustard oil for cooking.

In Homoeopathic system of medicine, the drug prepared from this herb is used to treat the problem caused by tape-worm.

Popular Ayurvedic Formulations: Svarnakshiri churna and tail

Other uses: The plant is found suitable for the reclamation of alkaline soils.

Dried and powdered plants are recommended as green manure as it contain sufficient amount of Nitrogen, Phosphorus and Potassium.

Oilcake is used as manure.

Seed oil, popularly known as Satyanashi oil is used as an illuminant, lubricant, in soapmaking, and for protection from termites.

Chemical Constituents: The plant contains alkaloids as berberine, protopine, sarguinarine, optisine, chelerytherine etc. The seed oil contains myristic, palmitic, oleic, linoleic acids etc.

Jack-In-The-Pulpit

Arisaema triphyllum (L.) Schott.

Synonym.—*Arum triphyllum* L.

Other common names.—Wild turnip, arum, three-leaved arum, Indian-turnip, wakerobin, wild pepper, dragon-turnip, brown dragon, devil's-ear, marsh turnip, swamp turnip, meadow turnip, pepper turnip, starchwort, bog onion, priest's-pintle, lords-and-ladies.

Figure 69.—Jack-in-the-pulpit (*Arisaema triphyllum*)

Habitat and range.—Jack-in-the-pulpit inhabits moist woods from Canada to Florida and westward to Kansas and Minnesota.

Description.—The jack-in-the-pulpit has one or two smooth leaves consisting of three leaflets from 3 to 6 inches long and from 1 1/2 to 3 1/2 inches wide. The flower, which is either all green or green with dark purple stripes, is readily recognized on account of the similarity of its form to that of the calla lily. In autumn the fruit ripens in the form of a bunch of bright, scarlet, shining berries. The underground portion, usually referred to as the root but botanically known as a corm, is shaped like a turnip. The lower part is flat and wrinkled, while the upper part is surrounded by coarse wavy rootless. It has an extremely burning taste.

Part used.—The dried corm, collected in the summer, is sliced crosswise and dried. Drying and heat diminish its burning taste, which disappears rapidly with age.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Snakeroot

(1) *Aristolochia serpentaria* L.; (2) *A. reticulata* Nutt.

Other common names.—(1) Virginia snakeroot, Virginia serpentaria, serpentary, snakeweed, pelicanflower, snagrel, sangrol, sangree-root; (2) Texas snakeroot, Texas serpentaria, Red River snakeroot.

Figure 99.—Snakeroot (*Aristolochia serpentaria*)

Habitat and range.—Virginia snakeroot is found in rich woods from Connecticut to Michigan and southward, principally among the Alleghenies, and Texas snakeroot occurs in the Southwestern States, growing along river banks from Arkansas to Louisiana.

Description of Virginia snakeroot.—This plant is nearly erect, the slender, wavy stem sparingly branched near the base growing usually to about a foot in height sometimes, however, even reaching 3 feet. It has thin leaves, heart-shaped at the base and pointed at the apex, about 2 1/2 inches long and from 1 to 1 1/2 inches wide. The dull-brown, somewhat leathery flowers are produced individually from near the base of the plant on slender stems. The fruit is round, about half an inch in diameter, and contains numerous seeds. Serpentaria has a short rootstock with many thin, branching, fibrous roots. The rootstock has a very agreeable, aromatic, camphorlike odor and a warm, bitterish, camphoraceous taste.

Description of Texas snakeroot.—This plant has a very wavy stem with oval, heart-shaped, clasping leaves which are rather thick and marked with a network of veins. The entire plant is hairy, with numerous long, coarse hairs. The small densely hairy, purplish flowers are produced from the base of the plant. The rootstock of this species is larger and has fewer small roots than that of the Virginia snakeroot.

Part used.—The roots of both species, collected in autumn.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Arjun or Koha [*Terminalia arjuna* (Roxb.) W. & A.]

Contributor: Pankaj Oudhia

Copyright (c) 2002. All Rights Reserved. Quotation from this document should cite and acknowledge the contributor.

English Name: White Marudah

Common (Indian) Names

Hindi: Arjun, Arjuna, Koha, Kahu, Arjan
Gujrati: Arjun - Sadada, Sadado
Canarese: Bili-Holo-Nir-Tora Matti, Maddi
Marathi: Arjuna, Arjun Sadada, Sadura
Sanskrit: Arjuna, Dhanvi, Indradruma, Kakubha, Karvirak.
Oriya: Arjuna, Sahajo
Tamil: Vellamatta
Telugu: Yerra maddi
Assam: Orjun
Bengali: Arjhan
Punjabi: Arjuna

Family: Combretaceae

Botany: Tree up to 25 meter hight; bark grey, smooth; leaves sub-opposite, 5–14 × 2–4.5 cm., oblong or elliptic oblong, glabrous, often inequilateral, margin often crenulate, apex obtuse or sub-acute, base rounded or sometimes cordate; petioles 0.5–1.2cm; glands usually two. Flowers small, white. Fruit 2.3–3.5 cm long, fibrous woody, glabrous with 5 hard wings, striated with numerous curved veins. Flowering time April–July in Indian conditions. Seeds hard germination 50–76 days (50–60%)

Related Species: The genus *Terminalia* consist large hard wooded trees. Over 100 species widely distributed in the tropices (*Terminalia* originated from Latin ward *Terminus*, alluding to the leaves being borne on the tips of the shoots). In India, *Terminalia chebula*, *T. bellrica* and *T. ciliata* are major related species.

Distribution: Common in almost every part of India. Grows well along bank of streams, rivers, ravines, dry water courses, reaching very large sizes on fertile alluvial loam.

Useful Parts: Every parts useful medicinal properties Arjun holds a reputed position in both Ayurvedic and Yunani Systems of medicine. According to Ayurveda it is alexiteric, styptic, tonic, anthelmintic, and useful in fractures, uclers, heart diseases, biliousness, urinary discharges, asthma, tumours, leucoderma, anaemia, excessive prespiration etc. According to Yunani system of medicine, it is used both externally and internally in gleet and urinary discharges. It is used as expectorant, aphrodisiac, tonic and diuretic.

Ayurvedic Formulations: Arujanarishta, Arjunghrita, Arjunakhsirpak, Arvindasava, Devadarvy - arishta etc.

Other Uses: Recommended for reclamation of saline, alkaline soils and deep ravines. Used for agro and social forestry. Timber is locally used for carts, agricultural implements, water troughs, traps, boat building, house building, electric poles, tool-handles, jetty-piles and plywood. Fodder is useful for tassar silkworm. It is one of the major tannin yielding trees. Bark (22–24%), leaf (10–11%) and fruit (7–20%) contains tannins.

Chemical Constituens: A glucoside - arjunetin - has been isolated from bark. Recently new flavance - arjunone has been isolated from fruits alongs with cerasidin, β-sitosterol, friedlin, methyl oleanolate, gallic, ellagic and arjunic acids.

Artificial Propagation: It can be artificially propagated through seeds, coppicing, pollarding, root-suckers, stumps and air-layering. It is initially slow-growing but later fast-growing. It attains 2–3 m height in 3 years. Arjun yields up to 45 kg dry bark chips on a three year cycle without injury.

Tall oatgrass

Gramineae, Poaceae *Arrhenatherum elatius* (L.) Presl

Source: Magness et al. 1971

Tall oatgrass, native to Europe, was brought to the United States early in the last century. It is now grown widely in the central and northern states, and in the Pacific Northwest. It is a hardy, upright perennial bunchgrass reaching to 5 feet, with many leaves. The seed head resembles that of oats, hence the name. It tends to grow in bunches and is well adapted to light textured soils. It is suitable for pastures and yields a palatable hay. It is frequently seeded in combination with other grasses and legumes as sweet and red clovers. It is shorter lived than most bunchgrasses.

Last update June 28, 1996 bha

Eruca sativa Miller

Diplotaxis tenuifolia (L.) DC.

Lakoocha: A Multipurpose Tree of Warm Climate

Nirmal Joshee, D.R. Bastola, V.P. Agrawal, and A.K. Yadav*

INTRODUCTION

Artocarpus lakoocha Roxb., Moraceae, is a valuable tropical tree species native to India and used for fruit, furniture, timber, and feed. The lakoocha fruits are generally eaten fresh. Each fruit contains 20–30 seeds that are fleshy with thin seed coat. The edible fruit pulp is believed to act as a tonic for the liver. Raw fruits and male flower spike (acidic and astringent) are utilized in pickles and chutney (sauce). The lakoocha tree is also valued for feed and timber. The hardwood sold as lakuch, is comparable to famous teak wood. Lakuch which is durable outdoors as well as under water, is used for construction, furniture, boat making, and cabinet work. Tree bark containing 8.5% tannin is chewed like betel nut, and is also used to treat skin ailments. It yields a durable fiber good for cordage. The wood and roots yield a lavish color dye. Lakoocha seeds and milky latex are purgative. Seeds contain artocarpins (ALA I and ALA II), the isolectins which exhibit high haemagglutination activity (Wongkham 1995). However, the agglutinin (ALA) from *Artocarpus lakoocha* is not organ specific. Moreover, the haemagglutination activity of ALA was demonstrated in various organs of the plant except fruit flesh. The highest and the lowest activities were found in the seeds (14,400 units/g fwt) and leaves (5 units/g fwt), respectively.

BOTANY AND DISTRIBUTION

The genus *Artocarpus*, Moraceae, which consists of jackfruit (*Artocarpus heterophyllus*), lakoocha or monkey jack (*A. lakoocha*), chempedak (*A. integer*), breadfruit or breadnut (*A. altilis*), and marang (*A. odoratissima*), comprises over 50 distinct species of monoecious evergreen trees (Drew 1997). Compound fruits are derived from swollen flower heads. *Artocarpus* species display high levels of genetic variability, both between and within species. This is evident from the wide range of locally distributed *Artocarpus* genotypes. Breadfruit cultivars are triploid and seedless. Lakoocha seedling trees take five years to come into bearing. The orange-yellow male flowers and reddish female flowers of lakoocha are borne separately on the same trees. Fruits are nearly round or irregular, from 5 to 12 cm in diameter and have a velvety surface (Fig. 1). The lakoocha fruits are dull-yellow with pink tinge and sweet-sour pulp. Fruit yield can be up to 80 kg/tree with fruit weight ranging from 200 to 350 g.

Fig. 1. A developing fruit (60%) of *Artocarpus lakoocha*.

The lakoocha is popularly known as "monkey jack" or "*lakuchi*" in India, "*badahar*" in Nepal, "*tampang*" in Malaya, and "*lokhat*" in Thailand. A native of the humid sub-Himalayan regions of India, it grows up to 1,200 m altitude. The lakoocha trees grow 6 to 9 m tall with large, leathery and deciduous leaves (Fig. 2).

Fig. 2. A mature tree of *Artocarpus lakoocha*.

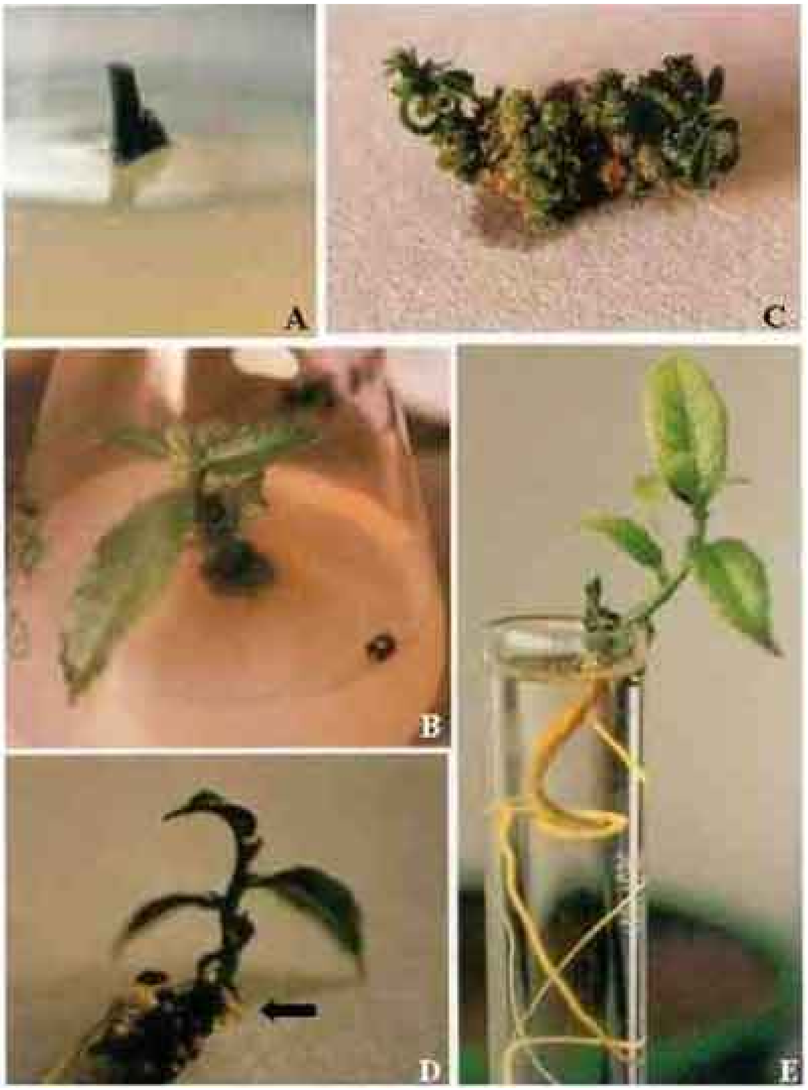
PROPAGATION

There are a number of Important problems associated with regeneration and propagation of lakoocha: (1) tree population of lakoocha is gradually decreasing due to poor seed viability and extensive exploitation for food, timber, and other uses; (2) seeds, once extracted from the fruit, quickly loose viability within a week, or sometimes even in few days; and (3) vegetative propagation methods such as rooting of hardwood or softwood stem cuttings have not been successful (Napier and Robbins 1989).

Protocols were developed for micropropagation of lakoocha seedlings. Lakoocha fruits were collected just before maturity and stored at 4°C. Fruits were washed under running tap water for 1 hr, then washed with detergent and rinsed 3 times with sterile distilled water. Fruits were dipped in 70% ethanol for 1 min, air dried and flamed to evaporate ethanol. Following this, fruits were cut open to remove seeds. Air dried seeds were germinated on sterile sand and slanted agar in test tubes. Germination medium contained 0.8% agar and 0.5% sucrose with pH adjusted to 5.7–5.8. Six-week-old seedlings were utilized to prepare leaf disc, nodal segment, and shoot tip explants.

Aseptic cultures using leaf discs, nodal segments and shoot tip explants were initiated on MS basal medium containing NAA and BA alone and in combination along with a control without growth regulators. Leaf discs did not show any response in different media. Nodal and shoot tip explants (Figs. 3A, C) initiated calli at cut ends. Shoot tips were more responsive and highly prolific in initiating shoot buds. Optimum results for multiple shoot induction were obtained with MS supplemented with 1.0 to 2.0 mg L^{-1} BA. Rooting was observed in 2 to 3 weeks in MS medium supplemented with 2.0 mg L^{-1} IBA (Fig. 3D).

Fig. 3. Sequential stages in the complete in vitro regeneration of lakoocha plantlets. A. Nodal explant. B. Elongation of axillary bud in nodal explant. C. Shoot tip producing callus and numerous shoot bud primordia. D. Elongated shoots initiate rooting in the induction medium, arrow points to a root. E. Complete plantlet developed with well defined shoot and root at the end of 4–5 months in culture.



CONCLUSIONS

In vitro micropropagation protocol for rapid multiplication of lakoocha is required to maintain an adequate supply of plants to establish new plantations and to conserve desirable genotypes. It is also considered important to develop somatic embryogenesis protocols for in vitro regeneration to enhance genetic improvement of desirable lakoocha genotypes.

Bamboo

Bambuseae *Arundinaria* sp., *Phyllostachys* sp., *Bambusa* sp., *Dendrocalamus* sp.

Source: Magness et al. 1971

According to Bailey (Stan. Cyclo. Hort.), more than 200 species of bamboo are recognized, varying in size from a few feet to more than 100 in height. The tender, young shoot growth of many of these species is used as food, in the United States mainly in Chinese dishes. Sprouts harvested in the United States are limited to Hawaii and Puerto Rico, but substantial quantities are imported. Since new sprout growth quickly becomes hard and woody, the maximum period of exposure of edible parts to direct pesticide application would be approximately a month.

Canada Wildginger

Asarum canadense L.

Figure 32.— Canada wildginger (*Asarum canadense*)

Other common names.—Asarum, Indian ginger, Canada snakeroot, Vermont snakeroot, heart snakeroot, southern snakeroot, black snakeroot, coltsfoot snakeroot, black snakeweed, broad-leaved asarabacca, false coltsfoot, colicroot.

Habitat and range.—This inconspicuous little plant frequents rich woods or rich soil along roadsides from Canada south to North Carolina and Kansas.

Description.—Canada wildginger, better known perhaps as Canada snakeroot, is a small plant, apparently stemless, and not more than 6 to 12 inches in height. It usually has but two leaves, which are borne on slender, finely hairy stems. The leaves are kidney-shaped or heart-shaped, thin, dark green above and paler green on the lower surface, and from 4 to 7 inches broad. The solitary flower is borne on a short, slender stalk produced between the two leaf stems, and on account of its closeness to the ground it is not readily noticeable. It is bellshaped and of a dull-brown or brownish-purple color, the inside being darker than the outside. The plant has a creeping, yellowish rootstock with thin rootless produced from joints which occur about every inch. It has a fragrant odor and spicy taste.

Part used.—The rootstock, collected in autumn.

Botanical Description: Please see Table I

Useful Parts: Root, leaves, Green berries and seeds.

Medicinal Uses: According to Ayurveda, the root is bitter, acrid, heating, aphrodisiac, tonic, alternative, anthelmintic and useful in treatment of inflammations, psoriasis, bronchitis, asthma, consumption, ulcers, scabies, marasmus of children, insomnia, senile debility etc. According to Unani system of medicine, the root is bitter, tonic, aphrodisiac, emmenagogue, good in asthma, inflammations, leucoderma, bronchitis, lumbago, thirst etc.

Major Alkaloids: Somniferine, somnine, somniferinine, withananine, pseudo-withanine, tropino, pseudotropine, choline, cuscohygrine, isolettetierine, anaferine, anahydrine, 3-alpha-gloyloxy tropane, etc.

Common differences between *Withania somnifera* and *Withania coagulans*

	Withiania somnifera	*Withania coagulans*
Synonyms	Physalis somnifera	*Punneria coagulans*
Local name	*Asgandh*	Punir
Plant	A much branched, erect, perennial undershrub, from a more or less tuberous root	A rigid, ashy-grey undershurb
Branches	Terete, clothed with mealy, stellate-hoary tomentum, at length some what glabrous	Woody, terete, densely clothed with mealy, stellate tomentum, sulcate when dry
Leaves	5-10×3.6 cm, ovate, obtovate, or oblong, subacute or rarely obtuse, entire, rounded or somewhat produced at base, Pubescent on lower surface and glabrous on upper surface	2-7×1-2.5 cm, elliptic-lanceolate or oblanceolate, coriaceous, obtuse at apex, both surfaces uniformly grey-tomentose due to thick coating of minute, stellate hairs
Flowers	in sessile, axillary, 4-6 flowered cymes, greenish-yellow	Unisexual
Fruits	Orange-red berry, smooth, more or less globose	Globose, smooth
Seeds	Yellow, somewhat scurfy	Ear-shaped, glabrous

Rhizophora mucronata Lam.

Rhizophoraceae
Asiatic mangrove

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

The wood (sp. grav. 0.81), durable except in the ground, and difficult to saw, is used for construction, fish traps, house frames, piling, and poles. Thousands of tons of mangrove woodchips are exported annually from Indonesia, Sabah, and Sarawak for pulp and for rayon manufacture (NAS, 1980a). Fruits may be eaten, after scraping off the outside and boiling with wood ashes, according to some skeptical accounts (Burkill, 1966). The Wealth of India describes the fruit as sweet and edible, the juice made into a light wine. Young shoots are cooked and eaten as a vegetable (C.S.I.R., 1948–1976). Bark, used for tanning and dye, may be removed from stems for sale as firewood. Leaves are the source of a black or chestnut dye (Burkill, 1966). Mangrove extract is used for maintaining oil-well drilling muds within a desired range of flow (C.S.I.R., 1948–1976). Planted along coastal fish ponds to stabilize the banks.

Folk Medicine

Reported to be astringent, Asiatic mangrove is a folk remedy for angina, diabetes, diarrhea, dysentery, hematuria, and hemorrhage (Duke and Wain, 1981). Leaves are poulticed onto armored fish injuries (Watt and Breyer-Brandwijk, 1962).Indochinese use the roots for angina and hemorrhage. Malayans use old leaves and/or roots for childbirth. Burmese use the bark for bloody urine, Chinese and Japanese for diarrhea, Indochinese for angina (Perry, 1980).

Chemistry

Wood contains 4.4% resin, 63.4% cellulose (List and Horhammer, 1969–1979) and 1.5% ash (Watt and Breyer-Brandwijk, 1962). Tannin may vary in dry bark from ca 13–50%, leaves contain 9.1%, green fruits 12.0%, and ripe fruits 4.2%. Spent mangrove bark, after tannin extraction, can be used as a source of furfural (C.S.I.R., 1948–1976). Spent bark from North Borneo yields an ash assaying 18% lime (70% $CaCO_3$).

Toxicity

Honey collected from the flowers is said to be poisonous (C.S.I.R., 1948–1976).

Description

Evergreen tree 25(–30) m high, 70 cm in diameter, with numerous branching arching stilt roots. Bark brown or blackish, smoothish, with horizontal fissures. Leaves opposite, elliptical to oblong, 8–15 cm long, 5–10 cm wide, acute, entire, without visible veins, thick and leathery, glabrous, black-dotted beneath. Petiole 3–5 cm long. Stipules paired, leaving ring scar. Flower clusters axillary, 2–3 times forked, with 3–8 flowers ca 15 mm long. Bell-shaped hypanthium with 4 pale yellow, pointed leathery sepals and 4 cream-colored petals 9 mm long. Stamens 8, stalkless, anthers 6–8 mm long, 4 opposite sepals and 4 opposite petals. Ovary half-inferior, conical, 2-celled, with 2 ovules in each cell, 2-lobed style. Berry ovoid or conical, 5–7 cm long, brown, leathery. Seed 1, viviparous, becoming cigar-shaped, to 40 cm long and 2 cm in diameter (Little, 1983).

Germplasm

Reported from the Africa, Hindustani, Indonesia-Indochina, and China-Japan Centers of Diversity, Asiatic mangrove, or cvs thereof, is reported to tolerate diseases, insects, pests, salt, and waterlogging (NAS, 1980a; Little, 1983). ($2n = 36$)

Distribution

Old World tropics from South and East Africa to Madagascar, Seychelles, Mauritius, southeastern Africa to southern China, Ryukyu throughout Malaysia to northeastern Australia, Melanesia, and Micronesia. Not widely introduced in Hawaii (Little, 1983).

Ecology

Estimated to range from Tropical Moist to Rain through Subtropical Moist to Rain Forest Life Zones, Asiatic mangrove is estimated to tolerate annual precipitation of 10 to 80 dm, annual temperature of 20 to 26°C, and pH of 6.0 to 8.5. Hou (1958) suggests that this is the only Malayan mangrove which can survive complete daily inundation. Little (1983) describes the habitat as brackish and saline salts of depositing shores and marshes. Of the Asian species this one is most likely to be found in deep soft mud.

Cultivation

According to the NAS (1980a), planting is usually not needed because natural regeneration is so successful. In Avicennia and Rhizophora, direct seeding results in ca 90% survival. Drying the seedlings in the shade a few days before planting seems to make them much less attractive to crabs, perhaps due to a buildup of tannin.

Harvesting

In Tamil Nadu, natural regeneration is abundant and plantations for fuel are managed on 30-year rotations. Clear fellings of Rhizophora may be replaced by Avicennia (Hou, 1958). Species of Rhizophoraceae, growing only from the tips of the branches, are often killed by indiscriminate lopping of branches(NAS, 1980a).

Yields and Economics

Virgin mangrove stands are reported from Mindanao, where there were 149 trees/ha over 25 cm DBH with 130 m^3/ha. Planted forests 40 years old are projected to yield 400 m^3/ha, an average of only 10 m/ha/yr (Hou, 1958). Cannell (1982) cites data on a mangrove forest dominated by Rhizophora, Ceriops, and Sonneratia, averaging 11 m tall, with an LAI (leaf area index) of 3.7–4.2. The stemwood and bark on a DM basis weighed 74.4 MT/ha, the prop roots 61.2 MT/ha, the branches 15.8, the foliage 7.4, the fruits 0.3, for a total standing aerial biomass of 157 MT/ha. The CAI (current annual increment) of stem wood, bark, and branches was 20 MT/ha/yr, foliage 6.7, fruits 0.3. These data, taken from a mangrove on Phuket Island, Thailand, regenerated following clear felling, Suggest annual productivity may attain 20 MT/ha/yr in Asian mangroves.

Energy

Mangrove was the main fuel in the Philippines until World War II (NAS, 1980a). One great advantage in the eyes of firewood dealers is the ease with which, the wood is split. With a calorific value higher than oak, it burns with even heat. Five tons of mangrove firewood is said to equal three tons of Malayan coal, two tons of Indian or Japanese. It makes an excellent charcoal, rather high in sulfur (Burkill, 1966). Wood affords good fuel with high calorific value (4,888 cal, 8,799 Btu) and makes high quality charcoal. In Bangkok, mangrove charcoal, which burns steadily, giving off intense heat without sparking, sells for twice the price of other charcoal (NAS, 1980a).

Biotic Factors

Crabs, great enemies of the seedlings, may damage starting plantations. Browne (1968) lists the following: Crustacea, *Sesarma* spp.; Coleoptera, *Poecilus fallax*; and Mammalia, *Macaca irus*.

Garcinia hombrioniana: A Potential Fruit and an Industrial Crop

Hj. Serudin D.S. Hj. Tinggal*

Southeast Asia is regarded as a major center of origin and evolution of many cultivated crops particularly tropical fruits. A great variety of fruits, some wild, others cultivated are located in Brunei. Species of *Artocarpus*, *Durio*, *Garcinia*, *Mangifera*, *Musa*, and *Nephelium*, to mention only a few, occur as scattered species amidst forest trees or growing alongside homes, in backyards or mixed orchards. These indigenous species together with introduced cultivars represent invaluable genetic resources waiting to be collected, identified, and tested for commercial development.

One of these potential new fruit crops is *Garcinia hombrioniana* Pierre, locally called Assam Aur Aur, a close relative of the mangosteen, *G. mangostana* L. The attractive fruit contains white segmented luscious pulp, sweet with a pleasing fragrance similar to apricot (Fig. 1). The pulp has many uses. The dried crimson rind of the fruit for example, is commercially important and used extensively as sour relish in curries and culinary dishes requiring an acidulous base. Demand for this condiment is seemingly unsatisfiable and at every fruit season, housewives gather the fruits, remove the pulp, and sun-dry the rind (Fig. 2). The market price is attractive and keeping quality for properly dried pulp is good.

BOTANY

Origin

Assam Aur Aur is native to the Brunei Bay region of the states of Sabah and Sarawak of Malaysia and Brunei. The tree probably originated in the rainforests and was cultivated in the coastal and riverine regions to serve the culinary uses of the early settlers. Currently, the distribution is still restricted to the riverine and coastal alluvial regions. Some trees are found in the interior settlements, probably introduced, as coastal and riverine dwellers moved to settle inland. The fruit has never achieved the importance of mangosteen and early explorers and naturalists have largely neglected the small fruit for the larger, sweeter mangosteen.

Morphology

Assam Aur Aur is a handsome evergreen closely resembling the mangosteen in shape and canopy structure, except that Assam Aur Aur has smaller, more elliptical leaves. Mature trees can reach 10 m in height with numerous radially arranged spreading branches. Much of the leaves are held by tertiary branches. Inflorescence are borne on these branchlets in clusters of not more than five small flowers. Very little is known about the morphology of the flowers and owing to the smallness and almost fused structures, the flowers have received very little attention. It is likely that the flowers are hermaphroditic and the few seeds produced apomictic. Seedlings derived from seeds are always identical to the mother plant; there is no known genetic variation. Subtle differences in size (3 to 5 cm in diameter) and shape of fruits could be attributed to environmental influence. The population is generally homogeneous making selection for superior types difficult. However, this homogeneous attribute can be advantageous as fruit and fruit products derived from the fruits are fairly uniform.

HORTICULTURE

Culture

Assam Aur Aur is a tropical species requiring humid conditions of uniform annual rainfall exceeding 2,000 mm and mean temperature of 27°C. The tree shows a wide range of soil adaptability and will grow on damp alluvial soil as well as free draining upland soils. However, the preference is for well-drained fertile alluvial soil where water is not limiting.

Seeds, with the pulp removed, germinate within one week and can be shown direct into plastic bags. Early growth requires protection from full sunlight; 50% shading is recommended and progressively removed to harden the seedlings for field planing when 6 to 8 months old.

There is no commercial planting of Assam Aur Aur to provide cultural recommendations. However, based on observations and experiences, trees grow best at 5 m spacing. Nurse shade between 50 to 60% is essential at planting. Growth is rapid. Prunning of lower branches, weeding, and fertilization will bring the trees to bear after four years. Recommended fertilizers consist of

NPK (12-5-14) to enhance fruiting. Mulching with dry litter will help to retain soil moisture and prevent erosion which appears to be essential for healthy growth of the plant.

As long as the trees are healthy, problems of diseases appear minimal. However, ripe fruits are susceptible to infection by fruit flies (*Dacus* spp) causing damage to the pulp. The rind is unaffected and can still be processed into condiments. Fruit fly damage is more prevalent when few fruits are in season. Spraying with insecticides may reduce the damage, but, generally control of fruit fly is difficult in the tropics.

UTILIZATION

Bruneians, for centuries, have found many uses for the fruits. The young fruits that drop to the ground are collected and sliced into thin pieces or chunks and sun-dried. The final product is a fig brown condiment ready to give the needed tang to Brunei dishes. Currently, there is a limited amount in the market. The mature fruit has multiple uses with a fragrance reminiscent of apricot. Early Bruneians fermented the pulp into organic vinegar. The flavor is distinct, fruity, and strong. In recent years, efforts of the Department of Agriculture have produced suitable cordials and jams from the pulp (Fig. 3). The quality of the cordial is still questionable but the jams have penetrated a limited market. Research is still in progress.

The greatest commercial value of the fruit is the crimson rind. Dried in the sun, the shiny rind turns dull mauve in the process. Packed into small plastic bags, the rind is ready for sale as an essential ingredient for many Brunei dishes. The best condiment exudes some oil when pressed between fingers and quality rind, properly dried, will eventually turn black without being moldy (Fig. 4). Dark colored rind does not affect the culinary quality.

FUTURE PROSPECTS

Assam Aur Aur has tremendous opportunity as a specially fruit. Strong promotional support will strengthen marketing. The research programs of the Department of Agriculture can explore postharvest and handling technology to establish quality and standards. However, it is the inherent quality of fruit that will attract connoisseurs. The strategy is to introduce this fruit into specially markets.

Another area of interest is the acidulous quality of the rind. It is already in great demand. Opportunity exists for more systematic and scientific approach to rind processing, packaging, and marketing. Greater efforts will be required to evaluate value-added products such as jams, juices, and food colors.

---

*There is no known published data on Assam Aur Aur. The information presented has been collected by the author during various field trips to the countryside and discussion with farmers and their families. Officers of the Department of Agriculture provided valuable information on its culture and food processing.

Royse, D.J. 1996. Specialty mushrooms. p. 464-475. In: J. Janick (ed.), Progress in new crops. ASHS Press, Arlington, VA.

Specialty Mushrooms*

Daniel J. Royse

Total mushroom production world-wide has increased more than 10-fold in the last 25 years from about 350,000 t in 1965 to about 4,300,000 t in 1991. The bulk of this increase has occurred during the last 10 years. A considerable shift has occurred in the composite of genera that constitute the mushroom supply. During the 1979 production year, the button mushroom, *Agaricus bisporus*, accounted for over 70% of the world's supply. By 1991, only 37% of world production was *A. bisporus*. Mainland China is the major producer (2,200,000 t--or about 50% of the total) of edible mushrooms. In 1993 to 94, the United States produced 346,188 t (or about 8% of the total world supply) of mushrooms. *Agaricus bisporus* accounted for over 90% of total mushroom production value while *Lentinula*, *Flammulina*, *Pleurotus*, *Hypsizygus*, *Hericium*, *Morchella*, and *Grifola* were the main specialty genera cultivated. The value of the 1993 to 94 specialty mushroom crop in the U.S. amounted to $28.7 million--a 75% increase over the previous season (USDA 1994). Based on recent and historical trends, it is expected that diversification of the mushroom industry will continue in the United States and many other western countries. The development of improved technology to cultivate each species more efficiently, will allow consumer prices to decline.

PRODUCTION TECHNOLOGY

A list of cultivated species and their common English and Japanese names is given in Table 1. Twelve genera comprise the bulk of cultivated mushrooms as outlined below.

Auricularia spp.

Commonly known as wood ear, *Auricularia auricula* is the first recorded cultivated mushroom (Chang 1993). Total production of *Auricularia* spp. in 1991 exceeded 465,000 t (fresh weight; Table 2). This value is an increase of 346,000 t or 290% over 1986 levels (Chang 1993). *Auricularia* spp. production now represents about 11% of the total cultivated mushroom supply world-wide.

Auricularia auricula and *A. polytricha* commonly are produced on a synthetic medium consisting of sawdust, cotton seed hulls, bran, and other cereal grains or on natural logs of broad-leaf trees (Quimio 1982; Chang and Quimio 1982; Oei 1991). For cultivation on natural logs, members of the oak family (Fagaceae) are preferred, but many other species of both hard and softwoods may be used.

For synthetic medium production of Auricularias, the substrate may be composted for up to 5 days or used directly after mixing. In either case, the mixed substrate (about 2.5 kg wet wt) is filled into heat resistant polypropylene bags and sterilized (substrate temperature 121°C) for 60 min. Composted substrate is prepared by mixing and watering ingredients [sawdust (78%) : bran (20%) : $CaCO_3$ (1%) : sucrose (1%)] in a large pile. The pile then is covered with plastic and turned (remixed) twice at two-day intervals. For direct use of substrate, a mixture of cotton seed hulls (93%), wheat bran (5%), sucrose (1%), and $CaCO_3$ (1%) is moistened to about 60% moisture and then filled into polypropylene bags.

After the substrate has cooled, it is inoculated with either grain or sawdust spawn. The spawn then is mixed into the substrate either mechanically or by hand, and the mycelium is allowed to colonize the substrate (spawn run). Temperatures for spawn run are maintained at about 25°C±2°C for about 28 to 30 days. Light intensity of more than 500 lux during the spawn run may result in premature formation of primordia. Temperature, light intensity and relative humidity all interact to influence the nature and quality of the basidocarps.

In Fujian, China a system has been worked out to intercrop *Auricularia* spp. with sugar cane. Bags containing colonized substrate are suspended in mid air on a rope stretched between rows of sugar cane. The bags then are covered with a thin layer of plastic to help regulate relative humidity. Carbon dioxide generated from the growing mycelium apparently stimulates the growth of the sugar cane (Oei 1991).

Flammulina velutipes

Worldwide production of *F. velutipes* (enokitake) has increased from about 100,000 tonnes in 1986 to about 187,000 t in 1991 (an 87% increase). Japan is the main producer of enokitake (Furukawa 1987). In 1986, Japan produced 74,387 t; by 1991, production had risen to 95,123 t. In 1993, Japan produced 103,357 t--an increase of about 8%. From these data, it is evident that a faster growth rate, in terms of total production, is being enjoyed by other countries. In the United States, for example, enokitake production has increased at an estimated rate of 25% or more per year for the last four years.

Production of most enokitake in Japan is based on synthetic substrate contained in polypropylene bottles (Fig. 1). Substrates (primarily sawdust and rice bran; 4 : 1 ratio) are mechanically mixed and filled into heat resistant bottles with a capacity of 800 to 1,000 ml. Sawdust consisting primarily of *Cryptomeria japonica*, *Chamaecyparis obtusa* or aged (9 to 12 months) *Pinus* spp. appears to offer the best yields. In the United States, a bran-supplemented medium, consisting primarily of corn cobs, serves as the primary medium. After filling into bottles, the substrate is sterilized (4 h at 95°C and 1 h at 120°C), mechanically inoculated and incubated at 18° to 20°C for 20 to 25 days. When the substrate is fully colonized, the original inoculum is removed mechanically from the surface of the substrate and the bottles may be placed upside down for a few days. At the time of original inoculum removal, the air temperature is lowered to 10° to 12°C for 10 to 14 days.

To further improve quality during fruiting, temperatures are lowered to 3° to 8°C until harvest. As the mushrooms begin to elongate above the lip of the bottle, a plastic collar is placed around the neck and secured with a Velcroreg. strip. This collar serves to hold the mushrooms in place so that they are long and straight. When the mushrooms are 13 to 14 cm long, the collars are removed and the mushrooms are pulled as a bunch from the substrate. The mushrooms then are vacuum packed and placed into boxes for shipment to market.

Ganoderma lucidum

Known as reishi or mannentake to the Japanese and Ling Zhi to the Chinese, *G. lucidum* is renown for its medicinal properties (for an extensive review see Willard 1990). Reishi often is associated with health and recuperation, longevity, wisdom, and happiness (Stamets 1990, 1993). It is believed that certain triterpenes and polysaccharides may account for the multiple activities of Reshi. Thus, considerable time and effort has gone into the isolation and characterization of these compounds. About 100 triterpenes have been isolated from either the fruitbodies or mycelium but only a few have been tested for bio-activity (Mizuno et al. 1995).

Most cultivation of *G. lucidum* is on supplemented sawdust contained in heat-resistant polypropylene bottles (Fig. 2) or bags. Sawdust of hardwoods is supplemented with rice bran (10%) and $CaCO_3$ (3%), moistened with water and filled (700 g) into plastic bags. A plastic collar then is fitted onto each bag and stoppered with a cotton plug. After heat treatment (95° to 100°C for 5 h) the substrate is allowed to cool overnight and then inoculated with grain or sawdust spawn. The inoculated substrate is then incubated for 3 to 4 weeks or until the spawn has fully colonized the substrate.

Mushroom production is initiated by maintaining air temperature at about 28deg.C with relative humidity in the range of 85% to 90%. Basidiocarps begin to appear in about 1 to 2 weeks after initiation. Approximately 2 to 3 months after the appearance of primordia, mushrooms are ready to harvest. A mushroom is considered mature when the whitish margin around the edge of the basidiocarp has turned red. The substrate may yield another harvest of mushrooms after removal of the first flush.

Grifola frondosa

Japan is the major producer and consumer of *G. frondosa* (Maitake). Commercial production of maitake in Japan (325 t) began in 1981 (Takama et al. 1981). By 1986, production was 2,203 t and, by 1991, production reached 7,950 t (a 261% increase). Japanese production of maitake reached 9,617 t in 1993 (Table 3) and was produced primarily in the provinces of Niigata, Nagano, Gunnma, and Shizuoka.

Commercial production of most *G. frondosa* is on synthetic substrate contained in polypropylene bottles or bags (Fig. 3). A common substrate used for production is composed of sawdust supplemented with rice bran or wheat bran in a 5 : 1 ratio, respectively (Takama et al. 1981). For bottle production, the containers are filled with moistened substrate and sterilized or pasteurized prior to inoculation. Most growers use automated inoculation equipment thereby saving on labor costs. For production in bags, the moistened substrate (2.5 kg) is filled into microfiltered polypropylene bags and sterilized to kill unwanted competitive microorganisms. After cooling (16 to 20 h), the substrate is inoculated and the bags are heat sealed and shaken to uniformly distribute the spawn throughout the substrate. Spawn run lasts about 30 to 60 days depending on strain and substrate formulation. Temperatures then are lowered from about 22° to 14°C to induce fruiting and fruitbody maturation.

Most Maitake is marketed as food. However, Maitake has been shown to have both anti-tumor and anti-viral properties (Jong and Birmingham 1990; Jong et al. 1991; Mizuno and Zhuang 1995). Powdered fruitbodies are used in the production of many health foods such as Maitake tea, whole powder, granules, drinks, and tablets.

Hericium erinaceus

In the wild, *H. erinaceus* occurs on old logs and stumps and on wounds of living trees, especially, maple, beech, oak, and hickory. The fruiting body is formed as a large white mass (5 to 30 cm across) that is toothed in many small tufts. The Chinese were the first to domesticate the fungus and, in 1991, production reached 66,000 t (Table 1). In Japan, the mushroom is cultivated on synthetic substrate in bags and bottles and on logs. It is sold for 1,000 to 1,500 yen per kg ($5.25 to $7.87 per pound).

Polysaccharides in *Hericium* spp. are believed to inhibit a variety of cancers by enhancing the hosts' immune functions (Mizuno 1995b). It also has been suggested that the phenol-analogous compounds hericenone-C, -D, -E, and Y-A-8-c, which induce the synthesis of nerve growth factor, might be effective in treating patients suffering from Alzheimer's disease (Mizuno 1995b).

Hypsizygus marmoreus

Japanese are the main producers and consumers of *H. marmoreus*. Bunashimeji production has increased steadily over the last few years although not as fast as some other types of mushrooms (Royse 1995). In 1986, production of Bunashimeji was 11,439 t in Japan; by 1991 production reached 36,623 t--an increase of 220% (Table 3). Production of *H. marmoreus* increased 38% in the two year period 1991 to 1993.

Bunashimeji usually is produced in polypropylene bottles contained in plastic trays. After the completion of vegetative mycelial growth, bottle lids are removed and the colonized substrate subjected to environmental conditions known to stimulate fruiting. When the mushrooms are mature, the entire cluster of fruiting bodies are removed from the bottles. The mushrooms are packaged by placing an entire cluster (or multiple clusters) into each over-wrapped package. Only one flush of mushrooms is harvested prior to mechanical removal of the "spent" substrate from the bottles. The bottles then are refilled with fresh substrate and the process is repeated.

The antitumor polysaccharide, ß-(1-3)-D-glucan, isolated from *H. marmoreus* showed very high activity (Ikekawa 1995). The water solubility of the polysaccharide was much higher than the same polysaccharide isolated from other fungi. Dried mushroom powder from this mushroom is believed to stimulate the radical-trapping activity of blood (Ikekawa 1995). Excessive free radicals in the blood stream are believed to hasten the aging process.

Lentinula edodes

The cultivation of *L. edodes* (shiitake) first began in China about AD 1100 (Nakamura 1983; Royse et al. 1985; Chang and Miles 1987, 1989). It is believed that shiitake cultivation techniques developed in China were introduced to the Japanese by Chinese growers (Ito 1978).

Cultivation on natural logs. Various species of trees have been used for the cultivation of shiitake

(San Antonio 1981). One of the primary species used in one area of Japan in past years was the shii tree--thus the derivation of the name shii-take (Singer 1961). Most production today, however, is on various species of oak (Harris 1986; Stamets and Chilton 1982).

Natural logs usually are cut in the fall (after leaf drop) and may be inoculated within 15 to 30 days of felling. Trees that are cut in the fall also may be left intact through winter and, just before inoculation, cut into lengths of about one meter. Trees that are cut in the summer tend to have bark that is more loosely bound and sugar contents usually are lowest during this time. If trees are cut during the summer, the bark may strip off more easily, increasing the chances of contamination of the wood by competitive organisms. The most efficient log diameter appears to be in the 7- to 15-cm range (Ito 1978). Logs greater than 25 cm in diameter often are cut in half prior to inoculation (Royse et al. 1985).

Growers who inoculate the logs with wood-piece spawn drill holes in the logs with high speed drills to correspond to the diameter and length of the wood-piece spawn. Enough holes are drilled in the log to provide spacing of about one hole per 500 cm^2. The wood spawn then is driven into the holes with a hammer and then usually covered with hot wax to prevent excessive drying of the spawn. Sawdust spawn sometimes is used instead of wood-piece spawn.

Spawn run may last from 6 to 9 months, depending on the tree species, log size, spawn cultivar, moisture, temperature, and other variables (Leatham 1982). After the spawn run period the logs often are transferred to a "raising" yard. Raising yards usually are cooler and more moist than the spawn run area. The change in conditions provides an optimum environment for the growth and development of mushrooms. In the raising yard, the logs are arranged to provide for convenient harvesting of the mushrooms. Most production occurs in the spring and fall when conditions are most favorable. However, prices received by the growers usually are lowest during these periods.

Growers may use greenhouses for winter production of mushrooms (Przybylowicz and Donoghue 1988). More overall production is possible, and prices for fresh mushrooms are considerably higher, in winter than during the rest of the year. In the greenhouse method, logs usually are soaked in water (usually less than 48 h) and vibrated mechanically for various periods prior to placement in the greenhouse. After the mushrooms are harvested, the logs are incubated further (up to three months) and the process is repeated (up to five times).

Synthetic log production. Sawdust (Fig. 4a) is the most popular basal ingredient used in synthetic formulations of substrate used to produce shiitake (Miller and Jong 1987). Other basal ingredients that may be used include straw and corn cobs or mixtures thereof. Regardless of the main ingredient used, starch-based supplements such as wheat bran, rice bran, millet, rye, corn, etc. are added to the mix in a 10% to 40% ratio (dry wt) to the main ingredient. These supplements serve as nutrients to provide an optimum growing medium (Royse et al. 1990).

Once the proper ratio of ingredients are selected, they are combined in a mixer and water is added to raise the moisture content of the mix to around 60%. On large farms, the mix then is augured to a machine that fills and weighs the substrate so that a uniform amount is filled into each bag (Fig. 4b). The filled bags are stacked on racks, loaded into a industrial-sized autoclave, sterilized for 2 h at 121°C, cooled and inoculated with shiitake spawn.

After a 20- to 25-day spawn run (Fig. 4c) the bags are removed and the substrate blocks are exposed to an environment conducive for browning of the exterior log surfaces. As the browning process nears completion (4 weeks), primordia begin to form about 2 mm under the surface of the log indicating that the log is ready to produce mushrooms.

Primordium maturation is stimulated by soaking the substrate in water (12°C) for 3 to 4 h. Soaking allows water rapidly to displace carbon dioxide contained in air spaces, providing enough moisture for one flush of mushrooms. Approximately 9 to 11 days after soaking, mushrooms are ready to harvest (Fig. 4d).

The main advantages of using synthetic medium over natural logs is time and efficiency. The cycle for synthetic medium cultivation lasts approximately 4 months from time of inoculation to cleanout. Biological efficiencies for this method may average from 75% to 125%. In contrast, the natural log cultivation cycle usually lasts about 6 years with maximum efficiencies around 33%. The time required on synthetic substrate, therefore, only is about 1/15th that of the natural system with about 3 times the yield efficiency. As a result of these developments, shiitake production in the United States has increased dramatically in the last nine years (Fig. 5).

Shiitake is one of the best known and best characterized mushrooms used for medicinal purposes. Several medicinal properties have been attributed to shiitake in recent years. These properties include antitumor polysaccharides activity (Breene 1990; Mizuno 1995a) and glycoproteins, antiviral nucleic acids, platelet agglutination inhibitive substances, and anti-cholesterol active substances (Tokuda et al. 1974; Fujii et al. 1978; Suzuki et al. 1979; Tokuda and Kaneda 1978; Mizuno 1995a).

Morchella esculenta

Morels (Fig. 6) are some of the most highly prized mushrooms found in the wild. Researchers have long sought to consistently cultivate the morel; until recently this was not possible. In 1982, a report describing the successful production of ascocarps of *Morchella esculenta* under laboratory conditions appeared in the literature (Ower 1982). Since that first report, several patents (Ower et al. 1986, 1988) have issued describing a process for the commercial cultivation of these fungi. While patents have revealed some of the processes involved in predictable production of sporocarps, attempts to practice the invention have met only with limited success.

At present, one company in the United States is producing morels on a commercial scale. Commercial cultivation involves the production of sclerotia, an early overwintering stage of the mushroom. "Nutrient primed" sclerotia are produced in soil placed on a layer of sterilized wheat or rye grain. The production of nutrient primed sclerotia requires about 18 to 21 days under optimum conditions. The sclerotia are harvested, soaked in clean water for 24 h and distributed into a thin layer of pasteurized bark/soil mix. The sclerotia germinate via the production of mycelium. After the mycelium has spread throughout the soil mix, a continuous (12 to 36 h) fine mist of clean water is provided to stimulate the formation of ascocarps.

Several problems have yet to be solved in the commercial production of morels. Consistent fruiting, control of competitive weed molds, poor yields, and small mushroom size are just a few of the problems facing successful cultivation. A better understanding of the many factors contributing to increased yields and quality should lower the cost of commercially produced morels to consumers.

Pleurotus spp.

Oyster mushroom production has increased at rapid rate world-wide during the last few years (Table 2). From 1986 to 1991, oyster mushroom production increased from 169,000 t to 917,000 t (442% increase). China was responsible for most of the production increase. In the United States, production of oyster mushrooms was 882 t in 1994, up 94% from the previous year (USDA 1994). *Pleurotus* spp. (*P. ostreatus* and *P. cornucopiae*) production in Japan peaked in 1989 at about 36,000 t. Production was 24,000 t in 1993, a decrease of 33% in four years.

In the United States, the primary ingredients used for *Pleurotus* spp. production is chopped wheat straw or cottonseed hulls or mixtures thereof. For production on wheat straw, the material is milled to a length of about 2- to 6-cm. The pH of the material is adjusted with limestone to about 7.5 or higher to provide selectivity against Trichoderma green mold (Stolzer and Grabbe 1991).

After completion of pasteurization (60°C for 1 to 2 h) the substrate is cooled and spawned with the desired strain. At time of spawning, a delayed release supplement (rates of 3% to 10% of dry substrate wt) may be added to increase yield and size of the mushroom (Royse and Schisler 1987; Royse et al. 1991; Royse and Zaki 1991). Use of supplements, however, may cause overheating of the substrate if growers are not able to anticipate and control air temperatures to maintain a steady substrate temperature.

Production of *Pleurotus* spp. on cotton seed hulls has some advantages over straw-based production systems in that chopping of the hulls is not required (Royse 1995). The pasteurized, supplemented hulls are spawned and filled (12 to 15 kg) into clear or black perforated polyethylene bags and then incubated at 23° to 25°C for 12 to 14 days.

In Japan, bottle production of oyster mushrooms is most common (Fig. 7). Substrate is filled into bottles, sterilized and inoculated with *Pleurotus* spawn. Upon completion of spawn run, bottle lids are removed and mushroom emerge from the surface of the substrate. After the mushrooms are harvested they are weighed and packaged for shipment to market.

Pholiota nameko

Japan produced 21,738 t of *P. nameko* in 1991--an increase of only 1,700 t (8% increase) from 1986 levels (Table 2). World-wide production increases averaged 60% over the same time period. In 1991, Japan produced about 54% of the total world production of nameko compared to 80% of total production in 1986. Thus, production of nameko rapidly is gaining popularity in other Asian countries.

Nameko (Fig. 8) means "viscid mushroom" in Japanese. This mushroom is prized for its gelatinous viscosity and for its flavor and is generally used in miso soup, cooked fresh with grated radish, and steamed in pipkin.

Preparation of the medium for nameko production is similar to that for enokitake except that a higher moisture content of the substrate is desirable. A substrate of broad leaf tree sawdust is preferred but research has shown that sawdusts from conifers such *Pinus* spp. and *Cryptomeria japonica* are suitable for growth. Rice bran usually is added as a supplement in the ratio of 15% for conifer sawdust and 10% for broad-leaf sawdust.

Mushrooms are harvested from the substrate by cutting the stems near the base with scissors. The harvested mushrooms are washed and packed for shipment to market.

Tremella fuciformis

Known as the white jelly fungus or silver ear, *T. fuciformis* has been used as a delicacy food in China for many years. This mushroom can be cultivated on natural logs or on synthetic medium (Quimio et al. 1990). Cultivation techniques used to produce the mushroom on natural logs is similar to that used for shiitake production. In recent years, most production of *T. fuciformis* has been on synthetic substrate using a mixed culture inoculum technique first developed in Fujian, China (Huang 1982).

The mixed culture technique involves the use of "helper" mycelium of *Hypoxylon archeri*, an ascomycete commonly associated in nature with decaying wood. *Hypoxylon archeri* increases the ability of *T. fuciformis* to digest the substrate thereby increasing mushroom yields. Exploitation of this mycelial association is accomplished through use of dual cultures to make mother spawn (Quimio et al. 1990).

Substrate used for mushroom production is the same as that used for spawn production. The supplemented substrate is packed into plastic bags (50 cm long; 9 cm diameter) and ends of the bags are tied with cotton string. Six holes (1 cm diam) then are punched in the filled bags and covered with a breathable fabric. The substrate is sterilized for 6 to 8 h, cooled and inoculated with the mother culture.

After about 30 days of vegetative mycelial growth, the hole covers are removed and the exposed substrate is exposed to conditions favorable for primordia formation (Huang 1982). If optimum conditions are maintained in the growing houses, clusters of jelly fungus should be ready for harvest within 12 to 15 days. Yield for each bag of substrate is in the range of 350 to 500 g fresh weight (35 to 50 g dry weight).

Volvariella spp.

The straw mushroom derives its name from the substrate on which it originally was grown (San Antonio and Fordyce 1972). Cultivation of *Volvariella* was believed to have begun in China as early as 1822 (Chang 1977). In the 1930s, straw mushroom cultivation began in the Philippines, Malaysia, and other Southeast Asian countries (Chang 1982). Production of the straw mushroom increased from 178,000 t in 1986 to about 253,000 t in 1991--a 42% increase. *Volvariella* accounts for approximately 6% of the total world-wide production of edible mushrooms (Table 2).

Many agricultural by-products and waste materials have been used to produce the straw mushroom. These include paddy straw, water hyacinth, oil palm bunch, oil palm pericarp waste, banana leaves and sawdust, cotton waste, and sugarcane waste (Chang 1982; Ho 1985). *Volvariella* is well suited for cultivation in the tropics because of its requirement for higher production temperatures. In addition, the mushroom can be grown on nonpasterized substrate--more desirable for low input agricultural practices.

In recent years, cotton wastes (discarded after sorting in textile mills) have become popular as substrates for straw mushroom production (Chang 1982). Cotton waste give higher and more stable biological efficiencies (30% to 45%), earlier fructification (four days after spawning) and harvesting (first nine days after spawning) than that obtained using straw as a substratum. Semi-industrialization of paddy straw cultivation on cotton-wastes has occurred in Hong Kong, Taiwan, and Indonesia as a result of the introduction of this method (Chang 1979).

MARKETING

Marketing of specialty mushrooms in the United States is a relatively new enterprise. Since 1984, some farms have seen their production rise as prices have fallen. For example, Donovan (1991) indicates that production of shiitake on their farm has increased from slightly less than 1 t per week in 1984 to over 7 t per week in 1990. At the same time, the price has decreased from US $12.50/kg ($5.50 per pound) to about US $ 8.80/kg ($4.00 per pound). In the 1993 to 94 growing season, the price growers received for shiitake was about $8.14/kg ($3.70 per pound; USDA 1994). Over the past seven years (1987 to 1994) the price of shiitake has declined an average of $0.19/kg ($0.09 per pound) per year (USDA 1994).

In recent years, the trend for specialty mushroom sales has been toward the retail market (Gunn 1992; Sorenson 1992). This trend is driven partly by an increased interest in specialty mushrooms and by the convenience packaged products offer to the consumer. In some retail markets, only 10% of the customers buy 90% of the specialty types (Gunn 1992).

Some merchandisers have projected a steady growth in consumption of specialty mushrooms. As consumers become more aware of specialty mushrooms, demand is expected to increase. Aggressive marketing will help to find new markets for these relatively new products. Therefore, specialty mushroom producers seeking new outlets for their mushrooms may want to check sources listing reputable produce industry firms (Anon. 1995a, b).

Specialty mushrooms are sold fresh, dried, or processed in Japan and China. Most fresh shiitake is collected and shipped to central wholesale markets where brokers and other participants buy the mushrooms through a bidding process in Japan (Hara 1988). Mushrooms then are distributed to retailers for consumer purchase. Other mushrooms, such as *Pleurotus*, may be packaged at the farm and shipped directly to brokers or to retailers.

Dried shiitake is distributed through traders specializing in this mushroom (Hara 1988). These traders (about 400 in Japan in 1988; data not available for China) buy shiitake at special bidding markets and then distribute the product to retailers for in country consumption or to trading firms for overseas export. In recent years, however, exports of shiitake from Japan have declined as the number of shiitake producers have declined and shiitake production has decreased (Anon. 1992; Royse 1995). On the other hand, Chinese production of shiitake and exportation of the product to Japan have increased dramatically in the last five years.

FUTURE OUTLOOK

Production and consumption of specialty mushrooms in the United States and other western countries is expected to increase at an accelerated rate in the years to come (Farr 1983; Royse 1995). As production technology is improved through interdisciplinary efforts, the retail price for specialty mushrooms should decrease. As economies improve in Latin America, production of specialty mushrooms could increase at an even faster rate than in the United States. The culinary advantages offered by specialty mushrooms bode well for the continued growth and development of the specialty mushroom industry worldwide.

Table 1. Scientific and English and Japanese names for some cultivated specialty mushrooms.

Scientific Name	English name	Japanese name
Agrocybe cylindracea (DC.: Fr.) Maire	South Popular	Yangimatusutake
Armillaria mellea (Vahl:Far.) Kummer	Chiodini, Honey	Naratake
Auricularia auricula (Hook) Underw.	Black ear, Wood ear	Kikurage
Auricularia polyticha (Mont.) Sacc.	Cloud ear, Tree ear, Wood ear	Angekikurage
Coprinus comatus (Mull.:Fr.) S.F.Gray	Shaggy ink cap, Lawyer's wig	
Cordyceps sinensis (Berk.) Sacc.	Chinese catepillar fungus	
Creolophus pergamenus Karsten	Bear's head	Banshariake
Dictyophora indusiata (Vent.:Pers.) Fisch.	Bamboo sprouts, Collared stinkhorn	
Flammulina velutipes (Curt.:Fr) Karst.	Winter, Velvet stem, Golden, snow puff	Enokitake

Casuarina equisetifolia J.R. & G. Forst.

Syn: *Casuarina litorea* L.
Casuarinaceae
Sheoak, Beefwood, Australian pine, Polynesian ironwood, Horsetail tree

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Extensively cultivated for fuel, erosion control, and as a windbreak. It can be trimmed and used as a hedge. The bark, used for tanning, penetrates the hide quickly, furnishing a fairly plump, pliant, soft leather of pale reddish-brown color. With the neutral sulfite semichemical process, wood yields a good pulp. The wood is used for beams, boatbuilding, electric poles, fences, furniture, gates, house posts, mine props, oars, pavings, pilings, rafters, roofing shingles, tool handles, wagon wheels, and yokes. The needles have been employed in preparing active carbon by the zinc chloride method (C.S.I.R., 1948–1976). Hill tribes of New Guinea use *Casuarina* in rotation to restore nitrogen to the soil. They even use *Casuarina oligodon* as a cover crop for coffee.

Considering its unique ability to grow well, even in highly eroded areas, Aspiras (1981) recommends it for Philippine barren hills and watersheds. "It is not known to deplete the soil of important nutrients unlike other fast-growing species now being grown in the countryside. Aside from its ability to raise the N status of the soil when grown in rotational agriculture or in stabilizing road embankments, it also produces good quality timber of high energy value. It may even be raised as a nurse plant to pine, just like *Myrica*, or planted between coconut trees for its nitrogen and timber." (Aspiras, 1981). In the Philippines, this is recognized as one of the best trees for planting in sites covered by Imperata grass (NAS, 1983e). In Thailand it is planted along coastlines to produce the poles used in building fish traps as well as fuelwood. In the Dominican Republic, it has been used to reclaim stripmine lands. Egyptians plant the trees along the coast to Protect houses from the wind and salt spray.

Folk Medicine

Reported to be astringent, diuretic, ecbolic, emmenagogue, laxative, and tonic, beefwood is a remedy for beri-beri, colic, cough, diarrhea, dysentery, headache, nerves, pimples, sores, sorethroat, stomachache, swellings, and toothache (Duke and Wain, 1981). In Ternate, the seeds are used for passing blood in diarrhea (Burkill, 1966).

Chemistry

Asparagine and glutamine accounted for 92% of the total amino acid in the nodules. The bark contains 10% catchol tannin, the root 15%.

Description

Tall evergreen tree to 30 m, the branches often drooping, sulcate, green, with 6–8 scalelike leaves. Internodes 5–7.5 mm long on the branchlets, only 2.5 mm on main shoots. Main shoots minutely hairy, with small recurved scales ca 2.5 mm long, usually 8 in a whorl. Male spikes usually numerous, terminating the branches on which the female "cones" are borne lower down, cylindric to fusiform 12–24 mm long. Female "cones" subglobose to ellipsoid, 10–20 mm in diameter. Seeds ca 660,000–990,000/kg.

Germplasm

Reported from the Australian Center of Diversity, beefwood, or cvs thereof, is reported to tolerate calcareous soils, drought, granitic soils, poor soil, salt and salt spray, sand, waterlogging, and wind. In Kenya, it grows around cement works, in Hawaii in sterile pumice, in Malaysia on sterile tin tailings, near Hilo Bay on tidal rocks with its roots in salt water (NAS, 1983e). It is sensitive to fire, grazing, and, in early stages, weed competition. Older trees are problems in hurricanes. It is one of the most fire-sensitive of the *Casaurina* species. Subspecies incana is a small tree possibly useful for low growing shelter belts (NAS, 1983e) ($2n = 18$).

Distribution

Said to be indigenous from Indonesia and Malaysia to India and Sri Lanka and to north and northeast Australia, the Australian Pine is now one of the most common trees on frost-free beaches anywhere in the world.

Ecology

Ranging from Subtropical Thorn Woodland to Wet through Tropical Thorn to Wet Forest Life Zone, *Casuarina* is reported to tolerate annual precipitation of 6.4 to 43 dm (mean of 49 cases = 16.0) (but 2–50 possible, NAS, 1983e), annual temperature of 22.1 to 26.9°C (mean of 34 cases = 25.2), and pH of 5.0 to 7.7 (mean of 2 cases = 6.4) (Duke, 1978, 1979).

Cultivation

Seeds have been successfully stored for 24 months at ca -7°C to 2°C with moisture content of 6–16% (Ag. Handbook 450). In Hawaii seeds are broadcast in spring and covered with less than 1 cm soil. Seedling density should be about 21–32/1000 sq cm. Mulching is not required. Normally seedlings are raised in nurseries to outplant taking advantage of the rainy season, 4–18 months after sowing. Irrigation may be needed during dry periods over the first three years. In new areas, seeds have to be inoculated. They should also be treated to repel ants. Cuttings strike root readily. Trees are usually spaced 2–4 m apart. WARNING: *Casuarina* can exhaust the soil moisture, lower the water table, and restrict understory growth, leaving the soil exposed. Some species are agressive weed species. Trees may die young under unfavorable circumstances (C.S.I.R., 1948–1976). According to the National Academy of Sciences, this has become an undesirable weed in Florida (NRC, 1982).

Harvesting

Although other *Casuarinas* coppice readily, this one does not. *Casuarina* plantations are worked under a clear-felling system, with a rotation of 7–35 years. Some estimates showed a long rotation (33 years) gave greatest volume, but a shorter rotation (15 years) is preferred. In Madras State, the plantations are worked with a short rotation of 7–15 years (usually 10 years), while in North Kanara a 30-year rotation is followed. From a purely silvicultural consideration, the proper rotation appears to be 7 years. In parts of the Philippines, this has outgrown *Gmelina arborea* and *Leucaena* (NAS, 1983e).

Yields and Economics

With plants spaced 2 m apart, on a 7–10-year rotation, the trees may yield 75–200 MT wood/ha, i.e. 10–20 MT/ha/yr. Higher yields have been reported. Citing literature yields of 58–229 kg/ha/yr nitrogen, Aspiras (1981) notes that *Casuarina equisetifolia* fixes 1,742 nmoles C_2H_4/24 hrs/g dry weight, compared to 4,479 for *Casuarina rumphiana,* 4,545 for *Casuarina montana*, 2,267 for *Elaeagnus philippensis,* 225 for *Alnus maritima*, 626 for *Alnus hepalensis,* 7,242 for *Coriaria intermedia*, and only 13 for *Myrica javanica.*

Energy

Litter fall from *Casuarina littoralis* is said to run 29 MT/ha/yr. However, in China litterfall from *C. equisetifolia is* 4 MT/ha/yr with a mean annual wood increment of 4–5 m^3/ha (NRC, 1982).

In India:

5 year-old trees averaging ca 22 cm DBH, 6+ m tall yielded ca 14 m^3/ha
10 year-old trees averaging ca 42 cm DBH, 11+ m tall yielded ca 28 m^3/ha
15 year-old trees averaging ca 56 cm DBH, 16+ m tall yielded ca 54 m^3/ha
20 year-old trees averaging ca 70 cm DBH, 24+ m tall yielded ca 94 m^3/ha
25 year-old trees averaging ca 80 cm DBH, 31+ m tall yielded ca 140 m^3/ha
30 year-old trees averaging ca 90 cm DBH, 35 m tall yielded ca 190 m^3/ha
35 year-old trees averaging ca 96 cm DBH, 36+ m tall yielded ca 210m^3/ha
40 year-old trees averaging ca 100 cm DBH, 37+ m tall yielded ca 240 m^3/ha
indicating yields of ca 6 cubic meters per year. *Casuarina equisetifolia* fixes ca 60–230 kg N/ha/yr (Aspiras, 1981). The wood, burning with immense heat, even when green, has been called the best firewood in the world. In India, it is used to fuel locomotives. It makes a good charcoal. In China the wood is used for firing brick kilns. With a specific gravity of 0.8–1.2, the wood has a calorific value of 4,959 kcal/kg (8,910 Btu). The charcoal has a calorific value of 7,181 kcals/kg, one of the highest reported values. The yields of 10–20 MT/ha/yr are roughly equivalent to 25–50 barrels of oil/ha/yr.

Biotic Factors

In Puerto Rico, natural regeneration is rare because ants consume nearly all the seeds; many trees are killed by disease. The Puerto Rican dieback of 1940, followed by stemcanker, has been blamed on *Diplodia natalensis*. Nursery seedlings in India are attacked by crickets (*Brachutripes achatinus*). Other insect pests, e.g., *Arbela tetraonis*, the bark-eating caterpillar, *Celosterna scabrator*, a longicorn, and grubs of the rhinoceros beetle, *Oryctes rhinoceros,* also cause considerable damage to plantations. Infection by the root fungus *Trichosporium vesiculosum* is among the more serious diseases affecting *Casuarina* (favored by excessive watering and congestion). Early thinning checks it to some extent. Trees infected by insects and fungi should be removed and the stumps grubbed up. Keeping an interval of two years between felling and replanting, and planting of other trees such as *Anacardium occidentale, Azadirachta indica, Pithecellobium dulce, Pongamia glabra, Sapindus laurifolius,* and *Syzygium cumini,* along with *Casuarina* are recommended to segregate the plants, minimizing the spread of infection. It also helps attract insectivorous birds which are remarkably scarce in *Casuarina*. A symbiotic fungus *Phomopsis casuarinae* F.Tassi has been recorded in all organs of *Casuarina* (C.S.I.R., 1948–1976). Browne (1968) lists quite a few diseases. Bacteria: *PseudoNonas solanacearum.*

Fungi: *Armillaria mellea, Corticium salmonicolor, Fomes badius, Fomes durissimus, Fomes fastuosus, Fomes senex, Ganoderma lucidum, Macrophomina phaseoli, Phoma casuarinae, Phytophthora cambivora, Poria hypolateritia, Schizophyllum commune, Sclerotium rolfsii, Trichosporum versiculosum, Ustulina deusta, Xylaria hypoxylon.* Nematodes include *Helicotylenchus cavenessi, Radopholus similes, Rotylenchulus reniformis, Tylenchus* sp., *Xiphinema ifacolum.* Angiospermae: *Cuscuta campestris, Dendrophthoe falcata, Dendrophthoe lanosa.* Coleoptera: *Amblyrrhinus poricollis, Anoplophora chinensis, Celosterna scabrator, Ceresium furtivum, Cratopus punctum, Cryptocephalus sehestedti, Doliopygus chapuisi, Doliopygus serratus, Hamartus instabilis, Hypomeces squamosus, Hypothenemus birmanus, Lixus camerunus, Lixus spinimanus, Myllocerus curvicornis, Myllocerus fabricii, Myllocerus sabulosus, Myllocerus undecimpustulatus, Platypus hintzi, Sthenias grisator.* Hemiptera: *Anoplocnemis tristator, Ceroplastes ceriferus, Clastoptera undulata, Delococcus tafoensis, Duplaspidiotus tesseratus, Ferrisia virgata, Halys dentatus, Icerya aegyptiace, Icerya formicarum, Icerya nigroareolata, Icerya purchasi, Icerya seychellarum, Naiacoccus serpentinus, Nipaecoccus vastator, Parthenolecanium persicae.* Isoptera: *Glyptotermes dilatatus, Neotermes greeni, Odontotermes obesus, Odontotermes wallonensis, Postelectrotermes militaris.* Lepidoptera: *Acanthopsyche reimeri, Ascotis selenaria, Eumenodora tetrachorda, Eumeta crameri, E. variegata, Indarbela quadrinotata, Indarbela tetraonis, Labdia xylinaula, Maruca testulalis, Melasina energa, Metarmostis asaphaula, Sahyadrassus malabaricus, Spodoptera litura, S. mauritia, Zeuzera coffeae.* Orthoptera: *Brachytrupes portentosus, Gymnogryllus erythrocephalus, Gymnogryllus humeralis, Schistocerca gregaria.*

Chemical Analysis of Biomass Fuels

Analysing 62 kinds of biomass for heating value, Jenkins and Ebeling (1985) reported a spread of 19.44 to 18.26 MJ/kg, compared to 13.76 for weathered rice straw to 23.28 MJ/kg for prune pits. On a % DM basis, the wh. plant contained 78.94% volatiles, 1.40% ash, 19.66% fixed carbon, 48.61% C, 5.83% H, 43.36% O, 0.59% N, 0.02% S, 0.16% Cl, and undertermined residue.

Euphorbia tirucalli L.

Euphorbiaceae
Petroleum plant, Aveloz, Milk bush

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Probably most familiar as a subtropical and tropical ornamental, aveloz has recently made popular headlines as a potential "cancer cure" and more important, as an energy source. Growing in rather arid zones as well as more mesophytic zones, the species makes a good living fence post. A large shrub, *Euphorbia tirucalli*, is used as a hedge in Brazil. According to Calvin, these plants grow well in dry regions or land that is not suitable for growing food. He estimates that the plants might be capable of producing between 10 and 50 barrels of oil per acre. Cut near the ground, they would be run through a mill like a cane crushing mill, while the plants would regrow from the stumps. Crude obtained from these plants would run $3.00 to $10.00 per barrel. Calvin discussed this concept with Petrobas, the Brazilian national petroleum company, which is investigating. Calvin's most exciting statement, if true, would be a boon to Brazil and the United States. "He estimates, assuming a yield of 40 barrels per acre (100 barrels per hectare) that an area the size of Arizona would be necessary to meet current requirements for gasoline" (in the U.S.). (Science 194: 46, 1976). The latex is toxic to fish and rats. Africans regard the tree as a mosquito repellent. In Ganjium, rice boiled with the latex is used as an avicide. Aqueous wood extracts are antibiotic against *Staphylococcus aureus*. The wood, weighing 34 pounds per cu. ft., is used for rafters, toys, and veneer. The charcoal derived therefrom can be used in gun powder. Since the latex contains rubber, whole plant harvesting seems most advisable from an energy point-of-view (if the tree coppices well) with rubber, petroleum, alcohol as energy products, and resins, which may find use in the linoleum, oil skin, and leather industries. In Brazil, *Euphorbia gymnoclada*, very similar to *tirucalli* (both are called aveloz), is much used for firewood. One cu. m. of wood yields 2 kg latex with the fibrous residue usable for paper pulp.

Folk Medicine

Recently (SPOTLIGHT July 14, 1980) Alec de Montmorency kindled long-sleeping interests in aveloz (*Euphorbia* spp. including *tirucalli*) inferring that it "seems to literally tear cancer tissue apart." Several Brazilian Euphorbias, *E. anomala, E. gymnoclada, E. heterodoxa, E. insulana, E. tirucalli,* known as aveloz, have local notoriety as cancer "cures," and often find their way into the U.S. press as cancer cures. I fear they are more liable to cause than cure cancer. Still the following types of cancer are popularly believed in Brazil to be alleviated by aveloz: cancer, cancroids, epitheliomas, sarcomas, tumors, and warts. Hartwell (1969) mentions *E. tirucalli* as a "folk remedy" for cancers, excrescences, tumors, and warts in such diverse places as Brazil, India, Indonesia, Malabar and Malaya. The rubefacient, vesicant latex is used as an application for asthma, cough, earache, neuralgia, rheumatism, toothache, and warts in India. In small doses it is purgative, but in large doses it is an acrid irritant, and emetic. A decoction of the tender branches as also that of the root is administered in colic and gastralgia. The ashes are applied as caustic to open abscesses. In Tanganyika, the latex is used for sexual impotence (but users should recall "the latex produces so intense a reaction ... as to produce temporary blindness lasting for several days." In Zimbabwe, one African male is said to have died of hemorrhagic gastroenteritis after swallowing the latex to cure sterility.) The root is used as an emetic for snakebite. In Malabar and the Moluccas, the latex is used as an emetic and antisyphilitic. In Malaya, the stems are boiled for fomenting painful places. The pounded stem is applied to scurf and swelling. In the Dutch Indies, pounded stems are used as a poultice for extracting thorns. The root infusion is used for aching bones, a poultice of the root or leaves for nose ulcers and hemorrhoids. The wood decoction is used for leprosy and for paralysis of the hands and feet following childbirth. Javanese use the latex for skin complaints and rub the latex over the skin for bone fractures.

Chemistry

The latex contains 53.8–79.9% water and water solubles and 2.8–3.8% caoutchouc. Fresh latex contains a terpenic alcohol, isoeuphoral ($C_{30}H_{50}O$) identical with euphol from *Euphorbia resinifera*. Dried latex contains no isoeuphorol but a ketone euphorone ($C_{30}H_{48}O$). Taraxasterol ($C_{30}H_{50}O \cdot CH_3OH$) and tirucallol ($C_{30}H_{50}O$) have also been isolated. Resin, however, is the principle constituent (75.8–82.1%) of the dried latex. According to Hager's Handbuch (List and Horhammer, 1969–1979), the stem contains hentriacontene, hentriacontanol, the antitumor steroid β-sitosterol, taraxerin, 3,3'-Di-O-methylellagic acid, ellagic acid, and a glycoside fraction which hydrolyses to give kampferol and glucose, and a ca 0.1% sapogenin acetates. The whole plant contains 7.4% citric acids with some malonic and some bernstein (succinic) acids.

Description

Dioecious, succulent, cactus-like milky tree, devoid of spines, to 10 m tall, the branches often arranged in pseudowhorls. Leaves small, early deciduous, alternate, 1–2.5 cm long, ca 3–4 mm broad, oblanceolate, acute at tip, tapered to the sessile base. Flowers in yellow head, stalkless at the end of twigs.

Germplasm

Reported from the African Center of Diversity, aveloz, or cvs thereof, is reported to tolerate drought, poor soil, sand, and slope.($2n = 20$)

Ecology

Ranging from Tropical Thorn to Moist through Subtropical Thorn to Moist Forest Life Zones, the milkbush is reported to tolerate annual precipitation of 2.5 to 40 dm (mean of 6 cases = 11), and estimated to tolerate annual temperature of 21 to 28°C, and pH of 6 to 8.5. Calvin suggests that it grows well where annual precipitation is 2.5 to 5 dm and where there is no frost. Ive seen it as a cultivar in almost every tropical site I have visited.

Cultivation

According to Melvin Calvin, *Euphorbia tirucalli* "will grow in the same soils sugarcane will grow in, even without irrigation" (Gogerty, 1977). Calvin notes that 5 cm cuttings take readily and increased one-thousand fold in one growing season, attaining more than 50 cm height in the first growing season (Calvin, 1980).

Harvesting

Harvested in 1978, the 5 cm cuttings that grew to more than 50 cm, weighed roughly 2 kg and produced the equivalent of 15 barrels of oil per acre. It could be mowed, or possibly after reaching full size, tapped (Calvin, 1980). For energy purposes, Calvin suggests they be "cut near the ground and run through a crushing mill in much the same fashion as if done with sugarcane... The plants themselves would regrow from the stumps, so replanting might be necessary only once every 20 years or so." (Maugh, 1976).

Yields and Economics

As early as 1941, French scientists (Steinheil, 1941) reported yields of 3 MT oil per hectare from a similar Moroccan species, *Euphorbia resinifera* (10,000 liters latex/ha). In 1976, Calvin "optimistically estimates that the cost of crude hydrocarbons obtained in this manner would be somewhere between $13 and $10 per barrel. The oil furthermore, would be practically free of sulphur and other contaminants." (Maugh, 1976). California associates of Calvin have since projected $150 to $200 per barrel for *Euphorbia* oil. Philip Leakey, from Kenya, claims to be getting 400 MT biomass (fresh weight = 85% moisture) per ha in Kenyan areas with a rainfall of ca 20 inches per year. I can see 60 MT DM in a several year old stand but do not think Dr. Leakey meant to imply that these were annual yields. Leakey claims to be getting, now, 20 MT/ha charcoal from similar plantations, renewably. Such figures, if replicated, should be very encouraging to arid land inhabitants (Philip Leakey, personal communication, September 28, 1981).

Energy

Back in 1976, Melvin Calvin was quoted as saying the plants might be capable of producing 10 and 50 barrels of oil per acre per year (Maugh, 1976). Back in 1977, Melvin Calvin was quoted as saying, "A cultivated field would yield the equivalent of 2 to 20 barrels of crude oil per acre per year, possibly for as little as $3 per barrel. OPEC oil costs three times that much." (Gogerty, 1977). Back in 1979, Calvin was quoted as saying the growth was 1,000 fold when 5 cm cuttings were inserted in the field. Calculations by a Japanese firm, based on plantings in Okinawa, showed the possibility of producing 5–10 barrels of oil per acre per year. Calvin (1980), however, quotes these same sources as 10–20 barrels per acre.

Biotic Factors

Dehgan and Wang describe the plant as having "no natural enemies". Golden (p.c. 1984) notes that *Meloidogyne* may affect the plant.

Avicennia germinans L.

Syn: *Avicennia nitida* Jacq.
Avicenniaceae
Black mangrove

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Information on *Avicennia* species is confused, due to the difficulty, historically at any rate, of distinguishing the species. Regarding the timber useage, Burkill quotes Foxworthy, "altogether it a very unsatisfactory wood—the least useful of the mangrove-swamp woods—and the tree is usually considered as a weed in the swamps." Little (1983) says it is used for crossties, marine construction, piers, posts, utility poles, and wharves. Ashes are added to water as a soap substitute. Bark is used for tanning. Smoke from the wood is said to constitute an effective mosquito smudge (Duke, 1972). Flowers are a major source of honey.

Folk Medicine

According to Hartwell (1967–1971), the resin is used in folk remedies for tumors in the West Indies. Reported to be astringent, insect repellent, rubefacient, and tonic, black mangrove is a folk remedy for diarrhea, dysentery, hemorrhage, hemorrhoids, rheumatism, swellings, throat ailments, tumors, and wounds (Duke and Wain, 1981; Garcia-Barriga, 1975). Salvadorans use the resin for chest complaints and sore throat. Bahamans believe it restores lost vitality (Morton, 1981) and use it in baths for rheumatism. Colombians say gargling with the bark decoction alleviates cancer of the larynx and malignant ulcers of the throat (Garcia-Barriga, 1975).

Chemistry

Per 100 g, the seed is reported to contain 354 calories, 9.8 g H_2O, 5.6 g protein, 0.5 g fat, 81.3 g total carbohydrate, 4.0 g fiber, 2.8 g ash, 207 mg Ca, and 117 mg P. Leaves contain on a zero-moisture basis, 10.7% protein, 4.0% fat, 69.2% total carbohydrate, 23.9% fiber, and 15.7% ash (Duke and Atchley, 1983).

Toxicity

Fruits, though edible after processing, are said to be toxic raw (Little, 1983).

Description

Evergreen shrub or small tree 3–12(-25) m high; trunk 30–60 dm in diameter. Masses of small air roots 15–45 cm long sometimes hang from upper part of large trunks. Pneumatophores often rise 5–10 cm from the long horizontal roots. Bark dark gray or brown and smooth on small trunks, becoming dark brown, fissured, scaly, and thick. Leaves opposite, lanceolate or narrowly elliptical, 5–11 cm long, 2–4 cm wide, acute or blunt at tip, entire, thick, leathery. Fine hairs giving a grayish hue to foliage; both surfaces often with scattered salt crystals and salty taste. Petiole 3–15 mm long. Spikes or panicles headlike, upright at and near ends of twigs. Flowers several, crowded, sessile, 6 mm long, 10 mm across. Calyx cup-shaped, deeply 5-lobed; corolla tubular, hairy, white but yellowish at base, with 4 slightly unequal spreading, rounded, or notched lobes, stamens 4, 5 mm long in notches of corolla tube near base; pistil with imperfectly 4-celled ovary, slender style, and 2-forked stigma. Capsule elliptical, flattened, 2.5–3 cm long, often splitting into 2 parts. Seed 1, large, flattened, often germinating on tree (Little, 1983).

Germplasm

Reported from the Middle and South American Centers of Diversity, black mangrove, or cvs thereof, is reported to tolerate disease, insects, pests, salt, and waterlogging. Seems to tolerate prolonged flooding.

Distribution

Along coasts of tropical America. Atlantic Coast; Bermuda, Bahamas, West Indies, southeastern US, northern Florida, southeastern Texas, northern Mexico southward on Atlantic Coast to Brazil and on Pacific Coast to Ecuador including Galapagos Islands and northwestern Peru. The same or very closely related species on coasts of western Africa. Not widely planted or introduced elsewhere (Little, 1983).

Ecology

Estimated to range from Tropical Dry to Wet through Subtropical Dry to Wet Forest Life Zones, black mangrove is reported to tolerate annual precipitation of 8.7 to 20.6 dm (mean of 4 cases = 14.1) and annual temperature of 25.3 to 26.6°C (mean of 4 cases = 25.9). Common in mangrove swamp forests, mainly on the landward side in brackish water in mud flats of tidal zones of protected silty shores and at the mouths of rivers.

Cultivation

According to the NAS (1980a), planting is usually not needed because natural regeneration is so successful. In Avicennia and Rhizophora, direct seeding result in ca 90% survival.

Harvesting

Since this mangrove can regrow rapidly from buds beneath the bark along the trunk and branches, it is said to suffer little from removal of much of the branchwood (NAS, 1980a).

Yields and Economics

Good mangrove stand can show annual productivity of 10–20(-25) MT/ha/yr, but for firewood purposes, I would reduce that to 10–20(-25) m^3/ha/yr, figuring that at optimal rather than average. Litterfall may account for 1/3– 1/2 of above ground productivity. Because of the heaviness of the wood, a cubic meter of mangrove is generally more valuable than other species.

Energy

Generalizing about the genus *Avicennia*, Burkill (1966) notes that when freshly cut, the heartwood floats, but the sapwood sinks. "It gives indifferent firewood...not liked because it cannot be split. It is used, however, when better is not easily procurable. It burns smoulderingly. The fisher-folk like it for smoking fish, to which it is said to give an agreeable flavor. It is used, also, for smoking rubber" (Burkill, 1966). Still in Latin America the wood is valued "mainly for fuel, charcoal" (Morton, 1981). "Wood used for fuel and charcoal, burning with intense heat" (Little, 1983).

Biotic Factors

No data available.

---

Last update December 29, 1997

Avicennia marina (Forsk.) Vierh.

Avicenniaceae
Grey mangrove

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Heavy even-textured wood used for poles and ribs of boats. Bark yields a brown dye. Leaves are used for camel fodder around the Red Sea. Branches are lopped and fed to cattle in India and Australia.

Folk Medicine

According to Lewis and Elvin-Lewis (1977), the tree possesses a bitter aromatic juice, used as an abortive in tropical Africa and Asia. Root and bark are used as aphrodisiac, the wood for snakebite, the aqueous extract of the seed for sores. Unripe fruits are poulticed onto wounds and leaves onto skin ailments (List and Horhammer, 1969–1979).

Chemistry

Bark and roots contain tannin, the bark with lapachol ($C_{15}H_{14}O_3$) the compound supposedly responsible for the overblown virtues of "lapacho" (*Tabebuia* spp. from Brazil).

Toxicity

Lapachol is an allergic sensitizer.

Description

Evergreen shrub or small tree 1–10 m high, trunk to 40 cm in diameter. Numerous upright pneumatophores 10–15 cm high and 6 mm in diameter. Trunk often with masses of small air roots but no prop or stilt roots. Bark whitish to grayish or yellow-green, smooth, often powdery with raised dots, scaly, exposing greenish inner bark. Leaves opposite, ovate, lanceolate to elliptical, 3.5–12 cm long, 1.5–5 cm wide, mostly acute at both ends, entire, thick leathery, shiny green and hairless upper surface, pale whitish-gray and finely hairy underneath. Petiole 5–10 mm long, hairy. Heads or cymes ball-like, upright on long stalks at ends and sides of twigs. Flowers few to many, sessile, 4 mm long, 5 mm across. Calyx 5-lobed, green, hairy, persistent; corolla tubular, white.turning yellow or orange with 4 nearly equal, short lobes (Little, 1983).

Germplasm

Reported from the African, Australian, Indonesian-Indochina Centers of Diversity, grey mangrove, or cvs thereof, is reported to tolerate disease,insects, light frost, pests, salt waterlogging (NAS, 1980a; Little, 1983). Little mentions five varieties, differing in leaf, flower, and geography.

Distribution

Coasts of East and South Africa, southern Asia, Australia, and Oceania. From Egypt and Arabia along shores of Red Sea and western Indian Ocean, eastward along shores of Arabian Sea, Bay of Bengal, southeastern and eastern Indian Ocean, South China Sea north to Hong Kong and Taiwan, and islands of the Philippine Sea, Coral Sea, and South Pacific to Western Australia and New Zealand. Not widely introduced (Little, 1983).

Ecology

Estimated to range from Tropical Moist to Wet through Subtropical Moist to Wet Forest Life Zones, grey mangrove is estimated to tolerate annual precipitation of 10 to 45 dm, annual temperature of 17 to 26°C, and pH of 6 to 8.5. Often a pioneer in muddy areas, this species, intolerant of shade, cannot succeed itself. Mostly on saline silts of depositing shores and marshes (Little, 1983).

Cultivation

According to the NAS (1980a), planting is usually not needed because natural regeneration is so successful. In *Avicennia* and *Rhizophora*, direct seeding results in ca 90% survival.

Harvesting

Since this mangrove can regrow rapidly from buds beneath the bark along the trunk and branches, it is said to suffer little from removal of much of the branchwood (NAS, 1980a).

Yields and Economics

This small tree could not be quite so productive as other mangroves, though I estimate 10 MT/ha year is possible.

Energy

Used for firewood and fuel for lime kilns.

Biotic Factors

No data uncovered.

Last update December 30, 1997

Avicennia officinalis L.

Avicenniaceae
Indian mangrove

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

The wood, used to construct boats, houses, and wharves has been studied as a pulp source, and the bark and roots are used for tanning. The bark is used for dying cloth, the ash for washing it in India (Watt and Breyer-Brandwijk 1962). Javanese and others may consume the bitter fruits and seeds after rather elaborate processing. Branches are lopped and given to cattle for fodder. The wood has been recommended for creosoted paving blocks. Its wood is attractive enough of grain to be useful in cabinetry.

Folk Medicine

According to Hartwell (1967–1971), the fruits are plastered onto tumors in India. Indian mangrove is a folk remedy for boils and tumors (Duke and Wain, 1981). Kirtikar and Basu (1975) suggest that the roots are aphrodisiac. Unripe seeds are poulticed onto abscesses, boils, and smallpox sores.

Indochinese use the bark for skin afflictions, especially scabies. According to Perry (1980), quoting other sources, "A resinous substance exuded from the bark acts as a contraceptive, and apparently can be taken all year long without ill effects. Philippines use the seed for ulcers, the resin for snakebite."

Chemistry

Tanganyikan wood specimens (zero moisture basis) contained 54.7% cellulose, 2.3% ash (C.S.I.R., 1948–1976). The wood ash is said to be rich in alkali. A green, bitter, medicinal resin oozes from the bark. Bark contains tannin and lapachol (Perry, 1980), but the tannin content may be only 2.5% (C.S.I.R., 1948–1976).

Description

Evergreen tree, sometimes to 25 m, trunk to 1 m in diameter. Numerous upright pneumatophores rise above soil from long shallow, horizontal roots. Bark brownish-gray, thin, becoming rough and blackish, or outer bark yellowish-green and inner bark whitish. Leaves opposite obovate or broadly oblong, 4–12 cm long, 2–6 cm wide, rounded at tip, acute or rounded at base, thick, leathery, edges slightly rolled under, upper surfaces shiny green and hairless, underneath with fine gray-green hairs and resin dots. Cymes headlike in panicles, upright near ends of twigs, to 15 cm long and wide. Flowers many 2–12 together, sessile, malodorous, 7–10 mm long, 12–15 mm across. Calyx 5-lobed, hairy on edges, with resin dots; corolla bell-shaped, tubular, yellow or yellow-brown, turning orange, with 4 unequal spreading lobes, stamens 4, inserted in notches of corolla tube; ovary conical, hairy, imperfectly 4-celled with 4 ovules, style threadlike; stigma 2-forked. Capsule broadly ovoid, flattened, 2.5 cm long. Seed 1, large, flattened, without seed coat, germinating in water (Little, 1983).

Germplasm

Reported from the African, Australian, Hindustani, and Indonesian-Indochina Centers of Diversity, Indian mangrove, or cvs thereof, is reported to tolerate alkali, disease, insects, high pH, pest, salt, and waterlogging (NAS, 1980a; Little, 1983).

Distribution

Coasts of southern Asia to Australia and Oceania. From East Pakistan, Tanasserim, Andaman Islands, and Sri Lanka through coasts of Vietnam, Thailand, and Peninsular Malaysia to the Philippines, Sumatra, Madura, Java, Borneo, Celebes, Sunda Islands, Molucca Islands, and New Guinea; south in Australia to New South Wales. Near sea level, to 50 m in Papua. Not widely introduced elsewhere (Little, 1983).

Ecology

Estimated to range from Tropical Moist to Wet through Subtropical Moist to Wet Forest Life Zones, Indian mangrove is estimated to tolerate annual precipitation of 10 to 45 dm, annual temperature of 20 to 26°C, and pH of 6 to 8.5. Mostly on brackish or saline silts of depositing shores and marshes.

Cultivation

According to the NAS (1980a), planting is usually not needed because natural regeneration is so successful. In *Avicennia* and *Rhizophora* direct seeding result in ca 90% survival.

Harvesting

Since this mangrove can regrow rapidly from buds beneath the bark along the trunk and branches, it is said to suffer little from removal of much of the branchwood (NAS, 1980a).

Yields and Economics

Good mangrove stands can show annual productivity of 10–20(-25) MT/ha/yr, but for firewood purposes, I would reduce that to 10–20(-25) m^3/ha/yr, figuring that at optimal rather than average. Because of the heaviness of the wood, a cubic meter of mangrove is generally more valuable than other species. Litterfall may account for 1/3–1/2 of aboveground productivity.

Energy

Brittle wood used for firewood.

Avocado oil

Lauraceae *Persea americana* Mill.

Source: Magness et al. 1971

The edible pulp of the avocado, which surrounds the seed, contains from 8 to 30% of a non-drying oil. Oil is separated by dehydrating the pulp, then pressing or extracting with solvents. The oil is used in cosmetics, and to some extent in salad dressings.

Halevy, A.H. 1999. Ornamentals: Where diversity is king—the Israeli experience. p. 404–406. In: J. Janick (ed.), Perspectives on new crops and new uses. ASHS Press, Alexandria, VA.

Ornamentals: Where Diversity is King—the Israeli Experience

Abraham H. Halevy

In the increasingly competitive international cut flower and pot-plant market, novelty of crops plays an important role in maintaining and expanding market share. The ornamental industry is unique among the agricultural industries in that novelty is an important attribute. Customers always seek "something new." Although the standard major ornamental crops will continue to constitute an important part of the market, a distinct trend towards increasing the share of "new crops" is clearly evident in recent years. These new products normally fetch higher prices than the traditional crops for a certain period, but quite often the prices drop when the market is saturated, and the attraction novelty lessens. By that time new products should be ready to enter the market. Research on introduction of new ornamental crops is therefore an endless project.

The floriculture industry in Israel is relatively new. Until about 30 years ago cut flowers and pot-plants were only produced on low-scale for the limited domestic market. In recent years ornamental plants became a major agricultural exportable product of over 250 million US$ per annum. Israel is now second only to Holland in flower export in Europe.

Initially Israel produced and exported mainly the major traditional cut flowers, such as carnations, roses, and gladiolus. Gradually the share of these crops declined and those of new minor crops increased, so that the "new crops" now constitute over 60% of the exportable cut flowers (Fig. 1). None of these "new crops" has become a major crop as roses or carnations, but together they are and will certainly continue to be the major part of our exportable ornamental products.

Introduction of new crops includes many research stages that begins with the initial search and screening and is concluded when the product is introduced commercially.

The introduction and adaptation of new exportable crops normally includes the following stages:

1. Searching for optional crops.
2. Selection and improvement.
3. Developing propagation methods.
4. Studying the growth and flowering physiology and developing practical means for their control.
5. Evaluation of horticultural practices.
6. Studying postharvest physiology and developing practical methods for postharvest handling, transport, and storage.
7. Semi-commercial export shipments to markets abroad.

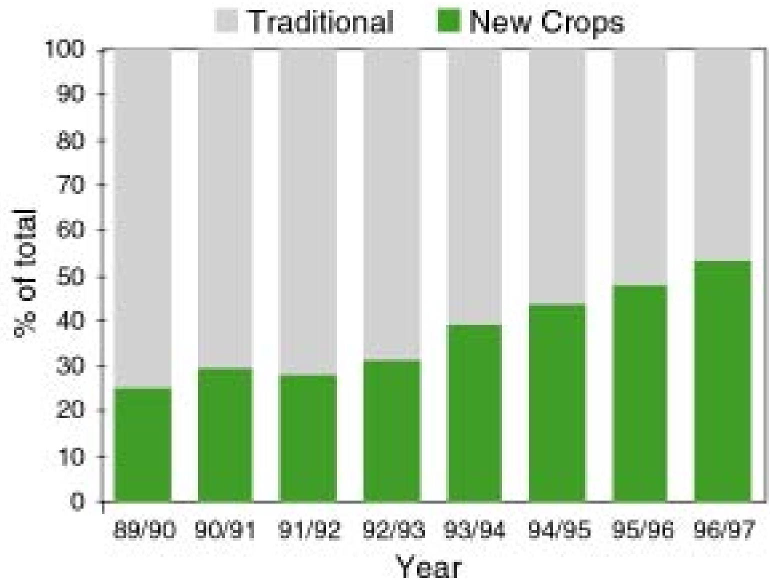

Fig. 1. Relative percentage of "traditional" and "new" cut flowers exported from Israel from 1989/90 to 1996/67.

Some important cut flowers (in European markets), which we introduced and developed in Israel, were "new crops" about 25 years ago such as Gypsophila and Geraldton wax flower. The development of these and other crops are described in the following examples of successful introduction projects.

GYPSOPHILA (BABY'S BREATH)

Gypsophila (*Gypsophila paniculata* L., Caryophyllaceae) is really not a new crop. It has been cultivated for many years as a minor field crop for harvesting in the natural summer flowering season. Today, Gypsophila is a major cut flower in Israel, grown in over 200 ha of greenhouses for the autumn to spring export season. It is now the main flowering shoot used as a "filler" in flower arrangements, in both Europe and the US.

The introduction and development of this crop involved many aspects (Shillo and Halevy 1982; Shillo 1985b; Shillo et al. 1985).

1. Selection of superior clones for controlled cultivation.
2. Development of in vitro meristem culture method to obtain disease-free mother plants.
3. Propagation of clean, uniform commercial cuttings in controlled insect-free greenhouses.
4. Study the physiology of flowering and development of practical methods to control flowering. It was found that Gypsophila is an absolute long day plant, with quantitative response to vernalization. The methods developed to control flowering include cold storage of rooted cuttings prior to planting and supplementary night illumination. Spraying with gibberellic acid is also used to promote flower and shoot breaking and elongation.
5. Development of specific cultivation methods, such as pruning, watering, and feeding.
6. Study the postharvest physiology of the flower and development of methods for postharvest treatment of the flowers prior to shipment, to ensure their longevity and quality. When 15% to 30% of the florets are open, flowering shoots are harvested, treated with silver thiosulfate

(STS) to protect them from internal and external ethylene, followed by pulsing the flowers in sugar (7% to 10%) and germicides until about 2/3 of the florets are open.

The flowers of commercial *G. paniculata* plants are sterile and do not produce seeds. This prevented real breeding of this plant. Recently this obstacle was overcome and real new varieties were introduced by Dan Nursery in Israel. A major success is the cultivar Million Stars that was introduced last year, and is already grown this year on over 40 ha in Israel and over 100 ha worldwide.

GERALDTON WAX-FLOWER

Geraldton wax-flower (*Chamaelaucium uncinatum* Schauer, Myrtaceae) is a native shrub in Western Australia. It was introduced to southern California and grown outdoors as a minor cut flower. Most of the initial physiological and horticultural research was carried out in Israel, a fact that facilitated the rapid development of the plant as an important commercial crop (Shillo 1985a; Shillo et al. 1985; Halevy 1994). More recently important research is also conducted in its native country, Australia. In Israel this plant is currently a major commercial ornamental crop, grown on ca. 300 ha. It is used mainly for cut flower production, but also for cut shoots with flower buds, cut foliage, and flowering pot plants. Israel became the main exporter of wax flowers to Europe in the winter.

Plant material of native plants in Australia, as well as breeding, enabled the establishment of a wide assortment of various plant colors (pink, purple, white, lilac, and bicolors), which bloom from November to May. The selected plants are propagated by semi-woody vegetative cuttings in order to form uniform varieties. Recently, virus-free mother plants have been produced by meristem in vitro culture.

Studies on the physiology of flowering revealed that the wax flower is an absolute short-day plant under conditions of mild temperatures. At very high and very low temperatures no flowers are produced. At medium-low temperature some flowers are formed regardless of photoperiod. To advance flowering in the autumn, plants of several cultivars are covered in the field at the end of the summer to create artificial short days. An interesting physiological phenomenon, revealed for the first time in this plant, was that the young flower buds produce a factor that inhibits the formation of new flowers, even under inductive conditions (Shillo et al. 1984).

For production of flowering pot plants, plants are heavily pruned to promote branching and then treated with growth retardants (CCC or paclobutrazol). Controlled photoperiod is employed to extend the flowering period.

Abscission of individual flowers during shipment and handling is a problem of the cut flowering shoots. This problem can be ameliorated by dipping the cut flowering shoots in auxin (NAA) solution and hydrating them in cold water.

PEONY

Peony (*Paeonia lactiflora* Pall., Paeoniaceae) has been in cultivation in China for thousands of years, and have been grown as garden and outdoor cut flower plants in Europe and the US for many years. Cut flowers were, however, available only for a few weeks a year during the natural flowering season in late spring. Until recently, however, very little was known on the flowering physiology of the plant. We have found that flower bud initiation starts after the old leaves senescence in the summer and continues until late autumn when they become dormant. Release from dormancy requires a period of low temperatures, and can be accelerated by GA treatment. After the release from dormancy the plants may start growing and blooming under mild-warm temperatures (Wilkins and Halevy 1985; Byrne and Halevy 1986). This basic information enabled the development of a practical method for extending the flowering season and obtaining cut flower production in the winter, 2–3 months before the natural flowering season (Halevy et al. 1995). Plants are grown under ambient natural cold temperatures of the early winter. After sufficient cold units are accumulated, the structures are covered with polyethylene at mid-winter and the plants are drenched with GA solution. Sprouting and flowering soon follow.

The introduction and improvement of this "new crop" is actually developing new horticultural techniques for flowering control of a very old ornamental plant. One of the obstacles of rapid development of peony as a commercial crop is the slow rate of natural propagation by division of crowns. We are now developing a tissue culture propagation method that should solve this problem.

Rambai

Baccaurea motleyana Hook. f.

A fruit somewhat resembling the **langsat** (q.v.) but belonging to a different family, Euphorbiaceae, is the rambai, *Baccaurea motleyana* Hook. f., called *rambi* in the Philippines, *mai-fai-farang* in Thailand.

Description

The slow-growing tree, ordinarily to 30 or 40 ft (9-12 m), occasionally up to 60 ft (18 m), has a short, thick trunk, broad, dense, rounded crown and silky-hairy new branchlets. The leaves are evergreen, spiralled, 6 to 13 in (15-33 cm) long, 3 to 6 in (7.5-15 cm) wide; dark-green, glossy, with conspicuously indented veins on the upper surface; greenish-brown and hairy below. The small, fragrant male and female flowers are borne on separate trees. They are petalless, with 4 to 6 chartreuse, velvety sepals, the female arranged in racernes 10 to 30 in (25-75 cm) long; the male in racemes 3 to 6 in (7.5-15 cm) long. The fruits, in showy strands dangling from the older branches and trunk, are oval, 1 to 1 3/4 in (2.5-4.5 cm) long and 1 in (2.5 cm) thick, with thin, salmon-colored or brownish-yellow, velvety skin becoming wrinkled after ripening. The translucent, white, sweet-to-acid pulp is in 3 to 5 segments which separate readily, each segment containing a brown, flat seed about 1/2 in (1.25 cm) long, adherent to the pulp.

The rambai is native and commonly cultivated in the lowlands of Malaya, grows wild in Bangha and Borneo and is occasionally cultivated in Java. It is valued for its shade as well as its fruits, which are eaten raw, stewed or made into jam or wine.

The wood is of low quality but used for posts. The bark serves as a mordant for dyes and is employed to relieve eye inflammation.

The very similar *kapoendoeng*, *B. racemosa* Muell. Arg., native to West, Central and East Java, is commonly cultivated and is budded onto its own rootstocks or those of *B. motleyana*.

A lesser-known species, the so-called Burmese grape, *B. sapida* Muell.-Art., called *tempui* in Malaya, *lutqua* in India, and *mai fai* in Thailand, grows to 30 or even 70 ft (9-21 m). The leaves are rarely, and then only slightly, hairy; the fruit, in strands 6 to 12 in (15-30 cm) long, is smooth, nearly round or oval, 1 to 1 1/4 in (2.5-3.2 cm) long. The skin turns from ivory to yellowish or pinkish-buff or sometimes bright-red. The pulp is not translucent; is whitish, occasionally deep-pink near the seeds; varies from acid to sweet.

The tree grows wild from southern China, Thailand and Cambodia to Malacca and it is occasionally cultivated in northern Malaya and Thailand.

B. dulcis Muell.-Arg., the *tjoepa*, *toepa* or *ketoepa* of southern Sumatra, has relatively large, sweet fruits which are abundant on local markets. It is sometimes cultivated in West Java.

Bactris gasipaes Kunth

syn: *Guilielma gasipaes*

Arecaceae (Palmae)

Pejibaye, Peach palm

South American Fruits Deserving Further Attention

Richard J. Campbell

Considerable attention has been given in recent years to fruits with potential for further economic development (Clement 1983; Donadio 1983; Arkcoll 1990; Ferguson and Arpaia 1990; Lamberts and Crane 1990; Nerd et al. 1990; Campbell 1990; Silva 1991; Crane 1993). South America has been the focus of many of these previous studies due to the sheer number of edible fruit crops originating on the continent, which is considered an important center of diversity for fruit crops. Our study takes another look at South American fruit crops with potential for further economic development, emphasizing fruit crops not previously discussed in recent studies. Discussions for each individual fruit are preceded by a general overview of the family to which each fruit belongs, highlighting the characteristics of the family and some of its commercial members. The fruit crops discussed include crops presently grown on a limited commercial scale, as well as minor fruit which at present are of importance only on a subsistence level within their native range.

SPECIFIC FRUIT CROPS

Anacardiaceae

This family consists of 850 species, including fruit crops of great economic importance throughout the tropical and subtropical regions of the world. The mango, *Mangifera indica* L. (Asia) and the cashew, *Anacardium occidentale* L. (South America) are produced in most tropical and subtropical countries. Another genus, *Spondias*, consisting of 8 to 10 fruit species of American and Asian origin (Popenoe 1979) is also prevalent throughout the tropics. *Spondias purpurea* L. and *Spondias cytherea* Sonn. are both commercial fruit crops in the American and Asian tropics. Other *Spondias* species native to South America are of great local importance as subsistence crops.

Spondias tuberosa Arruda. Umbú. The umbú is native to the dry plains of northeastern Brazil. This fruit has been described as perhaps the best flavored among all of the *Spondias* species by Popenoe (1920). The tree can attain a height of 6 m, although it usually forms a low, spreading tree when left unmanaged (Martin et al. 1987). Fruit are oval, averaging 4 cm in length, with a 2 cm stone. When fully ripe the flesh is almost liquid, with a sweet, aromatic flavor. The fruit are sour if eaten before they are fully ripe. In its native region the umbú is consumed fresh, used in preserves, made into juices, or sweetened and mixed with milk to make "imbuzada," a typical drink of the region. Popenoe (1920) discussed the importance of this fruit to the people of northeastern Brazil, who consumed vast numbers of umbú during the fruiting season. The same can be said in the region today, as wild umbú trees are protected and visited by local residents while the trees are fruiting.

The umbú offers potential for arid tropical regions due to its production in the harshest of conditions. Annual production has been up to 300 kg/tree with good selections (Cavalcanti and Abilio de Queiroz 1992). There has been limited work on the identification and selection of superior clones of umbú; however, within Brazil clones have been identified which weigh nearly 90 g and have a pulp to seed ratio of 80% (Cavalcanti and Abilio de Queiroz 1992). Popenoe (1920) questioned why the umbú had not yet attained a greater status in the world due to its superior flavor, and today the same sentiment is commonly expressed. However, due to its short shelf life and delicate texture when mature, it is doubtful that the umbú could be a viable consideration as a fresh fruit beyond the local level. However, as a flavoring and/or juice crop for the arid, hot tropics, the potential is much greater.

Little is known about its adaptability to different climates. Young trees have been killed by freezes in the state of Sao Paulo, Brazil (Donadio 1983) and in Florida (Campbell et al. 1977). The growth of seedling umbú trees in the calcareous soils of South Florida has also been poor (Campbell and Sauls 1980). Umbú is graft compatible with other *Spondias* species (Popenoe 1920), possibly widening its adaptation to other climates and soil conditions.

Spondias mombin L. Yellow mombin. The yellow mombin is native to Central America and northern South America (Popenoe 1979) and can be found under semi-wild cultivation in most lowland areas of the American Tropics. The tree can attain a height of 10 m and is tolerant of most soil types and rainfall patterns. The fruit are ellipsoid about 2.5 to 4 cm in length and hang singly on the tree (Martin et al. 1977). There is great variation in quality among fruit from region to region, some being sweet and pleasant and others quite disagreeable in flavor (Martin et al. 1977;

Popenoe 1920). The fruit can be eaten fresh, used in preserves or as a flavoring. Although common in most of the lowland tropics, the yellow mombin has not been highly commercialized. It is generally considered inferior in quality to *S. purpurea*, which is grown in the same environments. Yellow mombin has been introduced to most tropical locations and performs well under varied conditions. Trees are severely damaged by freezing temperatures (Campbell et al. 1977). Trees are generally grown from vegetative cuttings, but patch budding has been used as well (Coelho Pedrosa et al. 1991). The fruit are consumed fresh on a local level; however, its potential is more as a processed fruit. It offers an adaptive advantage over other species of *Spondias* in some climates and soil types.

Annonaceae

This family is comprised of 2,050 species, many of which are cultivated for their fruit, both on a commercial and subsistence level (Leon 1987). The cherimoya (*Annona cherimola* Miller), guanabana (*A. muricata* L.), sugar apple (*A. squamosa* L.) and atemoya (*A. cherimola* x *A. squamosa*) are the major commercial members of the family in tropical and subtropical regions. Due to their unique appearance and flavor, many other members of this family from Central and South America have potential for further commercialization.

Rollinia deliciosa A. DC. Biribá. The biribá is native to northern South America and the Caribbean (Leon 1987). The tree is small, usually reaching a height of 6 to 10 m, with a dense, multiple-branched growth habit. Biribá is one of the most common home garden trees in the state of Para, Brazil (Clement 1983), where there is also limited commercial production (Cavalcante 1974). Biribá fruit from this region can sometimes be found in markets as far away as Rio de Janeiro. The fruit are globose and can weigh up to 1350 g (Cavalcante 1974). The mature fruit is yellow with multiple protuberances, which turn black as the fruit are handled. The flesh is translucent, juicy, and sweet with a somewhat mucilaginous consistency, which is objectionable to many. It is usually consumed fresh, but it is also used as a juice, a preserve, or a flavoring. Within its native region it is considered to be of the highest quality among the Annonaceae. Outside of northern Brazil, however, the biribá is much less common and not as highly esteemed. It can be found in germplasm collections throughout the lowland tropics, but the fruit encountered are generally of inferior-quality seedlings.

Production of biribá is limited to the hot, humid lowland tropics. Temperatures of -1° to -2°C can kill young trees (Campbell et al. 1977). The trees grow quickly and bear fruit from seed in 4 to 6 years. There is great variation in fruit quality among seedling trees. Biribá trees produce well without hand pollination, which is an advantage over many other Annonaceae. In order to increase the commercialization of the biribá, superior cultivars would need to be identified and selected. Research would also be required on storage, shipping, and handling procedures.

Caricaceae

In terms of fruit production, the Caricaceae is a small (31 species), yet important family throughout both the American and Asian tropics (Badillo 1993). The most widely known member of the family is the papaya (*Carica papaya* L.), which is cultivated commercially throughout most of the lowland tropics. There are, however, other species currently produced on a limited commercial scale in the South American highlands which have potential for greater exploitation, both within their present production areas and beyond.

Carica pubescens (A. DC.) Solms-Laub. Chamburo. This fruit is native to northern South America and is cultivated from Panama to Bolivia at elevations above 1,000 m. The plants often attain a height of more than 10 m and have a similar appearance to papaya. They can be distinguished by their variable leaf shape and pubescence, which covers the leaves and flowers. The fruit are from 5 to 20 cm in length, turning yellow or orange at maturity. The flesh is yellow and tart, even when fully ripe. Trees are grown from seed, and there are no widely recognized superior selections. The fruit are usually not consumed fresh; instead, they are processed into juices or preserved. Thinly-sliced chamburo flesh is preserved in sugar solutions and eaten as an accent at meals (e.g. with cheese) or used in cooking. Lizana et al. (1978) conducted experiments with the production of dehydrated slices of chamburo as a potential new product in Chile.

Carica xheilbornii var. *pentagona* Heilborn. Babaco. The babaco is a sterile hybrid between *C. pubescens* and *C. stipulata*. It is cultivated mostly in Ecuador at elevations above 1,000 m. The fruit range in diameter from 6 to 12 cm and can reach a length of 30 cm. The plants are precocious in cultivation and usually remain less than 4 m in height. The pulp is white, and like the chamburo is tart when ripe. Babaco is important locally as a juice or preserve and is extensively used in cooking. For commercial production, cuttings are used, as no seed are available due to sterility of the clone. There are only a few recognized cultivars of babaco and these selections are not widely distributed. Annual production at elevations of 1,500 to 2,000 m is up to 46 t/ha, with production beginning 10 months after planting (Camacho and Rodriquez 1982).

Throughout the highlands of South America, products made from chamburo and babaco are readily available in markets. Also, local residents use these fruit in all forms of cooking. Babaco has been tested as a commercial fresh fruit throughout the American tropics and in New Zealand, but consumer acceptance has been poor. The preserved products made from both fruit have a mild, widely acceptable flavor. If these two fruit are to significantly expand in production, these processed products will need to be successfully marketed; however, some competition can be expected from similar, readily available products such as green papaya preserves. However, given the precocity and heavy production of these fruit at elevations above 1,000 m, they remain candidates for further development in the highland tropics. Also, these two fruit are resistant to the papaya ringspot virus, a major limiting factor for papaya production in the tropics. The chamburo has been investigated as a potential source of resistant genes for imparting virus resistance to papaya (Moore and Litz 1984).

Chrysobalanaceae

This family has over 460 species, but few among them yield edible fruit. The icaco (*Chrysobalanus icaco* L.) is perhaps the most widely grown, with subsistence production throughout the lowland tropics, particularly in coastal regions.

Licania platypus Fritsch. Sunsapote. The sunsapote is native throughout the moist lowlands of Central America and northern South America. It forms a large tree up to 30 m and is usually found in secondary forests under semi-wild cultivation, or in small plantings of a few individual trees. The trees produce 1 to 5 large, oblong fruit per panicle that range from 10 to 15 cm in diameter and 15 to 20 cm in length, and weigh up to 900 g (Leon 1987; Martin et al. 1977). The fruit has a fibrous skin that is easily removed. The pulp is dry and sweet. The seed is large in most clones, often with fibers that protrude into the flesh. The fruit are generally consumed fresh, but can also be used as a flavoring. The fruit are highly esteemed in localized areas of Central and South America, but in northern Brazil, they are not preferred (Cavalcante 1974).

Trees are grown from seed and can require up to 10 years to come into production. There have been only limited trials of this fruit in orchard conditions within the lowland tropics. Trees grew well in Florida until damaged by freezing temperatures (Campbell et al. 1977). Fruit quality within the markets of Central and South America is highly variable because the fruit are often collected from seedling trees maintained in semi-wild cultivation. Martin et al. (1977) considered this fruit to have little potential for further commercialization. However, the fruit are large and can withstand handling, making them a candidate as a fresh fruit for the lowland humid and seasonally dry tropics. In order to improve the commercialization of this fruit, a concerted effort into the selection of superior cultivars would be needed, as well as research on production, and handling procedures.

Guttiferae

This is a large family (1350 species) that contains many fine-flavored fruit crops. Popenoe (1920) went so far as to proclaim one member of this family, the mangosteen (*Garcinia mangostana* L.), as perhaps the finest flavored of all of the fruit in the world. Other species in the family from South America also possess a superior flavor and may actually have greater potential for further commercialization than the mangosteen due to superiority in adaptation to diverse climates.

Platonia esculenta (Arruda) Rickett and Stafleu. Bacurí. The bacurí is native to northern South America and is now grown extensively throughout the Amazonian lowlands. The tree can attain a height of 25 m under optimal conditions. Fruit production is reported to be quite heavy in comparison to other Guttiferae (Cavalcante 1974), although specific yield records are not available. The fruit are yellow, with a leathery shell enclosing a creamy white flesh, which is usually divided into 6 sections (similar to mangosteen). The flavor is excellent, being sweet and aromatic and highly appreciated. Care must be taken when eating the fruit because the leathery shell contains a yellow latex that is quite bitter. The fruit range from 300 to 900 g and are 10 to 12 cm in diameter (Donadio 1983). There can be up to 6 seeds per fruit, weighing about 20 to 40 g each. Often the seeds abort, and edible flesh fills the space which would otherwise be occupied by the normal-sized seed. In contrast to mangosteen, the tree is tolerant of many different environmental conditions, including poor drainage (Martin et al. 1987). Trees are quite sensitive to temperatures below 0°C and to desiccating winds. Propagation is usually by seed, but bacurí is graft compatible with other *Garcinia* and *Rheedia* species.

Rheedia macrophylla Planch. et Triana. Bacuripari. The bacuripari is native to the Amazonian lowlands, where it grows as an understory tree. The tree can grow to 9 m, forming an attractive, pyramidal canopy (Campbell 1983). Trees are propagated by seed and may require 7 to 10 years to come into production. Fruit are variable in shape, averaging 4 to 5 cm in diameter and 5 to 6 cm in length. The fruit have a thick, hard outer wall containing a bitter latex, as in bacurí. Inside the hard shell is a white, creamy flesh surrounding 3 to 4 large seeds. The flesh is scanty in comparison to mangosteen or bacurí. The bacuripari is outstanding because it grows and produces a significant crop in shaded conditions (Campbell 1983). The trees are also tolerant of full sun and wind exposure, making them more adaptable to varied climates than the mangosteen. There is considerable variation in fruit quality among bacuripari from different regions of South America, and there may be different species involved.

Wherever bacurí, bacuripari or other *Rheedia* sp. are grown, the flavor is considered excellent. Although not superior to mangosteen in terms of flavor or edible flesh percentage, these other species have better adaptation to varied climatic and edaphic conditions, allowing for their production in many regions. The latex in both of these fruit can be a major obstacle to commercialization, because those unfamiliar with the consumption of these fruit are likely to ingest it, leading to an unpleasant taste experience. Silva (1991) reports that bacurí fruit can be stored a few days after harvest to reduce the amount of latex in the fruit. There has been little selection for superior clones among either bacurí or bacuripari, although there is considerable variation present among seedling trees.

Malpighiaceae

This family of 1100 species is best represented in fruit crops by the acerola (*Malpighia glabra* L.) which is widely cultivated on a commercial scale throughout the tropics as a fresh fruit, juice, and natural source of vitamin C. Other members of this family from South America are also widespread throughout the tropics as food sources on a local scale.

Byrsonima crassifolia (L.) H.B.K. Nance. This fruit is native from the Caribbean through Central America and throughout most of South America. It has one of the widest native ranges of all fruit crops in Tropical America. Trees are tolerant of a wide range of environments, from the coastal Caribbean, the semi-desert regions of northeastern Brazil, the humid tropical lowlands and the middle elevations (1,000 m) of Central and South America. Throughout their range, nance trees are left when forests are cleared, and maintained in a state of semi-wild cultivation. The fruit from these trees are harvested by local residents, consumed, preserved, or sold to local markets.

The tree can attain a height of 10 to 15 m. While in flower the tree is quite ornamental, with showy orange and yellow inflorescences. The fruit are variable, ranging in size from 2 to 5 cm throughout its range. The skin is usually yellow, with a yellowish, translucent flesh and a single seed. The flavor is sweet and aromatic, sometimes with an oily or musky flavor. The nance is consumed fresh, as a preserved product, a juice or a liquer. In the markets of the lowland tropics, it is commonplace to find nance packed in water in glass containers.

Propagation is generally by seed, but the trees are easily grafted and in some locations (Yucatan, MX) superior clones are commercially propagated by veneer or cleft grafting. Fruit of superior clones may be yellow or red, and up to 6 to 7 cm in diameter. These clones typically have a superior flavor to the wild types, and are commonly consumed as a fresh fruit. The trees are sensitive to cold, but have survived repeated freezes in South Florida (Campbell et al. 1977). Due to the wide-spread familiarity with this fruit there is the potential for the marketing of fresh fruit of superior cultivars. In addition, with its adaptation to varied climates, the nance could become an important processed fruit for the lowland tropics if it could be successfully marketed.

Bunchosia armeniaca Rich. The bunchosia is native to South America, and is uncommon in most other locations. The trees are found from low to middle elevations, producing a small, attractive tree up to 10 m. The trees are precocious, fruiting within 3 years from seed. The trees flower and fruit throughout most of the year. Fruit are ellipsoid and borne in clusters. The red or yellow fruit are from 3 to 4 cm in length with a cream-colored flesh. The flavor is sweet, but often astringent. Even in areas where the tree is common, the fruit are not highly esteemed for fresh consumption. They are more commonly used as a flavoring. Bunchosia is a common addition to the home garden, but only rarely used as a commercial crop. The trees are tolerant of freezes, being slightly damaged by temperatures of -2°C in Florida (Campbell et al. 1977).

Martin et al. (1977) finds the bunchosia to have little potential for further commercialization. However, it could have potential, given its precocity and adaptive nature if superior cultivars could be identified. New cultivars not withstanding, the tree has good potential as an ornamental in the low to middle elevations throughout the tropics (Donadio 1983), where it would be a pleasant addition to the home garden landscape. With the commercial importance of ornamental horticulture throughout the world, this aspect of the tree should not be ignored.

Myrtaceae

Of all of the tropical fruit families, the Myrtaceae has attracted perhaps the most attention for possible increased commercialization (Campbell 1977; Clement 1983; Donadio 1983; Arkcoll 1990). Among the 3,850 species within this family, many produce edible fruit of superior quality. These same species often possess unusual growth forms, making them good candidates for ornamentals as well. The guava (*Psidium guajava* L.) and the jaboticaba (*Myrciaria cauliflora* Berg) are two of the best known members of this family in terms of commercial use. There are, however, many others (particularly from South America) that deserve greater attention.

Eugenia luschnathiana Klotzsch ex. O. Berg. Pitomba. The pitomba is native to Brazil and is relatively uncommon outside of this region. As with many of the Myrtaceae, its growth rate is slow, particularly in calcareous soils, where micronutrient deficiencies are often problematic (Campbell 1977). In acid soils, the growth is much faster, and plants generally have a better nutritional status. The pitomba forms a bush or a small tree to 8 m. The fruit are yellow or orange, 2 to 3.5 cm in diameter, with orange flesh. The flavor is sweet and aromatic. The fruit can be eaten fresh, but more commonly are made into preserves or juices. Dorsett et al. (1917) commented that the tree had value as an ornamental in the correct environment, although Campbell (1977) noted that in Florida the tree is not as attractive as many other members of this family. Trees are grown from seed and can require 7 to 10 years to produce fruit. Grafting can be used to reduce the time to fruiting. The pitomba is not as productive as some Myrtaceae (Dorsett et al. 1917).

Marliera edulis Cambess. Cambucá. The cambucá is native to the coastal rain forests of Sao Paulo and Rio de Janeiro states, Brazil. It has long been known and consumed locally, but is uncommon today within its native region, and even lesser known outside of Brazil. The tree is attractive, but slow growing, eventually reaching heights of 5 to 12 m depending on the environmental conditions. The bark has the same attractive mottled appearance as a jaboticaba tree. The fruit, from 50 to 70 g in weight, are born on the trunk and larger limbs of the tree. They are yellow, with longitudinal ridges. The skin is leathery with a translucent and juicy flesh and 1 to 2 large seeds, leaving little flesh to eat. The flavor is excellent. In recent years this fruit has been described by many as superior to jaboticaba in flavor, but Dorsett (1917), describing the diversity of fruit available at that time in Brazil, considered the taste inferior to jaboticaba. There has been, however, little work done on selection due to the slow growth of the tree and the narrow genetic base.

The pitomba and the cambucá are both good examples of fruit which have truly excellent flavors, but are not likely to be developed in the future as fresh fruit. Instead, development will depend on some form of a niche market, taking advantage of their excellent flavor for ice creams, or juices. As with most of the Myrtaceae, the fruit of these two species are small and easily damaged by handling. Even if their excellent flavor can be exploited, their commercial future will depend on the selection of better clones and improvements in propagation and production techniques, allowing for feasible economic production.

Sapotaceae

The Sapotaceae, with 1,000 species, is a prevalent fruit crop family, particularly in the Caribbean. The sapodilla [*Manilkara zapota* (L.) P. Royen] and the mamey sapote [*Pouteria sapota* (Jacg.) H. Moore and Stearn] are commercial fruit crops throughout the Caribbean and Central America. In South America there are also representatives of this family which have potential for much wider cultivation than at present.

Pouteria caimito Radlk. Abiu. The abiu is native to the warm, moist lowlands of South America. Trees have been introduced to many other locations, but they are still relatively uncommon. The trees attain a height of 12 m under optimal conditions. The fruit are ellipsoid to spherical and can range from 4 to 10 cm in length. The skin color is yellow when ripe, with a translucent flesh surrounding 1 to 5 seeds. The skin is leathery, containing a sticky white latex. The abiu is common in local markets throughout South America, where fruit quality is highly variable, with round, oblong, pointed, and dorso-ventrally flattened fruit types.

The abiu has good potential for commercial development in warm, moist tropical climates due to its precocity and heavy production. Yet, propagation of this crop is still predominantly by seed. In order to further develop this crop there will need to be selection of superior clones. Clement (1983) discussed clones in the eastern Amazon of up to 1,000 g, but these are not widely available. In Australia several named varieties have recently been selected which are precocious and productive, and have good fruit quality. These new selections have been accepted in the Southeast Asian marketplace, and should also have potential in the American Tropics. As with the Guttiferae, the latex of the abiu could be a hindrance to the development of this fruit.

Pouteria obovata Baehni. Lucuma. The lucuma is native to the cool highlands of South American, above 1,000 m. Lucuma grows best in cool climates, and is difficult to cultivate in the lowlands. The trees attain a height of 12 m and yield an ovoid to ovate fruit 4 to 8 cm long. The fruit are yellow at maturity with a dry, yellow flesh. While the fruit are immature, it contains a bitter white latex. The fruit can be eaten fresh when ripe, but is generally consumed as a drink or a flavoring. In Chile and Peru the lucuma is a significant commercial crop (Lizana et al. 1986), and specialized grafting techniques to improve precocity are practiced by some nurseries. Within Chile and Peru, the lucuma fruit are usually dehydrated and ground into a fine powder and used as an additive to milk.

This fruit does have some potential for fresh consumption, and there has been research conducted on the harvest indices and storage characteristics (Lizana et al. 1986). The lucuma could fill the same niche in the tropical highlands as the canistel [*Pouteria campechiana* (Kunth) Baehni] does in the lowlands. However, canistel has not been successful as a fresh fruit in the U.S. market to date. There is little reason to assume that the lucuma would succeed as a fresh fruit when the canistel has failed. The greater potential for lucuma is probably as a processed product, such as the powder used as an additive to milk.

Sterculiaceae

This family with over 1500 species is best known for cacao (*Theobroma cacao* L.), used for chocolate and the cola nuts (*Cola* sp.) used for caffeine production. Within South America there are several other members of this family with potential. One of these species, the cupuaçu (*Theobroma grandiflorum* Schumann) was previously discussed in detail by Arkcoll (1990) and Cabral Velho et al. (1990).

Theobroma bicolor Bonpl. Mocambo. This fruit is commonly used as a beverage fruit within its native range of Central and South America, but is uncommon outside of this area. The trees are propagated by seed and can attain a height of 12 m, although they are usually found as smaller understory plants. The fruit are ellipsoid from 15 to 20 cm long and 10 to 15 cm wide, with a felty brown exterior. The pulp is sweet and pleasant and the seeds can be roasted for consumption. The odor of the fruit can be disagreeable to many. In Central America it is traditionally mixed with achiote (*Bixa orellana* L.) and sugar to make a sweet desert. As with cupuaçu, the mocambo will never have potential as a fresh fruit, but the flesh could be marketed as an additive for beverages as proposed for cupuaçu (Cabral Velho et al. 1990).

CONCLUSIONS

The commercial status of many of the fruit described in this paper has not changed dramatically from when they were described over 75 years ago by Dorsett et al. (1917) and Popenoe (1920). A narrow range of environmental adaptations, the lack of superior selections, difficulties in propagation, exotic looks and tastes, and ignorance about the proper use of the fruit may have doomed these fruit to obscurity to date. They were then, and remain today as "under-exploited" fruit crops.

Regardless of the reason for their continued obscurity, it is clear that a superior taste and an exotic appearance alone was not enough to insure greater economic development of these crops. There was not sufficient economic incentive for their development. It may require innovative methods of marketing and promotion to introduce the new tastes and sights, and gain greater acceptance of these products. Perhaps the time is right to market these fruit crops and their products as the "fruits of the rainforest," taking advantage of the present sentiment that they are the salvation of these endangered ecosystems (Schemo 1995).

The greatest challenge lies in the promotion of fruit that are not consumed "out-of-hand," but are better used as a juice or flavoring. A change is needed in the consumption habits of consumers to further develop these markets. Fresh or frozen juices will have to at least partially replace soft drinks and juices which include only small percentages of fruit juice. Prices of fresh fruit or frozen pulp will have to be affordable to allow the economical use of the fruit within the home. The promotion of these products as "all-natural" could also be a plus for their marketing.

The potential value of fruit crops in the home landscape should also not be ignored, providing both beauty and a nutritious product for the home. Campbell (1973) discussed the use of fruit trees in the home garden within metropolitan areas. South Florida is an excellent model of how fruit crops can be used profitably in this manner (Crane 1993; Lamberts and Crane 1990). With the continuing economic development of Latin America, the use of fruit crops as ornamentals and home landscape components will become more important.

Increased demand through the promotion of these fruits must be accompanied by the selection of clones that meet the needs of the market. Whether it is size, color, self-fruitfulness, or precocity, a concerted effort into the genetic improvement of these crops is vital. Finally, there must also be an effort put forth for trials in other locations and research into propagation and production for the fruit crop. Regardless of the fruit crop considered, further development will depend on sound economic principals (Campbell 1990). If the production of the fruit is not profitable within a particular region, its development will not proceed.

Bakupari

Rheedia brasiliensis Planch. & Triana

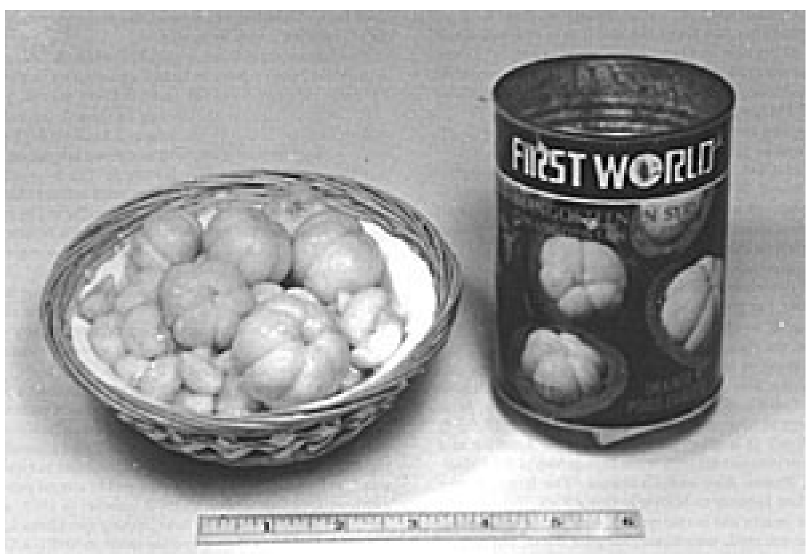
Of the approximately 45 species of *Rheedia* (family Guttiferae), several have edible fruits. Perhaps the best-known is the bakupari, *R. brasiliensis* Planch. & Triana, which is also known as *bacupary* or *bacoropary* in Brazil; as *guapomo* in Bolivia.

The very attractive tree is pyramidal like that of the bakuri but smaller; is equally rich in yellow latex. The leaves are short-petioled, ovate, oblong-ovate or lanceolate, narrowed at the base, blunt or slightly pointed at the apex, and leathery. The flowers, profuse in axillary clusters, are polygamous. The fruit, ovate, pointed at the apex, may be 1 1/4 to 1 1/2 in (3.2-4 cm) long, with orange-yellow, pliable, leathery, tough skin, 1/8 in (3 mm) thick and easily removed. The aril-like pulp is white, translucent, soft, subacid, of excellent flavor, and encloses 2 rounded seeds.

The tree grows wild in the state of Rio de Janeiro in southeastern Brazil and adjacent Paraguay; is rarely cultivated. It blooms in December and matures its fruit in January and February. The ripe fruit is mostly used in making sweetmeats or jam.

The seeds contain 8 to 9% oil (by weight) which is used in Brazil in poultices on wounds, whitlows, tumors and, externally, over an enlarged liver. An infusion of the pulp has a narcotic action with an effect like that of nicotine. The root bark extract contains rheediaxanthone and a polyprenylated benzophenone, other lesser constituents, and 3 new prenylated xanthones.

Related Species



The **mameyito,** *R. edulis* Triana & Planch. (syn. *Calophyllum edule* Seem.), is also known as *arrayan* and *palo de frutilla* in Guatemala; waiki plum in Belize; *chaparrón* in El Salvador; *caimito* or *caimito de montaña* in Honduras; *jorco* in Costa Rica; *sastra* in Panama; *berba* in the Philippines.

The elegant, erect tree, ranging up to 100 ft (30 m), has copious gummy, yellow latex and opposite, short-petioled, thick, leathery, elliptic-oblong or elliptic-lanceolate leaves, 3 3/16 to 6 in (8-15 cm) long, 3/4 to 2 in

(2-5 cm) wide, or much larger, with numerous lateral veins conspicuous on both surfaces; dark-green above, pale or brownish on the underside. Young foliage is reddish. The small, greenish-white or ivory flowers, densely clustered below the leaves, are 4-petalled, the male with 25 to 30 stamens, the perfect with 10 to 12. The fruit is oval or oblong, 3/4 to 1 1/4 in (2-3.2 cm) long, smooth, orange or yellow, the thin, soft skin easily peeled. There is a little flesh, sweet or acid, adhering to the 1 or 2 seeds.

Fig. 83-b: Peeled mangosteens, in light sirup, canned in Thailand, are appearing in Asiatic food outlets in the United States.[1] According to the *Wall Street Journal*, April 7, 1987, fresh fruits, cut open, inspected, sealed with tape, and quick-frozen, are exported from Malaysia to Japan where they sell readily at nearly $4 each. They are defrosted in boiling water for 2 minutes before eating.

The tree is native and common in humid forests on both the Atlantic and Pacific sides of Central America, from southern Mexico to Panama, up to an elevation of 4,000 ft (1,200 m). It is often planted in Central America as a shade or ornamental tree. It has been grown in the Philippines, Puerto Rico and California. The fruits mature from late January to March in Costa Rica.

The heartwood is rose-yellow, hard, medium-heavy, coarse-textured, with numerous gum ducts, but tough, strong, easy to work, fairly durable, and valued for construction because it is nearly immune to insects. It is also used for tool handles, fenceposts, and temporary railroad ties. The bark is rich in tannin.

The **bacuripari,** *R. macrophylla* Planch. & Triana, is also called *bacury-pary* in Brazil; *charichuela* in Peru.

It is a pyramidal tree, 26 to 40 ft (8-12 m) tall, with stiff, leathery, lanceolate-oblong or broad-lanceolate leaves, 12 to 18 in (30-45 cm) long and 3 to 7 in (8-18 cm) wide, pointed at both ends, with numerous lateral, nearly horizontal veins. New foliage is maroon. The 4-petalled, male and female flowers are home in small axillary clusters on separate trees, the male on delicate stalks to 1 1/2 in (4 cm) long and having numerous stamens, the female on thick, short stalks and sometimes having a few stamens with sterile anthers.

The fruit is rounded-conical, pointed at one or both ends, about 3 3/16 in (8 cm) wide, with thick yellow rind, usually smooth, sometimes rough, containing gummy yellow latex. The white, aril-like pulp, agreeably subacid, encloses 3 to 4 oblong seeds.

The tree is native to humid forests of Surinam and Brazil to northern Peru. The fruit is not much esteemed but widely eaten and sold in native markets. The bacuripari was introduced into Florida in 1962 and planted at the Agricultural Research and Education Center in Homestead, at Fairchild Tropical Garden and in several private gardens. One tree fruited in 1970, another in 1972, and the latter has continued to bear. Young specimens have been killed by drops in temperature to 29º to 30º F (-1.67º--1.11º C). Older trees have been little harmed by 27º to 28º F (-2.78º--2.22º C). The tree is accustomed to light-to moderate-shade. Seeds have remained viable for 2 to 3 weeks but require several weeks to germinate.

In Brazil, the tree blooms from August to November and the fruits mature from December to May. In Florida, flowers appear in April and May and a second time in August and September, and the fruits are in season from May to August and again in October and November. Some 15-to

20-year-old trees have produced 100 to 200 fruits when there have been no adverse weather conditions.

The **madroño,** *R. madruno* Planch. & Triana, may be called *machari* or *fruta de mono* in Panama; *cerillo* in Costa Rica; *cozoiba* in Venezuela; *kamururu* in Bolivia.

The tree is erect, lush, compact, with pyramidal or nearly round crown, 20 to 65 ft (6-20 in) high, and has much gummy yellow latex. The opposite leaves are elliptic to oblong, wedge-shaped at the base, rounded or pointed at the apex, 2 3/8 to 8 in (6-20 cm) long, 3/4 to 3 in (2-7.5 cm) wide; dark green above, paler beneath, with numerous veins conspicuous on both surfaces and merging into a thick marginal vein. The fragrant male and female flowers are borne on separate trees in clusters of up to 14 in the leaf axils; have 4 reflexed, pale-yellow petals; the male, 25 to 30 light-yellow stamens. The fruit is round or ellipsoidal, sometimes with a prominent nipple at each end; 2 to 3 in (5-7.5 cm) long, with thick, leathery, warty, greenish-yellow rind containing a deep-yellow, resinous latex. The white, translucent, juicy, sweet-acid, aromatic pulp adheres tightly to the 1 to 3 ovate or oblong seeds which are about 3/4 in (2 cm) long.

The tree is native to the Golfo Dulce region of Costa Rica, the Atlantic slope of Panama, and northern South America–Colombia and Ecuador through Venezuela to Guyana and Bolivia. It is particularly common in the Cauca Valley of Colombia where the fruits are marketed in quantity. It is limited to elevations below 4,000 ft (1,200 in). Dr. Wilson Popenoe collected seeds for the United States Department of Agriculture near Palmira, Colombia, in 1921 (S.P.I. #52301). The tree was introduced into Puerto Rico in 1923 and into the Philippines at about the same time. A few old trees have been fruiting more or less in southern Florida for many years, in midsummer. In Costa Rica, flowers are borne from December to February and fruits from May to August.

The yellow latex of the tree is used in Panama to treat ulcers and other sores. The wood is pinkish and hard but not commonly used.

Bakuri

Platonia insignis Mart.

Aristoclesia esculenta Stuntz

A relatively obscure member of the Guttiferae, the bakuri, *Platonia insignis* Mart. (syn. *Aristoclesia esculenta* Stuntz), is also called *bacurí*, *bacurí assu*, *bacurí do Pará*, *bacury*, *pacuri* or *pacoury-uva* in Brazil; *pakuri*, *pakouri* or *maniballi* in Guyana; *pacouri* in French Guiana; *packoeri*, *pakoeri* or *geelhart* in Surinam; *goherica* or *ko* by the Indians in Amazonian Colombia. It is, unfortunately, sometimes referred to as *bakupari,* a name better limited to *Rheedia brasiliensis*, q.v. In Brazil the tree is called *bacurizeiro.*

Description

The tree is erect, to 80 ft (25 m) high, with pyramidal crown and copious yellow latex in the bark. The leaves are deciduous, opposite, oblong or elliptic, to 6 in (15 cm) long, dark-green and glossy above; leathery, with wavy margins. Borne singly or in 3's, the flowers are 2 3/4 in (7 cm) long, rose-colored, 5-petalled, with many stamens. The fruit is nearly round or ovoid, 3 to 5 in (7.5-12.5 cm) wide, weighing up to 32 oz (900 g); yellow when ripe. The rind is yellow, hard, fleshy on the inside, 3/8 to 3/4 in (1-2 cm) thick, and contains gummy, yellow, resinous latex. The white, pithy pulp, of pleasant odor and agreeable, subacid flavor, contains 1 to 4, rarely 5, oblong, angular seeds, dark-brown and 2 to 2 3/8 in (5-6 cm) long. The infertile seed compartments are filled with pulp called *'filho* "which is the part preferred.

Origin and Distribution

The bakuri was first reported in European literature in 1614. The tree is common, wild, in the Amazon region of northern Brazil from Maranhao, Goias to Paraguay. It is abundant in the State of Para, especially around Marajo and Salgado. Its native territory extends across the border into Colombia and northeast to the humid forests of Guyana. It is seldom cultivated but when the Indians clear the land for planting or pastures, they always leave this tree standing for the sake of its fruits. In Marajo, it is viewed as a weed because it proliferates from fallen seeds and, if felled, produces abundant suckers from the roots. In the district of Marapanim, there is a hamlet called Bacurteua because of its many bakuri trees.

Climate

The bakuri requires a moist, lowland, tropical habitat.

Season

In Brazil, the tree flowers in June and July, after the shedding of the leaves. The first fruits mature in early December and the season extends to the following May, the peak of the crop ripening in February and March.

Food Uses

The pulp is much eaten raw but is mainly used to make sherbet, ice cream, marmalade or jelly.

Food Value Per 100 g of Edible Portion*	
Calories	105
Moisture	72.3 g
Protein	1.9 g

Tryptophan	57 mg

*Analyses made in Brazil.

Other Uses

The sapwood is yellowish-white; the heartwood dull-yellow to orange-brown with many fine, dark, often black streaks. It is hard but easy to work and fairly durable. It is valued for construction, furniture, flooring, ship-building and general carpentry.

Medicinal Uses: The latex derived from the bark is used in veterinary practice in Guyana. The seeds contain 6 to 11% of an oil that is mixed with sweet almond oil and used to treat eczema and herpes.

Khareti or Bala (*Sida cordifolia* Linn.)

Scientific Name: *Sida cordifolia* Linn.
Family: Malvaceae
English Name: Country Mallow
Hindi Name: Khareti, Bala, Barial, Kumghi.

Botanical differences among the major species of *Sida* in India.

	S. cordifolia	*S. acuta* syn. *S. carpinifolia*	*S. alba* syn. *S. spinosa*	*S. ovata* syn. *S. grewioides*	*S. rhommbifolia*	*S. tiagii*
Plant	An erect, perennial undershrub, upto 1m. Tall	A much branched undershrub, 1-2 m tall	An erect undershrub, densely stellately pubescent all over	An erect shrub or undershrub,	An erect undershurb	A low, much branched, perennial undershrub, densely stellately-tomentose all over
Stem	Ascending, terete or sulcate, softly villious and densely stellate-pubescent all over	Glabrous or minutely stellately hairy, usually woody at the base		grey, tomentose, with stellate hairs	Stellately hairy, sulcate	Terete or sulcate, woody at base
Leaves	Ovate or ovate-oblong, obtuse or subacute at apex	Lanceolate or elliptic lanceolate, base obtuse or roundish, apex acute	Elliptic oblong, lanceolate or ovate, obtuse or rounded at apex	Elliptic-oblong or oblong-ovate, obtuse at apex	Oblong to lanceolate, rhomboid, cunneate, obtuse or rarely acute at apex	Ovate-oblong to obovate, roudned, entire, rounded or truncate at apex

Flowers	Yellow, peduncles, axillary, jointed much above the panicles, upper flowers nearly sessile and fasciculate towards the tip of the branches forming subspicate inflorescence	Petals pale yellow, ciliate	Fascicled in the axil of leaves, rarely solitary, Corolla white	Petals yellow	Petals yellow	Pale yellow
Fruits	Subdiscoid, 6-8 mm across, mericarps 10, 3 sided	Mericarps 5-6, 4 mm long, reticulately serrate	Mericarps 5, more or less finely reticulate	Mericarps 7-8, nearly glabrous	mericarps 8-12, pubescent	Pentagular ovoid, Mericarps 7-8
Seeds	Trigonous, glabours, tufted-pubescent near the hilum	Smooth glabrous, but pubscent around hilum	Smooth, dark brown, rounded at back, trigonous, glabous	Brown, smooth, with stellate hairs near the hilum	Smooth, glabrous, except for the pubescent area near the hilum	Black, glabrous with tufts of stellate hairs at hilum
Flowering & Fruiting Time	Sept.-Dec. in Indian conditions	Sept-Oct. in Indian conditions	Sept.-Jan. in Indian conditions	Oct.-Jan. in Indian conditions	Aug.-Oct. in Indian conditions	Aug.-Dec. in Indian conditions

General Description: It grows as wasteland weed. It is in use as folk medicine in India since time immemorial.

Useful Parts: Root, bark, leaves, flowers and seeds.

Traditional Medicinal Uses: According to Ayurveda, the plant is tonic, astringent, emollient, aphrodisiac and useful in treatment of respiratory system related troubles. Bark is considered as cooling. It is useful in blood, throat, urinary system related troubles, piles, phthisis, insanity etc.

Ayurvedic Preparations: Maha baladi Kvatha, Bala Taila etc.

Magness, J.R., G.M. Markle, C.C. Compton. 1971. Food and feed crops of the United States.

Balm-Of-Gilead Poplar

Populus candicans Ait.

Other common names.—Balsam poplar, balm buds.

Habitat and range.—The balm-of-Gilead tree, which has mostly escaped from cultivation, is found along roadsides or streams from Newfoundland to Minnesota and Georgia.

Description.—This is a large tree reaching a height of 100 feet with a maximum trunk diameter of about 6 1/2 feet with spreading branches, the young twigs slightly hairy, and with very resinous, fragrant buds. The broad, pointed leaves, 2 1/2 to 6 inches long, are somewhat heart-shaped at the base, fine toothed, dark green above, pale beneath, and hairy when young. The male and female flowers are borne in separate catkins 6 inches or less in length, which appear before the leaves.

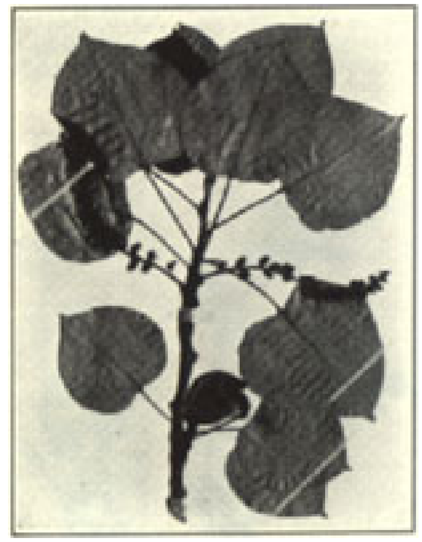

Figure 11.—Balm-of-Gilead poplar (*Populus candicans*)

Part used.—The leaf buds.

Balsam pear

Bitter melon, Cundeamor, La-kwa

Cucurbitaceae *Momordica charantia* L.

Balsam apple

***M. balsamina* L.**

Source: Magness et al. 1971

The balsam pear plant is an annual running vine, to 10 feet or more, with near round, lobed leaves. The fruit is 4 to 6 inches long, oblong, pointed and furrowed lengthwise. When full ripe it splits into 3 divisions. The immature fruit is boiled as a vegetable. A pulpy aril surrounds the seeds, which is esteemed by Orientals. In culture, similar to cucumber. The related balsam apple has a smaller, egg-shaped fruit, and is used in a similar manner.

Season, **seed to harvest**: 3 to 4 months.

Production in U.S.: No data. Mainly oriental gardeners.

Use: As boiled vegetable. Seed arils eaten out of hand.

Part of plant consumed: Whole immature fruits. Seed arils.

Bamboo Greenbrier

Smilax pseudo-china L.

Other common names.—Bamboo brier, long-stalked greenbrier, American chinaroot, false chinaroot, bullbrier.

Habitat and range.—This plant occurs in dry, sandy thickets from New Jersey to Florida and west to Texas and Nebraska.

Description.—Bamboo greenbrier is a smooth vine with a tuberous rootstock and with the lower part of the stem smooth or sometimes beset with straight, needle-shaped prickles. The leaves, 2 1/2 to 5 1/2 inches long and 1 1/2 to 3 1/2 inches wide, are egg-shaped or sometimes narrowed at the middle, usually rough on the margin, and somewhat leathery when old. The greenish flowers, 12 to 40 in number, are borne in round clusters on flattened stalks 1 to 3 inches long. These are followed in autumn by one to three seeded black berries up to one-quarter inch in diameter.

Figure 12.—Bamboo greenbrier (*Smilax pseudo-china*)

Part used.—The root.

Bambusa arundinacea (Retz.) Willd.

Poaceae
Spiny bamboo, Thorny bamboo, Tziu chu, Kalak, Bans

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Very young shoots are consumed as food in some parts of India and China. In raw state, shoots (ca 8 cm in diameter and 37.5 cm long) are very acrid, but with two changes of water in cooking and with addition of salt and butter, they make a pleasant vegetable. Young shoots pickled or made into curries. Wood used by Chinese in household carpentry, furniture, boxes, ornamental vases, scaffolding, etc. Leaves used as fodder. Stems in great demand for manufacture of paper pulp of good quality. Seeds edible and used in times of scarcity of food. Other species of Bambusa, found in various parts of the tropics, are used for similar purposes: those used for the young shoots or buds as a vegetable include *B. cornuta* Munro, *B. multiplex* Raeusch, *B. oldhami* Munro, *B. spinosa* Roxb., *B. tulda* Roxb., and *B. vulgaris* Schrad.; species used for construction and other such purposes include *B. balcooa* Robx. (one of the best and strongest bamboos for building purposes), *B. multiplex* Raeusch (culms used for paper), *B. nana* Roxb. (fishing poles), *B. pervariabilis* McClure (heavy construction), *B. polymorphs* Munro (roofs of houses, floors and walls), *B. sinospinosa* McClure (sheaths made into sandals), *B. spinosa* Roxb. (timber bamboo), *B. texilis* McClure, *B. tulda* Roxb., and *B. tuldoides* Munro (weaving mats, hats, baskets and ropes), *B. vulgaris* Schrad. (paper pulp), *B. beecheyana* Munro [*Sinocalamus beecheyanus* (Munro)McClure] is an important source of commercial edible bamboo shoots.

Folk Medicine

An ointment from the root is said to be a folk remedy for cirrhosis and hard tumors, especially tumors of the abdomen, liver, spleen and stomach (Hartwell, 1967–1971). Tabasheer, a siliceous secretion (up to 97% SiO_2), considered aphrodisiac, cooling, and tonic, is used in asthma, cough and debilitating diseases (C.S.I.R., 1948–1976). Leaves given to horses suffering coughs and colds.

Chemistry

The stem consists almost entirely of cellulose and hemicellulose (xylans, arabans, polyuronides, etc.) and lignins, with a small amount of resins. Oven-dried stems contain 3.3% ash, 1.8% silica, 6.0% hot water solubles (see above), 19.6% pentosans, 30.1% lignin, and 57.6% cellulose. Analyses from paper pulping showed 8.5% water extract, 1.2% fat, wax, etc., 24.4% pectose, 15.6% lignin, 50.3% cellulose, and 1.6% ash. Per 100 g, the seeds are reported to contain 11.0% H_2O, 11.8 g protein, 0.6 g fat, 75.4 g total carbohydrate, 1.7 g fiber, and 1.2 g ash (C.S.I.R., 1948–1976). On a zero moisture basis the fresh leaves (57.1% DM) contain 18.6% CP, 24.1% CF, 11.8% ash, 4.1% EE, 41.4% NFE. With sheep the CP exhibits 72.4% digestibility, CF 49.1%, EE 10.8%, and NFE 48.8% (Gohl, 1981). Per 100 g, the shoot is reported to contain 29 calories, 90.7 gH2 0, 2.3 g protein, 0.2 g fat, 6.6 g total carbohydrate, 0.5 g fiber, 0.7 g ash, 33 mg Ca, 41 mg P, 0.4 mg Fe, 20 meg β-carotene equivalent, 0.15 mg thiamine, 0.7 mg riboflavin, 0.6 mg niacin, and 4 mg ascorbic acid (Food Comp. Table Latin America).

Toxicity

Eight grams of raw shoots or slightly more improperly cooked shoots can cause death. Young shoots contain 0.03% HCN (C.S.I.R., 1948–1976). Hairs on various bamboos, and fungi which live thereon, may cause dermatitis (Mitchell and Rook, 1979). Benzoic acid and traces of cyanogenic glucoside present in shoots have lethal effect on mosquito larvae (has antiseptic and larval properties).

Description

Tall woody bamboo, stems thorny, numerous, tufted, up to 40 m tall, curving at top; branches numerous, internodes 30–45 cm long, prominent, bearing in lower parts of stems dense half whorls of stiff, naked, horizontal branches, armed with 2–3 recurved, stout spines; lowest nodes rooting; stem-sheaths leathery, orange-yellow when young, hairy outside, shining and ribbed inside, 30–45 cm long; blade triangular, glabrous, covered with a brown felt of bristly hairs inside; leaves thin, linear, up to 20 cm long, glabrous above, hair beneath; leaf-sheaths hairy, small; inflorescence an enormous panicle, often occupying the entire stem; branchlets loose clusters of pale, glabrous spikes.

Germplasm

Reported from Asian Centers of Diversity, bamboos are reported to tolerate insects, laterites, low pH, slope, and weeds ($2n$ = 72, 70) (Duke, 1978).

Distribution

Wild in most parts of tropical India and Pakistan, growing up to 1000 m altitudes in the Nilgiris and hills of southern India; north into China.

Ecology

Probably ranging from Subtropical to Tropical Very Dry to Wet Forest Life Zones, spiny bamboo probably tolerates annual precipitation of ca 6 to 40 dm, annual temperature of ca 18 to 29°C, and pH of 4.3 to 7.3. Thrives in tropical to subtropical climates, growing in warm humid temperate areas as well, but thriving best under frost-free conditions, in rich to medium fertile soils with good water supply.

Cultivation

Bamboos may be produced by means of seeds, vegetative portions or by layering the stems and letting them root at the nodes. Seeds are sown in soil about 0.6 cm deep and about 2.5 cm apart in rows 7.5–10 cm apart. Germination occurs in about a week and seedlings grow rapidly. When plants are 15–20 cm tall, they are transplanted to individual containers. Transplanting to the field is done when plants are about 1 m tall. Growing plants from seed is the most economical and convenient method of propagating large numbers of plants. Clump division is the traditional and most generally prevalent method of propagating bamboos vegetatively. Active growth of young shoots from buds on the rhizome in this group of bamboos is initiated during the summer. The commonly recommended practice is to process vegetative propagules just before the initiation of growth of these buds. A clump is divided into two equal parts, retaining the root system, branches and leaves of each part as fully intact as possible. Properly set out, these propagules usually give the highest degree of success. Clump divisions taken from the edge of the clump are apt to give superior results. The rhizome should be severed at one point only, at the neck of the oldest rhizome axis in the propagule. Cut should be made at the slender neck where the minimum damage to the rhizome is done. Roots are best preserved and protected keeping them in a ball of earth when the propagule is taken from the parent plant. Some species, as *B. tulda*, has been successfully propagated by rhizomes planted *in situ*, with 95% survival not uncommon. Culm segments, with one or more nodes, bearing buds or branches, are used widely as a means of propagation in both the Old and New World. Branches are usually pruned to 30 cm or less, with no foliage retained. Such cuttings are set upright or at an angle, with at least one node well covered. *B. vulgaris* is often propagated this way.

Harvesting

Bamboos are harvested for food when the young shoots are 30–75 cm tall. Other parts of the plant are harvested whenever needed, as the leaves, branches and woody stems.

Yields and Economics

Finding no published data, I estimate the yields in excess of 10 MT DM/ha/yr. One of the most useful group of plants in the tropics, bamboos are used as food for man and fodder for livestock, for building materials, for weaving and cordage, for paper pulp and for making all types of utensils. Bamboos are very important in the economy of Oriental peoples; millions are occupied in growing and producing raw bamboo, and manufacturing of bamboo products.

Energy

New culms start growing slowly, growth soon approaching 30 cm/day with 75 cm having been recorded in one day in Sri Lanka. In Trinidad, *Bambusa vulgaris* produced more than 10 MT pure dry cellulose pulp per hectare per year on a three-year cutting cycle. The culms of *B. arundinacea* are said to be considerably more durable than those of *B. vulgaris*. With sheep, the ME of the leaves is 1.77 megacalories per kg dry weight.

Biotic Factors

Few serious diseases or pests of bamboos are reported. Bamboo borers can be problematical

Banana Passionfruit

Passiflora mollissima Bailey

Passiflora tomentosa var. *mollissima* Tr.& Planch

Tacsonia mollissima HBK.

A distinctive and much admired passionfruit relative, *Passiflora mollissima* Bailey (syns. *P. tomentosa* var. *mollissima* Tr. & Planch.; *Tacsonia mollissima* HBK.), was given this appealing and appropriate English name in New Zealand. In Hawaii, it is called banana *poka*. In its Latin American homeland, it is known as *curuba*, *curuba de Castilla*, or *curuba sabanera blanco* (Colombia); *tacso, tagso, tauso* (Ecuador); *parcha* (Venezuela), *tumbo* or *curuba* (Bolivia); *tacso, tumbo, tumbo del norte, trompos,* or *tintin* (Peru).

Description

The vine is a vigorous climber to 20 or 23 ft (6-7 m), its nearly cylindrical stems densely coated with yellow hairs. Its deeply 3-lobed leaves, 3 to 4 in (7.5-10 cm) long and 2 3/8 to 4 3/4 in (6-12 cm) wide, are finely toothed and downy above, grayish-or yellowish-velvety beneath. The stipules are short, slender and curved. The attractive blossom has a tube 3 to 4 in (7.5-10 cm) long, gray-green, frequently blushed with red, rarely downy; corolla with 5 oblong sepals and deep-pink petals flaring to a width of 2 to 3 in (5-7.5 cm); and a rippled, tuberculated, purple corona. The fruit is oblong or oblong-ovoid, 2 to 4 3/4 in (5-12 cm) long, 1 1/4 to 1 1/2 in (3.2-4 cm) wide. The rind is thick, leathery, whitish-yellow or, in one form, dark-green, and minutely downy. Very aromatic pulp (arils), salmon-colored, subacid to acid and rich in flavor, surrounds the small, black, flat, elliptic, reticulated seeds.

Origin and Distribution

The banana passionfruit is native and commonly found in the wild in Andean valleys from Venezuela and eastern Colombia to Bolivia and Peru. It is believed to have been domesticated only shortly before the Spanish Conquest. Today it is commonly cultivated and the fruits, which are highly favored, are regularly sold in local markets. In 1920, the United States Department of Agriculture received seeds from Guayaquil, Ecuador (S.P.I. No. 51205), and from Bogotá, Colombia (S.P.I. No. 54399). The vine is grown in California as an ornamental under the name "softleaf passionflower". It has never succeeded in Florida; is grown to some extent in Hawaii and the State of Madras, India. The climate of New Zealand seems highly suitable for it and it has been grown there, more or less commercially, for several decades.

Varieties

In general, the fruit is smaller in Peru than in Colombia and Ecuador. There are said to be several varieties. A form called *curuba quiteña in* Colombia is dark-green externally even when fully ripe, the apex is abruptly pointed and furrowed; the pulp is dark-orange or orange-brown.

Climate

This species is at home at elevations between 6,000 and 7,200 ft (1,800-3,200 m) in the Andes, and has adapted well to altitudes of 4,000 to 6,000 ft (1,200-1,800 m) in Hawaii and New Zealand. It can tolerate brief drops in temperature to 28.4º F (-2º C).

Propagation

The vine can be propagated from cuttings but is usually grown from seeds which normally germinate in 10 weeks. The time can be shortened to 5 weeks by preliminary soaking in lukewarm water.

Culture

The seedlings can be transplanted when 3 months old and need to be trained onto a horizontal trellis 6 1/2 ft (2 m) high with crosswires 16 in (40 cm) apart. At a vine spacing of 6.5 ft (2 m) each way, there will be 607 plants per acre (1,500 plants/ha). Less dense planting, allowing 10 ft (3 m) each way between vines, and 20 in (50 cm) between crosswires, will result in 445 vines per acre (1,100/ha). The first crop will be produced in 2 years. At dense spacing, and with good weed control and adequate fertilization, the annual harvest in Colombia will be 200 to 300 fruits per vine, amounting to 200,000 to 303,000 fruits per acre (500,000-750,000 fruits per ha), or about 31,000 to 47,000 lbs per acre (roughly the same number of kg per ha). The individual fruits range from 2 to 5 1/2 oz each (approximately 50-150 g). Some growers have practiced pruning, which improves air-flow, reducing disease, and facilitates weeding, irrigation, spraying and harvesting. It produces larger fruits but fewer and therefore is generally viewed as not practical as size is not important to the consumer. In India, the average yield is said to be 40 to 50 fruits per vine beginning with the 6th year from planting.

Season

There is more or less continuous fruiting the year around in Colombia. In New Zealand, the crop ripens from late March or early April to September or October.

Keeping Quality

The fruit stands shipment well and will keep in good condition in a dry and not too cold atmosphere for a reasonable length of time.

Pests and Diseases

In humid and poorly drained situations, some plantations suffer from nematodes *(Meloidogyne* sp.). Leaves and shoots may be attacked by leafhoppers *(Empoasca* sp.) and by *Dione* or *Agraulis, vanillae;* leaves and fruits may be plagued by mites *(Tetranychus* sp.); larvae of *Hepialus* sp. invade the flowerbud; stems may be bored and tunneled by *Heteractes* sp. and *Nyssodrys* sp. Occasionally the fruits are attacked by fruit flies. Young shoots are prone to powdery mildew *(Asterinia* sp.) and anthracnose *(Colletotrichum* sp.) may affect the vine and fruits. Boron deficiency causes cracking of fruits. Sometimes, for physiological reasons not yet fully understood, 50 to 60% of the fruits may drop prematurely.

Food Uses

The pulp is eaten out-of-hand or is strained for its juice which is not consumed alone but employed in refreshing mixed cold beverages. In Bolivia, the juice, combined with aguardiente and sugar, is served as a pre-dinner cocktail. Colombians strain out the seeds and serve the pulp with milk and sugar, or use it in gelatin desserts. In Ecuador, the pulp is made into ice cream.

The New Zealand Department of Agriculture has developed enticing recipes to encourage the growing and utilization of the seeded pulp as pie filling, and also for making meringue pie, sauce, spiced relish, jelly, jam and other preserves. It is also advocated as an ingredient in fruit salad, especially with pineapple, and for blending with whipped cream as a pudding, and for cooking and preserving as an ice-cream topping.

Canning the juice with benzoate of soda as a preservative loses much of the quality and, therefore, there is as yet no commercial processing.

Leonhardt, K.W. and Richard A. Criley. 1999. Proteaceae floral crops: Cultivar development and underexploited uses. p. 410–430. In: J. Janick (ed.), Perspectives on new crops and new uses. ASHS Press, Alexandria, VA.

Proteaceae Floral Crops: Cultivar Development and Underexploited Uses*

Kenneth W. Leonhardt and Richard A. Criley

The Proteaceae apparently originated on the southern supercontinent Gondwana long before it divided and began drifting apart during the Mesozoic era, accounting for the presence of the Proteaceae on all of the southern continents (Brits 1984a). The Protea family comprises about 1400 species in over 60 genera, of which over 800 species in 45 genera are from Australia. Africa claims about 400 species, including 330 species in 14 genera from the western Cape. About 90 species occur in Central and South America, 80 on islands east of New Guinea, and 45 in New Caledonia. Madagascar, New Guinea, New Zealand, and Southeast Asia host small numbers of species (Rebelo 1995).

Proteas are neither herbaceous nor annual, and they are always woody. Their structural habit is variable from groundcover forms with creeping stems, and those with underground stems, to vertical to spreading shrubs, to tree forms. The leaves are generally large, lignified, hard, and leathery. A mature leaf will generally snap rather than fold when bent. The leaf anatomy is specially adapted for water conservation and drought resistance. These characteristics and the high leaf carbon to nitrogen ratio render the leaves indigestible to most insect pests (Rebelo 1995), accounting for the relatively pest-free status of most commercial protea plantings.

The distribution of the family is linked to the occurrence of soils that are extremely deficient in plant nutrients (Brits 1984a). An accommodating characteristic of the family is the presence of proteoid roots. These are dense clusters of hairy rootlets that form a 2–5 cm thick mat at the soil surface which enhances nutrient uptake from the nutrient-sparse soils on which the Proteaceae evolved. All species examined so far, in at least ten genera, possess proteoid roots (Lamont 1986).

The capitulum, in which the flowers are borne on a flat or pointed receptacle, is the most common type of flowerhead. Involucral bracts surround the receptacle and may be prominent, as in *Protea*, or inconspicuous, as in *Leucospermum*. Involucral bracts in *Leucadendron* are also inconspicuous, but the floral bracts of female plants are large and develop into woody cones. An important taxonomic feature of the family is that its flowers do not have separate sepals and petals. The perianth is made up of a single set of four segments called tepals. As a bud opens, the perianth segments curl back to expose the style which extends from the superior ovary to the stigma. In some species, small floral nectaries at the base of the ovary secrete nectar to attract pollinators (Rebelo 1995). Another adaptation of evolution that has become important in the utilization of *Leucospermum* and *Protea* as cutflowers is bird pollination. The large, usually solitary, terminal flowers of these genera, and their predominant colors of creamy white, and blends of yellow, orange, and red, colors birds are attracted to, are probably adaptations to pollination by the Cape Sugarbird, *Promerops cafer*, and other nectar eating native birds. This is thought to be the prime reason why the South African species, and perhaps particularly *Leucospermum* and *Protea*, are the most attractive of the family and have excellent potential as cutflowers (Brits 1984a).

The floral biology of proteas is protandrous, with anthesis occurring prior to the stigma becoming receptive; a mechanism to help insure cross pollination. Most *Protea* seem incapable of self-pollination, although certain *Leucospermum* and *Serruria* species will produce seed when self pollinated. There are four types of pollinators, or pollen delivery; rodents, birds, insects, and wind. The flowerheads of certain *Leucospermum* and *Protea* species are visited by several species of gerbils, mice, rats, and shrews. Many *Leucospermum*, *Mimetes*, and *Protea* species are pollinated by birds. Since birds do not rely on smell, bird-pollinated species have little if any scent. The small species of *Leucospermum* and *Protea* are pollinated by bees and wasps and a few other insects; *Leucadendron* are pollinated by several beetle species, and most small-flowered genera are visited by a number of beetle, fly, and wasp species. Ten *Leucadendron* species are the only wind-pollinated proteas in southern Africa (Rebelo 1995).

The hermaphrodite species of protea are extremely low seed producers, with only one to 30% of flowers resulting in seed. It is surmised that a large percentage of hermaphrodite flowers function only as males. Another reason for low seed production may be the plant's need to produce nutrient rich seeds to reduce seedling mortality in a nutrient-poor environment. However, dioecious species generally have a high seed set, possibly because all flowers on a female plant are reproductively functional (Rebelo 1995).

HISTORICAL

In 1771, the great Swedish botanist Carl Linnaeus wrote a colleague in Amsterdam, "*Inexhaustum credo Cap. B. spei esse plantarum speciebus; certe nulla Flora ditior erit*." Freely translated this reads, "I believe the Cape of Good Hope is by no means exhausted of plant species; surely no other flora could be richer..." The Australian Proteaceae contain more genera, but it is the South African ones that have attracted the interest of the world, commencing with the attempts by Joseph Knight to cultivate them under artificial conditions in the late 1700s. They proved to be difficult subjects, but the first flowers produced outside of South Africa were shown at the Royal Botanical Gardens at Kew in 1774 and 21 species had bloomed there by 1810. In the 18th and 19th centuries they became a "patrician indulgence" as collections were found in the royal conservatories from St. Petersburg to Paris (Parvin 1984).

Although there has been much exploration of the Cape Floral Kingdom over the past 400 years, new species are still being found, many of them in the Proteaceae. The interest in this family began with the 1605 description by botanist Carolus Clusius of the flowerhead of *Protea neriifolia* as thistle-like, graceful, and unique. The Proteaceae are often the most prominent elements of the Cape fynbos with large, stiffly erect flowerheads. A cut flower industry developed around flowers harvested from the fynbos (Brits 1984b). A far-sighted Stellenbosch farmer, Mr. Frank Batchelor pioneered the development of the commercial protea industry in South Africa as he retired from deciduous fruit production. From wild-collected materials, he moved into selection, hybridization, and vegetative propagation, recognizing that superior quality was required for the marketplace (Soutter 1984).

Contemporaneously, Marie Vogts took up the challenge to learn more about the habits and production of proteas. Wild plants in their natural habitat were her reference books as she established cultivated plantings which could be studied and compared. By the late 1950s, she had acquired enough knowledge to conclude that proteas could be cultivated, and her book "Proteas: Know them and grow them" (1958) was published. The book focused attention on the economic possibilities of proteas. Continuing her work, she sought out the natural variants that occurred in the mountains and brought them into cultivation. Seeing horticultural potential as well as marketability in these variants, she recognized the variations in flowering times at different sites as important to extending the marketing season (Vogts 1984). She was instrumental in founding the Protea Research Unit of the South African Department of Agriculture and focusing its attention on the genetic variability of wild populations and interspecific hybrids, and initiating a research program to improve their adaptability to cultivation (Brits 1984b). Her four decades of research and investigation laid a foundation for an industry that benefits not only South Africa's landed establishment, but also their rural peoples, and that has reached beyond the Cape Floral Kingdom to Australia, New Zealand, Israel, California and Hawaii, Zimbabwe, El Salvador, Chile, the Canary Islands, France, and other distant lands. Thus, this "alternative crop/new crop" has a long and honorable history predating the 1990s interest.

The University of Hawaii became involved in 1964 when a visiting professor of Horticulture, Dr. Sam McFadden, imported seed of various Proteaceae for trial in Honolulu. The next year additional seed were planted at the Maui Agricultural Research Center, 1000 m up the slope of

Haleakala crater, where they flourished. Evaluations were made in 1969 separating 34 species into those suitable for cutflowers, for landscaping, and those unsuitable for either purpose. In 1970, 63 species of nine genera were imported, and a research program with emphasis on propagation and nutrition began to take form (Parvin et al. 1973). It was soon recognized that *Leucospermum* flowered on Maui as much as two months earlier than in California, suggesting the potential for a competitive advantage for a Hawaii export industry (Parvin 1984) if early flowering cultivars of horticultural merit could be obtained or created. The first pollinations in a new breeding program were made in 1972. The current research program emphasizes breeding for improved cultivars for cutflower production, the physiology of flowering, disease management, and postharvest handling and storage for *Leucospermum* and *Protea*.

The results from protea research programs in South Africa and Hawaii, and to an extent, Israel, have helped to stimulate protea cultivation in those and several other countries around the world, primarily for the international cutflower trade. Europe has been the traditional market for protea, but the United States and Japan have significantly expanded floral consumption and increased purchases of protea in recent years. Israeli market research recently reported that the world-wide cutflower markets can still absorb large quantities of proteas without lowering prices, but that the market is in need of new cultivars to refresh existing selections (Danziger 1997).

The emphasis on cultivar development is put into perspective by Soutter (1984); "It is generally said that a horticultural industry is only as good as its cultivars, and certainly in the case of floriculture, one can add the rate at which new cultivars are placed on the market." Numerous cultivars have been introduced by scientists and commercial breeders, hobbyists, and plant and flower collectors gathering from the native fynbos. *The International Protea Register*, Stellenbosch, South Africa, now in its fourth edition, keeps track of named cultivars along with their origin and brief descriptions to the extent it can obtain the information. This valuable resource allows researchers and producers to exchange plant materials and communications about known cultivars and their adaptability and performance in cultivated situations around the world. Table 1 summarizes the registered cultivars, and cultivars recognized but not yet registered, of four protea genera.

Table 1. Summary of cultivars in The International Protea Register (the number of interspecific hybrids is in parentheses).

Genus	Named cultivars					
	Registered		Recognized but not registered		Total	
Leucadendron	12	(5)	101	(18)	113	(23)
Leucospermum	30	(19)	58	(15)	88	(34)
Protea	42	(24)	139	(29)	181	(53)
Serruria	2	(2)	4	(1)	6	(3)
Total (4 genera)	86	(50)	302	(63)	388	(113)

The register also lists cultivars of unknown origin, including 14 *Leucadendron*, 14 *Leucospermum*, and 24 *Protea*. It lists only one intergeneric hybrid, (*Mimetes* × *Leucospermum*) 'Splendidus'. The

86 registered cultivars are authored by 20 registrants from five countries; Australia, New Zealand, South Africa, United States, and Zimbabwe (Sadie 1997).

The International Protea Association (IPA) supports the promotion and commercial production of protea as well as scientific research and conservation of native germplasm (Mathews 1984). The IPA held its 9th biennial conference in Cape Town, South Africa, in August 1998 with representatives from 12 nations participating. Regional production and marketing reports were made by industry leaders, while academics and graduate students gave oral and poster presentations on research progress in areas of conservation, pest and disease management, cultivar development, propagation, pruning, irrigation, nutrition, and postharvest physiology.

Economically, the most important protea species is *Macadamia integrifolia*, the only native food plant in Australia to achieve international status as a commercial nut crop. Macadamia breeding and selection work was initiated in 1934 by the University of Hawaii, and over the next 50 years 13 cultivars were introduced from 120,000 seedlings evaluated. Commercial development of this crop began in Hawaii in the 1940s (Hamilton and Ito 1984). Hawaii was the world's leading producer until Australia recently claimed that spot. Today, this gourmet dessert nut is cultivated commercially in Australia, Brazil, Costa Rica, Guatemala, Hawaii, Kenya, Malawi, South Africa, and Zimbabwe. Recently, China established commercial plantings on Hainan island.

Selected Proteaceae floral crops were analyzed for their potential profitability, on a hypothetical 4 ha farm, and determined to be profitable, given adequate farm management and marketing. A computerized spreadsheet model of protea production in Hawaii enables one to estimate profitability over a wide range of conditions (Fleming et al. 1991, 1994). The computerized program is available free by contacting fleming@hawaii.edu.

A variety of protea species have uses within or near their habitat. The seeds of *Brabeium stellatifolium* of South Africa are roasted and eaten or used as a coffee substitute. The seeds of *Finschia chloraxantha* from New Guinea and *Gevuina avellana* from South America are eaten by natives. The timbers of the Australian silky oaks *Cardwellia sublimis*, *Orites excelsa*, and *Grevillea robusta* are used in furniture and panelling. The Australian *Oreocallis wickhami* and *Banksia serrata* are used for yokes and boat knees, and the wood of *B. verticillata* for railway carriages and furniture. *Hakea leucopteris* and *H. vittata* wood is used for smoking pipes. The barks of *Faurea saligna* and *Leucospermum conocarpum* are used for tanning leather in South Africa. Species reported to have medicinal uses are *Faurea speciosa* for ear drops (root and leaf extract), and *F. saligna* to treat dysentery and diarrhea (root extract). Most protea flowers are of value to apiarists for their abundant nectar production (Rao 1971).

PROTEA

Protea is a large genus with 136 species of which 70 are distributed in the southern hemisphere temperate zones and the balance distributed in southern hemisphere sub-tropical to tropical zones, with 3 extending above the equator into the northern tropics (Rao 1971). Of the 117 species native to the African continent, 82 are from South Africa (Vogts 1982). A recent account of *Protea* species in Southern Africa lists 90 species and numerous subspecies (Robelo 1995). Linnaeus named the genus *Protea* in 1735 after the Greek god Proteus, who, according to legend, was able to transform his shape and appearance into numerous animate and inanimate forms at will (Robelo 1995). It was from the name *Protea* that the family name Proteaceae was assigned by the French botanist Jussieu (Rousseau 1970).

The natural habitat of *Protea* ranges in elevation from sea level to over 2000 m. In South Africa a rich diversity of species inhabit the well-drained, moderately-acid, low fertility, granite soils from Cape Town to the Table Mountain areas up to 1300 m (Parvin et al. 1973).

The genus is characterized by large bracts, often brightly colored, surrounding a composite type flower. The bracts are smooth or pubescent, with many species having bracts fringed with a dark "fur" lending a tactile as well as visual appeal. The range of colors includes red, pink, yellow, white, and occasionally green (Watson and Parvin 1973). The most widely recognized species in the genus is *Protea cynaroides*, the King Protea, the national flower of South Africa. It has flower heads up to 30 cm across, with widely spaced bracts arranged around a peak of flowers that vary in color from near white to soft silvery-pink to deep rose pink to crimson, in a few selected cultivars.

Many natural variants of *P. cynaroides* can be placed into three South African ecotypes. Those from the eastern cape and southern coastal plain have long leaves on long stems that terminate with relatively small but wide-open flower heads. They are very attractive but difficult to pack. The plants are vigorous and bear 10 to 20 heads per plant. Variants from the Outeniqua mountains region bear large bowl-shaped rose colored flower heads on thick stems. The heads are more easily packed because the bracts do not flare out. Average flower head yield is five to eight per plant. The variants from the Western Cape region are slow growing and average only about four heads per plant, but are described by Vogts (1980) as beautifully goblet-shaped. A miniature form of *P. cynaroides*, with flower heads the size of a typical pincushion protea, offers much promise for expanded florist use of this species. *Protea cynaroides* generally show good resistance to *Phytophthora* root rot (von Broembsen and Brits 1986).

Several clonal selections of *P. neriifolia* are grown commercially for their prolific production of fall and winter blooms. The plant becomes a large shrub with foliage resembling that of oleander. Flower heads range in color from light pink to rose to dark red, with some white selections known. Some selections have silvery hairs subtending tufts of black hairs at the bract tips. Plants of 20 years age have been reported to bear commercial quality flowers (Vogts 1980). This species also shows good resistance to *Phytophthora* root rot (von Broembsen and Brits 1986).

The grey-leaf sugarbush, *P. laurifolia* (formerly *P. marginata*), is similar to *P. neriifolia* for many characteristics, although their natural distributions do not overlap and natural hybrids between the two do not occur. To the non-taxonomist, foliage characteristics may be the most distinguishing feature between the two species. The leaves of *P. laurifolia* are grey-green to blue-green, elliptic and broader than the bright green leaves of *P. neriifolia* (Vogts 1982). If left unmanaged, *P. neriifolia* will grow to become an erect shrub 3 m tall while *P. laurifolia* will become an 8 m tall tree (Robelo 1995).

Protea magnifica, the Queen protea, is somewhat susceptible to *Phytophthora* (von Broembsen and Brits 1986) but is still grown for its large 15 to 20 cm flower heads of white to rose pink to salmon colors. Many cultivars have black-and-blond tufts of hair on the bract margins (Vogts 1980) and are sometimes referred to as woolly-beard protea.

The rose-spoon protea, *P. eximia*, gets its common name from the long spathulate inner bracts that are widely splayed and easily distinguish this large flowered species from others (Vogts 1982). These bracts range in color from pink to orange-brown. Awns extending from the perianth have purple-black velvety hairs. Plants generally range in height from 2 to 5 m, are sparsely branched, and flower from early winter through late spring (Robelo 1995). A tall tree-like variant reaches peak flowering in summer (Vogts 1982).

Long, narrow leaves, and flower heads with pointed bracts characterize *P. longifolia*. Bract color is variable from white to pink and green. Plant stature and growth habit are also variable in its native stands, where many natural hybrids with other *Protea* species overlapping its range have been found.

Protea grandiceps, also somewhat susceptible to *Phytophthora* (von Broembsen and Brits 1986) comes from high elevation mountainous regions that are snow-covered in winter. It is a slow growing long-lived plant that bears up to 40 salmon-colored flower heads of 10 to 15 cm. Plants can be cultivated for more than 20 years (Vogts 1980).

The sugar bush, *P. repens*, is widely grown commercially for its white to pink to deep red colors and long flowering season (Vogts 1980). It is another species with good resistance to *Phytophthora* root rot and can be used to replant *Phytophthora* infested fields (von Broembsen and Brits 1986).

Protea compacta has lanky flower stems on a stiffly upright, sparsely branched shrub that grows to 3.5 m tall. The rich pink bracts, with their light-reflecting fine-hair-fringed margins are longer than the cup-shaped flower heads. The prominent flower heads, unobscured by foliage, make fine winter cutflowers (Vogts 1982).

Numerous selections of these and other species, and of naturally occurring hybrids that have been identified from the South African fynbos, are cultivated by commercial growers. Cuttings of 22 named selections of *Protea* of South African origin were imported by the University of Hawaii in 1988, propagated, field planted, and evaluated for adaptability and plant growth characteristics at its Kula Agricultural Research Center on Maui. Yield, seasonality of bloom, and keeping quality were recorded from 1989 to 1993. The yield and seasonality over a 12 month period (August 1992 through July 1993) of the seven cultivars that produced 30 flowers or more are reported in Table 2. By careful evaluation of seasonality in localized climates, it is possible to select cultivars to cover a large portion of the year, although some months may not be well represented (Criley et al. 1996).

Table 2. Yields and seasonality on Maui for selected South African *Protea* accessions.

Cultivar	Yield (12 mo)	Months of flowering											
		Aug.	Sept.	Oct.	Nov.	Dec.	Jan.	Feb.	Mar.	Apr.	May	Jun.	Jul.

Protea can be propagated from seed, with the resulting variation expected of cross-pollinated heterozygous materials. Given the availability of clonal selections, the method of choice among progressive commercial growers is to propagate from cuttings. Terminal and sub-terminal cuttings are made from the current season's mature growth. Robust cuttings of 20 to 25 cm in length root readily, for most cultivars. Longer cuttings may be taken if the grower desires to have lower branches well above ground level. Removing half of each leaf of long leaf cultivars is a common practice. An IBA auxin treatment of 4000 to 8000 ppm is beneficial. The rooting medium should be very well aerated but not allowed to dry. Mixtures of 25% to 50% peat with the balance being polystyrene or perlite has given good results. Rooting is generally done under standard mistbed conditions. An approved fungicide sprayed over the cuttings following planting can prevent infections. Rooting time is variable among species, with *P. cynaroides* rooting quickly and *P. neriifolia* often taking many weeks (Mathews 1981).

When selecting a production site, good soil drainage is the most important requirement for protea production. Deep soils that allow expanded root development and can store a good supply of water and nutrients are preferred, but shallow soils can be suitable if drainage is rapid and frequent irrigation can be provided (Claassens 1981).

Relatively low concentrations of nutrients are required for normal growth of proteas. Most species react favorably to nitrogen, particularly in the ammonium form, while most are intolerant of amounts of phosphorus that would be considered moderate for non-proteaceous plants. Protea plants seem to have a very effective mechanism to scavenge phosphorous from soils with low phosphorus status (Claassens 1981, 1986).

Cresswell (1991) produced a tissue analysis standard for assessing the appropriate phosphorus status for two *Protea* cultivars. Only the desirable ranges are reported in Table 3. Values lower or higher than those reported here were considered low to deficient or high to toxic, respectively.

Table 3. Desirable ranges of phosphorus in tissues of two *Protea* cultivars.

Cultivar	Desirable phosphorus (ppm)		
	Stems	Recently matured leaves	Old leaves
Satin Pink	0.19–0.35	0.19–0.29	0.21–0.44
Pink Ice	0.06–0.29	0.06–0.27	0.16–0.46

The recommended developmental stage for harvesting most *Protea*, to insure market quality and acceptable postharvest life, is the so-called soft-tip stage when bracts have lost their firmness and begin to loosen but still cohere (Meynhardt 1976). At this stage, few insects are present because anthesis has not yet occurred, so there is little to attract them. However, flowers picked too early will not open (Coetzee and Wright 1991). A serious problem with marketing several species of *Protea* is the undesirable discoloration of leaves soon after harvesting. The problem is most pronounced in *P. eximia* and *P. neriifolia*, and their hybrids, and to a lesser extent with *P.*

compacta and its hybrids (Ferreira 1986; Paull 1988).

Leaf blackening, or browning as it is sometimes called, in *Protea* is caused by carbohydrate depletion due primarily to the sugar demand by the inflorescence for nectar production (Dai and Paull 1995). Low availability of mobile carbohydrates in the leaves, combined with the high respiratory demand of the inflorescence, resulted in a 70% decline in mobile leaf carbohydrate levels in *P. neriifolia* within 24 hours of harvest (Jones et al. 1995). Warm temperatures and low light in postharvest storage have been correlated with increased rates of leaf blackening (Ferreira 1986). Refrigeration, especially during postharvest storage, packaging, and shipping periods, has a most significant effect on delaying the onset of leaf blackening (Paull 1988). Refrigeration will slow respiration, reduce water stress, and slow nectar production by the inflorescence, thereby conserving carbohydrate reserves in the stem and foliage. A storage and transport temperature of 2° to 5°C will help ensure bloom quality and postharvest life (Coetzee and Wright 1991). Pulsing cut *Protea* stems in a 1% sucrose solution, or a floral preservative solution, before packing and especially post-unpacking is an effective treatment to delay the onset of leaf blackening (Brink and de Swardt 1986; Paull 1988). Another form of leaf browning results from fumigation with methyl bromide (Coetzee and Wright 1991), which imported shipments are often subjected to if insects are present. Growers should practice good field sanitation and appropriate postharvest disinfestation practices prior to packing, so that agriculture inspectors at the receiving end will not fumigate the shipment.

Natural hybrids within the genus *Protea* are not an uncommon occurrence where the geographic ranges of two or more species overlap. Scientists at the Fynbos Research Unit, Elsenburg, South Africa, have made a collection of such natural hybrids and in most cases have been able to determine their parentage (Table 4). Some of these meet standards of commercial horticulturists and have been released to South Africa's protea industry. Dr. Littlejohn, the protea breeder at Elsenburg, recently initiated a program to produce controlled hybrids in the genus *Protea* to further benefit the protea industry.

Table 4. Recent *Protea* hybrids of South African origin.

Sheila	(*P. magnifica* × *P. burchelli*)
Venetia	(*P. magnifica* × *P. neriifolia*)
Pink Duke	(*P. compacta* × *P. susannae*)
Candida	(*P. magnifica* × *P. obtusifolia*)

Venus	(*P. repens* × P. aristata)
Liebencherry	(*P. repens* × *P. longifoli*)
unnamed	(*P. cynaroides* × *P. nitida*)
unnamed	(*P. cynaroides* × *P. repens*)

LEUCOSPERMUM

Leucospermum species are evergreen woody perennials with growth habits that range from small trees to spreading shrubs to prostrate ground covers. The most widely grown species are floriferous, spreading shrubs on which relatively short-stemmed inflorescences are borne in the spring. Horticulturists have had to develop management practices to improve stem length and straightness for their use as cut flowers.

Rourke (1972) and Jacobs (1985) describe the inflorescence as a capitulum that develops from an axillary rather than a terminal bud, but that appears to arise distally. Inflorescences may be solitary, as in *L. cordifolium*, *L. lineare*, and *L. vestitum*, or in clusters (conflorescences), as in *L. oleifolium*, *L. tottum*, and *L. mundii*. The individual florets consist of a perianth formed by four fused perianth segments, one of which separates from the other three as the flower opens. The perianth curls back to display a prominent style; the striking appearance of the whole inflorescence of open flowers resembles a pincushion—thus one of the common names is pincushion protea. The styles, perianth, and involucral bracts may be white, yellow, pink, orange, or red and the combinations are responsible for the popularity of the pincushion proteas as cutflowers.

Although most of the *Leucospermums* are indigenous to nutrient-poor, coarse, acidic, sandstone-derived soils, they seem adaptable to a variety of soil types within a narrow range of pH and fertility levels. This is evidenced by their culture in several regions of southern Africa, southern California, Israel, Australia, and in the volcanic soils of Hawaii and the Canary Islands (Criley 1998).

Propagation of the commercial cultivars of *Leucospermum* is by cuttings, of which most root readily. While cuttings can be rooted at almost any physiological stage of development, a preferred cutting is the recently matured new growth, known as a semi-hardwood cutting (Malan 1992). This type of material is gathered in autumn after shoot growth terminates.

A tissue culture protocol for *Leucospermum* was developed using axillary bud explants induced to proliferate on a basal medium of half-strength Murashige and Skoog inorganic salts supplemented with sucrose and benzyl adenine (Kunisaki 1989, 1990). *Leucospermum* Hawaii Gold, propagated from tissue cultures, is flowering at the Kula Agriculture Research Center and appear identical to the type cultivar from which the explants were taken.

Grafting is often viewed as a solution to problems of root system adaptation to low or high pH soils, or soil-borne diseases. The selection of rootstock plays a significant role in improving adaptability and yield of *Leucospermum* (Van der Merwe 1985). Grafting onto lime-tolerant rootstocks, such as *L. patersonii*, has been recommended as an approach to problems of protea production on soils of neutral to slightly basic pH (Brits 1984b). The standard grafting technique is wedge-grafting of leafy semi-hardwood scions onto selected rootstocks (Rousseau 1966; Vogts et al. 1976). Cutting grafts, where the graft union develops while the cutting roots, is also recommended (Brits 1990b). Brits (1990c), in screening 19 species and several hybrids for their potential as rootstocks, determined that *L.* 'Spider' (a primary hybrid of *L. formosum* × *L. tottum*) has a degree of tolerance to *Phytophthora cinnamomi*. *Leucospermum* 'Spider' is presently being used as a rootstock by several commercial producers in South Africa. *Leucospermum saxosum* has also been determined to have low susceptibility to *Phytophthora* (Moffat and Turnbull 1994), and a selection of *L. patersonii*, designated 'Nemastrong', has tolerance to nematodes (Ackerman et al. 1995). Such rootstocks may have the potential to expand and increase yields of plantings where *Phytophthora* and nematodes are a problem.

The production period for *Leucospermum* is late winter to late spring. Parvin (1974) reported that 65% to 75% of the total crop of *L. cordifolium* 'Hawaiian Sunburst' was harvested from Dec. through Feb. in Hawaii. They are also high yielding. During a three-year study, beginning with 6-year-old plants, the per plant yields averaged 600 to 650 flowers.

Research on postharvest handling practices has shown that the pincushion protea will tolerate cool, dry, long-term storage and still provide a useful vaselife. *L. cordifolium* flowers that were cooled and hydrated at 1°C in water, wrapped in newsprint and bagged in plastic film withstood periods of three and four weeks at 1°C storage, and after rehydration, possessed an average vaselife of 8 days (Jones and Faragher 1990). Downs and Reihana (1986) found significant varietal differences in vaselife following a period of simulated transport, with the New Zealand cultivar 'Harry Chittick' at 35.5 days, a Hawaii hybrid of *L. lineare* × *L. cordifolium* at 29.7 days, and 'Veldfire', a South African hybrid at 16.9 days.

Parvin (1978) improved vaselife with 2% to 4% sucrose plus 200 to 600 ppm hydroxyquinoline citrate solutions. Silver nitrate at 1000 ppm did not benefit cultivars of *L. cordifolium* but improved vaselife for the hybrid *L.* 'Hawaii Gold' (Parvin and Leonhardt 1982). Criley investigated revival of wilted flowers with extruded styles, in order to increase packing densities for export shipments. Flowers pulsed with a preservative prior to partial dehydration (20% loss of FW) and storage (24 h at 13°C) could be revived, although vaselife was not as long as with fresh cut flowers (Criley et al. 1978a,b). Flowers cut in bud (7 cm diam.) offered better promise, with full development and less loss of vaselife than flowers cut at a younger stage (Criley et al. 1978a; Parvin and Leonhardt 1982).

While a number of Proteaceae may be grown as potted plants, the *Leucospermums*, with their relative ease of rooting and attractive floral display, have the greatest potential (Sacks and Resendiz 1996). Criley (1998) reported that budded cuttings flowered soon after rooting, adding confirmation to their potential as potted plants, and proposed that stock plants be manipulated to achieve stronger branches for this use.

Research on photoperiod responsiveness of *Leucospermum* (Wallerstein 1989; Malan and Jacobs 1990) indicates that daylength manipulation may have implications for potted flowering plant production. High light intensity was shown to be necessary for flowering (Jacobs and Minnaar 1980; Napier and Jacobs 1989; Ackerman et al. 1995) and to promote rapid rooting of cuttings.

Leucospermum species suitable for potted plants are of two types: those having a single large inflorescence, such as *L. cordifolium*, *L. lineare*, and *L. tottum*; and those with small multiple inflorescences (conflorescences) such as *L. oleifolium*, *L. muirii*, and *L. mundii* (Brits et al. 1992; Ackerman et al. 1995; Brits 1995a). It is important to select material that will root rapidly and support flower initiation and development on a young root system (Ackermen and Brits 1991; Brits et al. 1992).

Although the genus *Leucospermum* consists of 48 species (Rourke 1972), little genetic improvement through hybridization has taken place until relatively recently. Jacobs (1985) reported that only a few species were utilized as cut flowers (*L. cordifolium*, *L. patersonii*, *L. lineare*, *L. conocarpodendron*, *L. vestitum*), but that natural and man-made interspecific hybrids exist as clonal selections. Collection and introduction of natural interspecific hybrids has occurred (Brits and van den Berg 1991), and controlled crosses were made between species in efforts to produce later flowering, improve color and shape, and to introduce tolerance to *Phytophthora cinniamomi* (Brits 1992a). Today, active breeding programs are being conducted at the Fynbos Research Station, Elsenburg, South Africa (Brits 1992a,b; Littlejohn et al. 1995) and at the Maui Agricultural Research Station of the University of Hawaii (Ito et al. 1978, 1979, 1990; Leonhardt et al. 1995), and in Israel (Shchori et al. 1995).

As of the fourth edition of the *International Protea Register* (*International Registration Authority: Proteas 1997*), 30 cultivar names have been registered and another 58 have been noted but not registered for selections and interspecific hybrids (Criley 1998). Among the hybrids registered, only three are advanced hybrids (having more than two species in their genealogy). These hybrids, developed and registered by the University of Hawaii, are:

L. 'Rachel', with parentage (*L. lineare* × *L. vestitum*) × *L. glabrum*

L. 'Hawaii Moon', with parentage (*L. lineare* × *L. cordifolium*) × *L. conocarpodendron*

L. 'Kathryn', with parentage (*L. lineare* × *L. cordifolium*) × *L. conocarpodendron*

The criteria for developing new *Leucospermum* cultivars must consider the needs of growers, handlers, retailers, and consumers. The criteria developed for the Hawaii breeding program includes disease resistance, earliness to flower, an extended flowering season, long slender and straight stems, slender leaves, reduced leaf pubescence, ease of propagation, high yields, good postharvest characteristics, new and improved colors, and market acceptance (Leonhardt et al. 1995). Leaf and stem characteristics, and disease resistance are given emphasis.

Many commercial *Leucospermum* cultivars are bulky, heavy, and cumbersome to pack due to large stem diameters and large heavy-textured leaves. These are undesirable characteristics, particularly to exporters, because freight charges are based on a formula that considers cubic dimensions and weight of the box. A densely packed, light-weight box reduces the per-bloom freight charge and allows exporters to compete more favorably in overseas markets. The species *L. lineare*, and particularly the selection *L. lineare* 'Starlight', has slender, light-weight yet strong stems with narrow, nearly needle-like foliage. Breeding has demonstrated that these characteristics are heritable and that *L. lineare* hybrids have improved leaf and stem characteristics. *Leucospermum lineare* is also free of foliar pubescence. Foliar pubescence attracts and retains moisture, which provides an environment for fungal spore germination and infection (Leonhardt et al. 1995).

The most important diseases occurring on protea in Hawaii are root and collar rots caused by *Phytophthora cinnamomi*, *P. nicotianae*, and *Cylindrocladium* sp., stem and leaf scab caused by *Sphaceloma* (Elsinoe) sp., leaf spots and blights caused by *Drechslera biseptata* and *D. dematioidea*, leaf spec caused by *Alternaria alternata*, and root knot galls caused by *Meloidogyne incognita*, the root-knot nematode (Nagata and Ferreira 1993). Root-knot nematodes can severely limit growth and productivity of *Leucospermum*. Heavily infected plants show stunting and chlorosis, followed by death of the plant (Cho et al. 1976; Cho and Apt 1977). Wu reported that this nematode can reduce cut flower yields by at least 25% in infected fields compared to fumigated fields (Wu et al. 1978).

The Hawaii breeding program has utilized ten species and numerous F_1, F_2, and F_3 hybrids to produce seedling populations that are evaluated for disease resistance and other horticultural characteristics (Leonhardt et al. 1995). Some of the parental materials are used for very specific purposes. A selection of *L. saxosum* for example, was determined to be immune to *Sphaceloma* (Elsinoe scab disease) (Nagata et al. 1995) and has been used to impart resistance into commercial hybrids. Among hybrids, *L.* 'Rachel' has demonstrated a good level of resistance to *Sphaceloma*, and has also shown a good level of resistance to two isolates causing *Botrytis* blight and moderate resistance to two isolates causing *Drechslera* blight. The hybrid *L.* 'Ka Hoku Hawaii' (Hawaii Star), *L. cordifolium* × (*L. lineare* × *L. vestitum*), and the unnamed hybrids No. 36, *L. lineare* × [*L. conocarpodendron* × (*L. lineare* × *L. cordifolium*)], and No. 49, [*L. conocarpodendron* × (*L. lineare* × *L. cordifolium*)] × *L. cordifolium* 'Sweet Lemon', have shown a good level of resistance to both *Drechslera* isolates. The hybrids *L.* 'Pohaka La Hawaii' (Hawaii Sunbeam), (*L. lineare* × *L. glabrum*), and No. 36 have shown a good level of resistance to *Botrytis* isolates (Nagata et al. 1995; Leonhardt et al. 1995).

Commercial producers in Hawaii compete in North American markets with California producers. The flowering season for *Leucospermum* begins several weeks earlier in Hawaii than in California. Producers in Hawaii could enjoy this advantage for a longer period if earlier flowering cultivars could be developed. The species *L. patersonii* and *L. pluridens* are among the earliest-flowering, and are being used in breeding for that quality. Two accessions of *L. pluridens* × (*L. lineare* × *L. cordifolium*) flower earlier at the Maui Agriculture Research Station than the hybrid parent (Leonhardt et al. 1995).

LEUCADENDRON

The South African genus *Leucadendron* contains about 60 species, collectively referred to as the conebushes. They are easily identified since they are dioecious, having plants of separate male and female sexes. Both sexes have terminal flowerheads. Female plants produce woody cones containing fruits and seeds while male plants do not produce cones. The cones on female plants consist of spirally arranged floral bracts which partially cover the cone. Male plants are often larger and more heavily branched and may have smaller leaves than female plants (Robelo 1995).

As with most Proteaceae, the *Leucadendrons* grow best in areas with light, well-drained soils with low concentrations of dissolved salts, an adequate supply of fresh water, temperatures in the range of 7°C to 27°C, and frequent if not regular light winds. *Leucadendrons* require an acid soil with a pH not exceeding 5.0. Sandy soils with some humus provide the best growing medium (Vogts 1980).

Several species are cultivated commercially for their decorative foliage, including *L. argenteum, L. discolor, L. galpinii, L. laureolum, L. salicifolium, L. salignum, L. tinctum*, and *L. uliginosum*. *Leucadendron argenteum*, the 'Silver Tree', can grow to a 8 m tall tree if left unmanaged. Its leaves are grey-green with abundant fine satiny silver hairs that glisten in sunlight. It is grown for its long-lasting cut foliage, and also makes an attractive landscape plant. Its natural habitat is arid, and in cultivation it will succumb to overwatering, soil fungi, and nematodes. *Leucadendron discolor*, harvested in winter and spring, ranges in color from light to dark green to yellow to red, and is a spreading bush up to 1.5 m high. *Leucadendron laureolum* is chartreuse to bright yellow when flowering in winter and spring while *L. salignum* (formerly *L. adscendens*) is bright red, becoming more intensely colored as temperatures decrease. A particularly outstanding cultivar is the female selection *L. salignum* 'Safari Sunset'. *Leucadendron uliginosum* has elegant, slender shoots covered with numerous shiny, silvery leaves (Vogts 1980, Kepler 1988).

The genetic variation in *Leucadendron* is vast and largely untapped for breeding purposes (Littlejohn et al. 1995), although a few hybrids have been introduced to the commercial trade, mostly from South Africa. Hybrids cultivated by commercial growers include *L.* 'Silvan Red' and *L.* 'Inca Gold', both (*L. laureolum* × *L. salignum*), *L.* 'Kam-ee-lion' (*L. salignum* × *L. eucalyptifolium*), and the recent South African introduction *L.* 'Rosette' (*L. laureolum* × *L. elimense* ssp. *salterii*), which can be harvested as a green, yellow, or red-brown product, depending on the season (Littlejohn et al. 1998).

In addition to their highly colorful, easily packaged, long and long-lasting cut stems, a characteristic of many *Leucadendrons* that makes them commercially important is their potential for very high yields. Pruned and managed *L.* 'Silvan Red', in a 3 year study at 3 locations averaged 265 marketable stems per plant per year (Barth et al. 1996). This cultivar can be harvested in the fall as a red-foliaged stem, and in the winter as a tricolor stem with yellow, red, and green foliar bracts. *Leucadendron* 'Safari Sunset', a selection of New Zealand origin, is probably the most widely grown commercial cultivar, with extensive plantings in Australia, New Zealand, South Africa, and Israel. The erect bushy plant is vigorous and fast growing. Its deep wine-colored bracts have excellent keeping quality, lasting up to 60 days (Tija 1986). Dr. Ben-Jaacov, in his presentation at the International Protea Association Conference in Cape Town in 1998 reported that 'Safari Sunset', under intensive management in Israel, has given yields in excess of 600,000 marketable stems per hectare per year. Recent research in South Africa compared *L.* 'Rosette' with *L.* 'Safari Sunset' for yield and stem length. In the third harvest year *L.* 'Rosette' yielded 44.5 stems per plant with 20 stems 80 cm or longer while *L.* 'Safari Sunset' yielded 37.0 stems per plant with 10 stems 80 cm or longer (Littlejohn et al. 1998). Both cultivars are exceptional commercial materials.

Although more widely known as commercial cut foliages and landscape plants, *Leucadendrons* can be grown as colorful potted "flowering" plants. The male *L. discolor* 'Sunset' naturally flowers profusely in early spring with colorful flower-heads. Israeli research has demonstrated that flowering potted plants of 'Sunset' can be produced in 3–5 months by rooting large branched cuttings with initiated flowers. The basal stems of branched 15 cm long cuttings were dipped in a 4,000 ppm IBA solution prior to sticking in a styrofoam/peat medium under intermittent mist and 25% reduced natural light. Rooting began in 4 weeks. The stage of development of the flower-head at rooting was critical for the cutting's further development into a flowering potted plant. If not fully initiated as floral buds, the meristem aborted or reverted to the vegetative state. However, when cuttings were taken at the right stage of floral initiation, colorful flowering potted plants were produced in 3–5 months. Conventional technology for producing potted flowering plants of *L. discolor* by rooting small unbranched vegetative cuttings, growing them to the appropriate size, retarding them chemically, and bringing them to flower, would take 2 years or longer (Ben-Jaacov et al., 1986). The potential for using this technology to produce attractive *Leucadendron* flowering potted plants for the commercial nursery trade is significant.

BANKSIA

The fourth largest export wildflower crop of Australia (Sedgley 1996), the genus *Banksia* is named for the famous botanist, Sir Joseph Banks. Seventy-six taxa have been described under 2 sub-genera, 3 sections, and 13 series (Sedgley 1998). *Banksia* are evergreen, woody perennials with growth habits that range from prostrate ground-huggers to trees. Most of the species are found in the south-west with the remainder along the southern and eastern coasts and tablelands. Nearly all have ornamental features that confer horticultural potential, whether as fresh or dried cut flowers, cut foliages, or in the landscape (Elliott and Jones 1982; Joyce 1998; Parvin et al. 1973; Sedgley 1998; Wrigley and Fagg 1996).

Species widely grown for cut flowers and foliages are shown in Table 5. The most popular cut flower types bear their cylindrical flower spikes terminally, but a few terminal-flowering selections have been made of axillary bearers (Sedgely 1998). Some species produce attractive flowerheads upright on horizontal branches and would need considerable management to be suitable for the commercial markets. Although many commercial plantings are produced from seed and show considerable variability, progress has been made in cultivar development (Fuss and Sedgley 1991; Sedgley et al. 1991; Sedgley 1991, 1995a,b,c,d).

Table 5. Some Banksia species suitable for cut flower or cut foliage production. Sources: Parvin et al. 1973; Elliot and Jones 1982; Salinger 1985; Sedgley 1998.

Banksia species	Cut flower	Cut foliage
ashbyi	ü	
baxteri	ü	ü
burdettii	ü	
coccinea	ü	
ericifolia		ü
grandis	ü	ü
hookeriana	ü	
integrifolia		ü
menziesii	ü	
occidentalis		ü
prionotes	ü	
speciosa	ü	ü
victoriae	ü	

Concurrent with these developments is a need to improve the vegetative propagation systems, as cutting propagation often results in development of a large knob of callus (Hocking 1976). Cutting propagation yields variable results, but the use of intermittent mist (allowing some drying between cycles) and auxin stimulates better root development on semi-hardwood terminal cuttings (Bennell and Barth 1986; Sedgley 1995c). Grafting onto various disease resistant species such as *B. robur* and *B. spinulosa* offers some promise, but additional research is needed to establish successful techniques and timing and to determine compatibility relationships and tolerance to stresses. It is necessary to avoid rootstocks that form lignotubers as these may sucker and compete with the scion (Elliott and Jones 1982). Cutting grafts have been successful with a few species (Elliot and Jones 1982).

Seed germination is reliable, but not for the hybrids, and seed supplies are limited. *Banksia* seed is produced in a hard follicle that often requires heat or heat followed by immersion in water to cause it to open. Seedlings are susceptible to damping off and should be germinated in a sterile well-drained medium. Germination requires 21 to 90 days at 20°–25°C (Elliot and Jones 1982). The optimum medium temperature can range from a constant 10° to 25°C or fluctuate by 10° to 15°C (Bennell and Barth 1986). Transplanting is done as soon as the seedling is large enough to handle.

All species grow best in light, sandy soils of acid pH. They are adapted to soils of low fertility, but benefit from a supply of calcium and application of nitrogen, potassium and iron (Sedgley 1996, 1998). Like other Proteaceae banksias tend to be intolerant to high levels of phosphorus which interfere with iron uptake (Handreck 1991). In cultivation, pruning is necessary to remove shoots that will not flower and to encourage development of shoots with sufficient diameter to initiate the inflorescence (Fuss et al. 1992; Sedgley and Fuss 1992; Rohl et al. 1994; Sedgely 1996).

Sedgley (1996, 1998) notes that there has been little published research on postharvest care of cut *Banksia*. Sucrose pulses did not improve the 15 days vase life of *B. coccinea* (Delaporte et al. 1997), and anti-bacterials such as 0.01% chlorine, acidifiers such as 0.01% citric acid, and 0.02% aluminum sulfate have been recommended as a matter of course, but without verified results (Sedgely 1996).

GREVILLEA

A large genus (more than 340 species) of shrubs and trees from dry sclerophyll forests and heaths in Australia (5 species are found in New Caledonia, Sulewesi, and Papua New Guinea), grevilleas have many ornamental uses, especially in landscapes. Growth habits of the most popular species range from prostrate ground covers to mounded shrubs. Some have unusual, asymmetric, or layered habits. A tree form, *Grevillea robusta*, flourishes in sub-tropic climates and has potential as an invasive species because of its abundant seed production.

Grevillea have been in cultivation outside of Australia for over 200 years, with the earliest record of introduction of 3 species to England in 1791 and another 15 species in the 1820s (Elliot and Jones 1990). Nurseries in New Zealand and California also grow a wide range of species for landscape uses. As these locations and their native habitats suggest, many grevillea are frost and cold tolerant to –4°C (Elliot and Jones 1990). Drought tolerance is another quality to recommend many species in areas with dry summers.

Grevillea inflorescences are mostly toothbrush-like clusters, about 5 to 12 cm in length, and running the color gamut from white and greenish through yellow, orange, purplish, and red, and include some multi-colored forms. Other inflorescence categories include upright spider-like, pendant, or terminal cylindrical clusters. Some have very strong aromas while others are pleasant and sweet. Flowering tends to be seasonal, depending upon moisture, temperature, and daylength. Flowering is strongest in sunny locations and diminished in shade (Wrigley and Fagg 1996). There are also reports of skin irritation and rash from handling some prickly as well as non-prickly species.

While a number of hybrid grevilleas and more tropical species have been selected for large colorful inflorescences (Tully 1977), they are not widely marketed as cut flowers because of short vaselife and a tendency for floret abscission. Although the best can achieve a vase life of 7 to 10 days following cutting, production is said to be low (Olde and Marriott 1995). They are also alleged to be difficult to pack. The potential for their use is good if the problems can be overcome through the use of postharvest treatments, improved packaging, and breeding and selection (Joyce et al. 1996). A sugar, 2% citric acid, and bleach mixture has been recommended for home use, together with maintaining turgor by placing the cut stems in water.

Grevillea foliage displays a wide range of textures, colors, and shapes. The textures and shapes range from deeply divided, fern-like and fishbone-like leaves to entire or broadly-lobed shapes and pinnately-divided and regularly toothed and holly-like foliage. Colors range from silver-grey to dark glossy green. Many species have attractive undersurface of silver or bronze indumentum. These elements contribute to their value as landscape plantings, but also to their use as cut foliages. Cut as a growth flush matures, the foliage may last 30 days in water or commercial floral preservatives (Parvin 1991; Criley and Parvin 1993). It is this use that has potential in the floriculture trade. Management practices for cut foliage production need to be developed.

Potted grevillea plants have wide acceptance for patio and garden use both because of their foliage and flowers. They are easily rooted and managed, both by pruning and with growth regulators (Ben-Jaacov et al. 1989). The development of tissue culture techniques enables greater availability of attractive, but difficult-to-root cultivars such as 'Robyn Gordon' (Gorst et al. 1978, Watad et al. 1992). Several potted grevilleas have been introduced into the trade by Israel producers (Ben-Jaacov et al. 1989).

Grevillea may be propagated by seed, cuttings, layers, grafting, and tissue culture. Propagation by cuttings is said to be easy with mid to late summer matured growth (Wrigley and Fagg 1996). A Hawaii study indicated that quick dips in liquid auxin formulations (2000 to 4000 ppm) applied to terminal or immediately sub-terminal growth gave satisfactory results in 5 to 6 weeks (Groesbeck and Rauch 1985). Commercial liquid and powder auxin formulations provided good rooting for a number of species. Bottom heat of 29°C with no auxin stimulated 90% take on older wood of *G.* 'Robyn Gordon' (Dupee and Clemens 1981). Interesting landscape forms have been produced by approach-grafting weeping or prostrate forms onto rootstocks of *G. robusta* (Crossen 1990) or *G. banksii* or *G.* 'Poorinda Royal Mantle'(Wrigley and Fagg 1996). The cleft graft was reported successful as well (Dupee and Clemens 1981). However, it is recommended that a healthy top bud be left near the cut to prevent dieback below the graft (Elliot and Jones 1990). Air layering is reported as regularly successful (Tully 1977). Seed germination is enhanced by a presoak in 0.2% potassium nitrate for 12–24 hours, sowing in a sandy medium, and subjecting the seed to alternating warm (25°–33°C) temperatures (Heslehurst 1977). Germination required 4 to 5 weeks. Scarification or seedcoat removal also improves germination (Dupee and Clemens 1981).

More than one-half of the species have been tried in horticulture because of their wide adaptability to a range of soil conditions (Molyneux 1978). Many of the Western Australia species are found on infertile, non-calcareous soils, sands, and leached lateritic soils. Many of the eastern species can be found in clay or clay-loam soils. A few inhabit deserts or rainforests, and some tolerate slightly saline or alkaline soils (Elliot and Jones 1990; Olde and Marriott 1995). Many of the Western Australian species are not demanding of substrate as long as it is well-drained, although there are a few that will even tolerate poor drainage (Olde and Marriott 1995). While they respond to good fertility, high nutrient levels, especially phosphorus, are not required. Controlled release fertilization with careful attention to the form provided is recommended (Bowden 1987).

Longevity under well-fertilized conditions appears to be a problem, especially where the plants are also well-watered (Specht 1978). However healthy 10 to 15 year old plants can be found. These have generally benefited from regular pruning (Elliot and Jones 1990). *Phytophthora cinnamomi* is very devastating to grevilleas (Molyneux 1978).

ISOPOGON

Isopogon is native to temperate Australian regions, with the main distribution in southwestern Australia. Many are coastal or near-coastal in habitat and grow in well-drained, highly-leached sandy or lateritic soils and gravels or clay loams. They range from sea level to moderate altitudes and cope with a wide temperature range down to –7°C, where damage occurs. Full sun is the preferred light environment, but some tolerate semi-shade (Elliot and Jones 1990).

They offer some interesting, hardy plant materials for the landscape, and possibly for the cutflower trade. Most of the 35 described species are temperate zone shrubs of 1 to 2.5 m tall, but a few can grow into small trees (Foreman 1997). Most species are small to medium-sized shrubs while others are dwarf, spreading undershrubs. A number of species are adapted to container culture.

Cone- or drumstick-shaped flower clusters, of white to yellow to pink to mauve, are borne terminally or in the upper leaf axils. Flowering is chiefly in the spring months. A few species have good vase life and are grown commercially in Australia. Among species with cutflower potential are the winter-flowering *I. cuneatus*, and spring-flowering *I. latifolius* and *I. formosus* (Salinger 1985; Elliot and Jones 1990; Foreman 1997). While their cones are decorative, the scales are often shed with the seed.

Seed is not plentiful because it is often lost when the scales dehisce from the cone. Fresh seed, sown shallowly in a moist medium, germinates in 20 to 90 days. One pregermination recommendation is to lightly singe the seed with a flame (Elliot and Jones 1990). Cutting propagation is usually successful when aided by hormone rooting powders.

In culture, controlled release fertilizers with a low phosphorus content are recommended. Established plants are fairly drought tolerant, and over-watering contributes to loss of plants because the wet conditions favor *Phytophthora cinnamomi* infection. Tip pruning following flowering stimulates bushy growth. Species with lignotubers tolerate severe pruning.

DRYANDRA

These Australian natives (120 species) have a variable growth habit, ranging from prostrate shrubs to small trees. Foliage characteristics range from soft and needlelike to tough and prickly. The flowerhead resembles a shaving brush surrounded by basal bracts. Flower colors are mainly in the yellow to orange to bronze shades. Their potential as cutflowers needs further evaluation, but some species, such as *D. formosa*, dry nicely and could be added to this niche market (Joyce 1998). Among the recommended cut flower species are *D. formosa*, *D. praemorsa*, and *D. quercifolia* (Elliot and Jones 1984). Many species have foliage so spiny that they are not suitable for floral purposes (Salinger 1985).

Propagation is generally by sowing fresh or stored seed into a well-drained, loose medium; however, seed-feeding insects often render viable seed scarce (Elliot and Jones 1984). Pregermination treatments do not seem necessary (Cavanaugh 1994). Germination times range from 3 weeks to 3 months with an average of 5 to 8 weeks. Transplanting can be done fairly early, when seedlings have attained 50–75 mm in height. Cutting and grafting propagation successes have been reported for some species (Cavanaugh 1994), but neither practice is widely used. Softwood cuttings taken during winter and treated with rooting hormones have yielded some success (Elliot and Jones 1984).

Their native habitats include lateritic gravel, sandy, or granitic soils, always well-drained (Elliot and Jones 1984). Once established, they are said to be more drought tolerant than *Banksia* species (Elliot and Jones, 1984). Many species are fairly cold tolerant, tolerating light frosts or short-lived snowfalls. Cultural conditions for success include full sun, good drainage, and good air circulation. As with other Proteaceae, low fertility is adequate and high phosphorus levels are to be avoided. Chlorosis is a problem on some soils and may be countered with weak iron chelate drenches. A few species are recommended as container plants: *D. ferruginea*, *D. polycephala*, and *D. speciosa* (Elliot and Jones 1984).

TELOPEA

Five species of *Telopea* have been described, and a number of hybrids have been released (Dennis 1991; Nixon and Payne 1996; Wrigley and Fagg 1996). They are native to acid, infertile, well-drained soils in New South Wales, Victoria, and Tasmania. As small trees or managed shrubs, they have both landscape value and commercial cutflower use. All species produce terminal, brilliant to rose red (occasional pink, white or yellow) inflorescences up to 15 cm in diameter on stems of up to 1 m length. The florets are arranged spirally on elongated cones subtended by an involucre of similarly colored bracts. *Telopea speciosissima* and *T. oreades* are the principal species for commercial flower production. Unlike other proteas, there is little by-pass by lower shoots. Plants tend to be upright and vigorous.

The most important species, *T. speciosissima* is known as the waratah and is the floral emblem of New South Wales, Australia. Although blooms were originally wild-collected, commercial production has increased in Australia as well as in New Zealand, US (Hawaii), Israel, and South Africa (Offord 1996). Australian production has been reported at 20,000 to 50,000 stems/ha five years after establishment in high density plantings (Worrall 1994), with annual production estimated at 0.6 to 1.7 million stems (Worrall, cited in Offord 1996). The plants are long-lived and capable of production for many years with good management.

While telopeas occur in woodland situations, they flower best in full sun or light shade. Flowering occurs in spring to early summer, but the bloom period is only 4 to 5 weeks duration. Choice of location can influence flowering time as can selection of hybrids (Matthews 1993; Offord 1996). Floral display life is about 7 to 13 days (Dennis 1991) and browning of the bracts can be a problem. The inflorescence is usually harvested before all florets have matured, and is discarded when one-third have turned blue-red (Faragher 1986). Vase life could be extended 3 to 5 days by harvesting when only the first cycle of flowers has matured, by the use of 5% sucrose and a germicidal compound in the water, and by refrigerating the cut flowers at 2°C after hydration (Lill and Dennis 1986). Ethylene does not appear to be a critical factor in senescence (Faragher 1986). Selection for lack of bract browning and low nectar production is a consideration in developing commercial types (Salinger 1981).

Telopea are readily propagated from fresh seed with germination occurring in 2.5–4 weeks at 25°C (Worrall 1994; Wrigley and Fagg 1996). Seed can be stored at room temperature for 6 months and for at least 2 years at 5°C (Worrall 1994; Offord 1996).

Semi-hardwood terminal cuttings (20 cm length with 5–6 leaves) of *T. speciosissima*, treated with 2000 to 4000 ppm IBA as a quick basal dip rooted with success rates of 50 to 75% after 8 weeks (Worrall 1976). A talc dust of 0.3% IBA is also satisfactory. Bottom heat of 24°C enhances rooting as does intermittent mist (Worrall 1994). Response varied with season, and cuttings from actively growing mother plants responded better to the low levels of IBA than to cuttings taken in winter from dormant plants. Leaf bud cuttings have been used to increase selected plants when propagative material is limited (Ellyard and Butler 1985). Tissue culture has been successful as well (Seelye et al. 1986; Offord and Campbell 1992; Offord et al. 1992).

Telopea culture requires well-drained soils, full sun, and freedom from frost. While their native soils are deep sands, they also thrive on well-drained basaltic clays (Offord 1996). Water requirements are high during summer flower bud initiation. Established plants tolerate a temperature range from 3° to 24°C. Plants are spaced at 1.5 to 3 m in rows with 3 m between rows (Dennis 1991). Pruning at or soon after harvest is practiced to encourage new stems of suitable length for cutflowers in the next season. Rejuvenation pruning is practiced periodically to reduce plant height and encourage production of longer stems (Worral 1994). Pot culture is also possible, but the lignotuber produced by the plants requires a fairly large container (Offord 1996). Potting media need to be well-drained with a pH of 5.5 and low phosphorus content.

SERRURIA

Like many other South African proteas, the genus *Serruria* (50 species) occur in well-drained nutrient-poor soils of the winter-rainfall area (1000 mm) of the Cape Floral Kingdom of South Africa. Their distribution is limited to small, specific localities within this region (Rebelo 1995), and many are endangered because of loss of habitat (Worth and van Wilgen 1988).

The serrurias are small shrubs (prostrate habit to 2 m tall) with fine, feathery foliage and prominent, white to pink bracts subtending the individual flowers borne multiply on one to 11 capitula. Commonly called spiderheads in their native South Africa, serruria inflorescences may be solitary or consist of clusters of small flowerheads. The principal species in commercial culture are *S. florida* (Blushing Bride) and *S. rosea* and their hybrids.

The cutflower serrurias tend to be upright growers. The globose flowerheads range from 3 to 5.5 cm in diameter but appear larger because of the bracts. Flowering occurs in the late winter to early spring, and is known to be stimulated by the long days of the preceding summer and fall (Malan and Brits 1990). Initiation and early development required about 6 weeks and another 10 weeks was required to reach anthesis. Little work has been reported on improving vase life, which is about 7 to 10 days following cutting. The flowers also dry well (Matthews and Carter 1993).

Serruria potted plants have good floral display qualities and can be produced in less than one year (Malan and Brits 1990). Cuttings should be taken during the high light, long days of early spring and summer as induced cuttings taken in the fall had low rooting percentages (Ackerman et al. 1995). The flowering period ranges from 30 to 55 days under outdoor conditions. Short durations of darkness as in shipping are not damaging to the post-harvest life of potted plants. Growth retardants such as paclobutrazol inhibit shoot elongation, while ethephon increases branching and branch angle (Brits 1995).

Propagation of serrurias to establish desirable clones is by mainly by cuttings. Ten weeks is required for acceptable rooting, but up to 20 weeks may be required if cuttings are taken during late fall or winter. Cutting bases are dipped for 10 seconds into a potassium salt formulation of IBA at the rate of 4000 mg/L (Ackerman et al. 1995). Techniques to establish and proliferate *Serruria* in vitro have been reported, but the rooting of plantlets from such cultures was not described (Ben-Jaacov and Jacobs 1995). Seed is reportedly long-lived and germinates in response to soil temperature fluctuations following clearing of the understory by fire (Brits 1986a; Worth and Wilgen 1988), but soaking in 1% hydrogen peroxide has been shown to stimulate germination in the laboratory (Brits 1986b).

MIMETES

Known as the Pagoda flowers in their native South Africa, *Mimetes* species bear large terminal flowerheads containing smaller headlets (capitula) bearing few to many flowers. Leaves and bracts subtending these headlets are often brightly colored and may curl around to clasp the flowers. Some species in the Silver Pagoda group bear silvery hairs, making them attractive for this character rather than for colored bracts.

Most of the 13 species of *Mimetes* are rare and found in isolated habitats of the south and southwestern Cape (Rourke 1984), frequently at high elevations in low to moderate rainfall areas. Most are found on sandstone-derived soils, but a few are found in moist peaty soils along marshes and swamps (Rebelo 1995). Coastal species such as *M. cucullatus* also withstand salt winds. Repeated burning maintains the shrub in a rounded form with numerous upright unbranched stems arising from a woody, persistent lignotuber (Rourke 1984). Flowering is most profuse on the vigorous young growth, suggesting that commercial flower production will be dependent upon efficient pruning.

Mimetes cucullatus is one of the more widely distributed species. It flowers year around but most heavily during the fall and winter months and offers potential as a cutflower as it produces 30 cm stems tipped with scarlet red and yellow bracts. It is said to have good vase life as a cutflower (Matthews and Carter 1993). It is a long-lived shrub once established and tolerates heavy pruning. Other *Mimetes* species with attractive flowerheads are reportedly short-lived although the seed remains viable for many years, ready to germinate when the natural habitat is cleared by fire (Rebelo 1995).

Cultivation of *Mimetes* requires well-drained, acid soils with some organic matter. Studies of plant management are still needed. Propagation is by seed or semi-hardwood cuttings taken in the fall (Matthews and Carter 1993).

Yellow Wild-Indigo

Baptisia tinctoria (L.) R. Br.

Other common names.—Baptisia, indigo weed, yellow indigo, American indigo, yellow broom, indigo broom, clover broom, horsefly weed, shoofly, rattlebush.

Habitat and range.—This native herb grows on dry, poor land and is found from Maine to Minnesota and south to Florida and Louisiana.

Description.—Yellow wild-indigo is an erect, much-branched, very leafy plant about 2 to 3 feet in height with cloverlike leaves. The flowers are bright yellow, one-half inch in length, and are produced in numerous clusters from June to September. The root, which is round and fleshy, sending out branches and rootless almost 2 feet in length, has a white interior and a thick, dark-brown bark. The bark root has a bitter, nauseous taste.

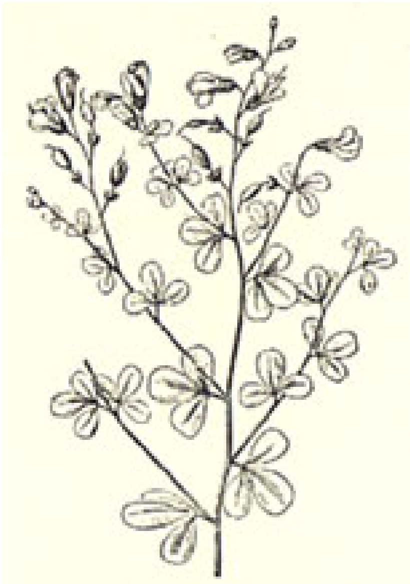

Figure 127.—Yellow wild-indigo (*Baptisia tinctoria*)

Other species.—A related species, said to possess similar properties, is *Baptisia alba* R. Br., called the white wild-indigo. This plant has white flowers and is found in the Southern States and on the western Plains.

Part used.—The herb and the root, the latter collected in autumn.

Scientific name: *Ficus benghalensis* L.
Synonyms: *Ficus indica* L
Family: Moraceae.
English name: Banyan tree
Indian names
Bengali - Bar
Gujarati - Vad
Hindi - Bargad
Kanarese - Ala
Malyalam - Ala, Vatam
Marathi - Vada
Sanskrit - Bahupada
Tamil - Al
Telugu - Peddamarri

Habitat: Monsoon and rain forests. Often planted throughout the forest tract of India. Hardy, drought resistance and withstands mild frost.

Botanical Description: Very large, fast growing, evergreen tree up to 3.0 meters, with spreading branches and many aerial roots. Leaves stalked, ovate-cordate, 3-nerved, entire, when young downy on both sides; petiole with a broad smooth greasy gland at the apex, compressed, downy; Fruit in axillary pairs, the size of a cherry, round and downy.

Propagation: Through seed, transplanting and stem-cutting.

Useful Parts: Bark, root-fibers, leaves, seeds, milky juice (i.e. latex).

Medicinal Uses and Properties: According to Ayurveda, it is astringent to bowels; useful in treatment of biliousness, ulcers, erysipelas, vomiting, vaginal complains, fever, inflammations, leprosy. According to Unani system of medicine, its latex is aphrodisiac, tonic, vulernary, maturant, lessens inflammations; useful in piles, nose-diseases, gonorrhea etc. The aerial root is styptic, useful in syphilis, biliousness, dysentery, inflammation of liver etc.

Other Uses
It is planted for soil conservation
Timber is used for well-curbs, furniture etc.
Suitable for paper pulp.
Leaf (Crude protein 9.63%) lopped for fodder
Fruits are used to prepare Shurbut traditionally.

Botanical Differences			
General Plant	Large evergreen tree with spreading branches, sending down to the ground many aerial roots, which afterwords develop into separate trunks.	A medium sized, glabrous tree	A small tree or large bush. Branches round, green or resset, covered with a coarse shortdown
Leaves	Coriaceous, 10-20x5-12.5 cm, ovate to elliptic, cordate or rounded base, shining above.	10-15x10-12 cm, ovate-round, entire, coriaceous, shining, apex long tailed.	Rough on the upper side coarsely downy beneath, cordate, 3-5 lobed or almost entire, coarsely sirrated

Fruit	Globose, with male, female and gall flowers.	Receptacles sessile, paired, smooth, depressed, globose, dark purple when ripe.	Solitary, axillary, more or less pear shaped or almost round, sweet, succulent and pleasant to the taste.
Medicinal Uses and Properties			
Ayurveda	Astringent to bowels; useful in treatment of biliousness, ulcers, erysipelas, vomiting, vaginal complaints, fever, inflammations, leprosy etc.	All parts cooling and useful in diseases of blood, vagina, uterus, leucorrhoea, burning sensation, biliousness, ulcers Ripe fruits are alexipharmic, good for foul taste, thirst, heart disease, Root good for sout whereas rooot bark good in stomatitis.	Fruit cooling, useful in diseases of head and blood, leprosy, nose bleed etc.
Unani	Its milky juice is aphrodisiac, tonic, vulnerary, maturant, lessens inflammations, useful in piles, nose-diseases, gonorrhoea.	Root bark aphrodisiac, good for lumbago; bark useful in inflammations and glandular swellings of neck; Fruits purgative, aphrodisiac, checks vomiting.	Roos tonic and useful in leucoderma, ringworm; Fruit antipyretic, purgative, alexiteric, aphrodisiac, lithotriptic, useful in inflammation, weakness, paralysis, thirst, liver and spleen diseases, pain in chest etc. Milky juice expectorant, iuretic, etc.

Barbados Gooseberry

Pereskia aculeata Mill.

Pereskia pereskia Karst.

Cactus pereskia L.

A climbing, leafy cactus, the Barbados gooseberry, *Pereskia aculeata* Mill., (syn. *P. pereskia* Karst.; *Cactus pereskia* L.), has various English names: West Indian gooseberry, Spanish gooseberry, lemon vine, sweet Mary, leaf cactus, blade apple, and gooseberry shrub–the latter in Barbados. It is known as *grosellero* or *ramo de novia* in Cuba; *buganvilla blanca* in Chiapas, Mexico; *guamacho* in Venezuela; *ora-pro-nobis* (pray for us) in Brazil; *bladappel* in Surinam. The generic name is sometimes spelled *Peireskia*, especially in Europe, for it was adopted in honor of Nicholas Peiresk, a senator of Aix in Provence, France, and a patron of botany.

Description

The plant is an erect woody shrub when young, becoming, with age, scrambling or climbing and vinelike, with branches up to 33 ft (10 m) long that may shroud a large tree. Spines on the trunk are long, slender, in groups; those on the branches are short, recurved, usually in pairs, rarely solitary or in 3's, in the leaf axils. The deciduous, alternate, short-petioled, waxy leaves are elliptic, oblong or ovate, with a short point at the apex; 1 1/4 to 4 in (3.2-10 cm) long, sometimes fleshy. To some people, the flowers are lemon-scented; others say sweet and pungent in odor; still others, of unpleasant or repulsive odor. They are borne profusely in panicles or corymbs; are white, yellowish or pink-tinted; 1 to 1 3/4 in (2.5-4.5 cm) across and the calyx tube is prickly. The fruit is round, oval or pyriform, lemon- or orange-yellow or reddish; 3/8 to 3/4 in (1-2 cm) wide, with thin, smooth, somewhat leathery skin. It is beset with the curling, leafy sepals of the calyx and often a few spines, until fully ripe, when it is juicy and subacid to tart. There are only a few flat, thin, brown or black, soft seeds about 1/6 in (4 mm) long.

Fig. 97: A leafy, spiny, climbing shrub, the Barbados gooseberry *(Pereskia aculeata)* is an atypical cactus.

Origin and Distribution

The Barbados gooseberry is believed to be indigenous to the West Indies, coastal northern South America and Panama. It is seldom found truly wild but is frequently grown as an ornamental or occasionally for its fruits in the American tropics, Bermuda, California, Hawaii, Israel, the Philippines, India and Australia. In many areas it has escaped from cultivation and become thoroughly naturalized. It was growing at the Agricultural Research and Education Center in Homestead in the early 1940's and running wild to some extent in the Redlands, but has since disappeared, possibly destroyed by winter cold or excessive rainfall. At least one nursery in Winter Haven, Florida, is now growing the plant in quantity. Gardeners had to give up the plant in South Africa in 1979 when it was banned as an illegal weed because it had been invading and overwhelming natural vegetation. It is frequently grown in greenhouses and as a house plant in temperate regions of both hemispheres. Horticulturists often use this species as a rootstock on which to graft other less vigorous cacti.

Fig. 98: The pecular yellow or reddish fruits of the Barbados gooseberry bear recurved, leafy sepals until fully ripe.

Varieties

There are 2 cultivars in the ornamental-plant trade:

'Godseffiana'–bushy, with broad leaves basically yellow-green variegated with scarlet and copper on the upper surface, purplish or rosy-red on the underside.

'Rubescens'–the leaves variegated with red.

Climate

The Barbados gooseberry is tropical and suited only to low elevations. In greenhouses, the favorable temperature range is from 68º F (20º C) at night to 99º F (37.22º C) in daytime. Chilling causes the leaves to fall.

Propagation

The plant is easily grown from seeds or cuttings of half-ripe wood.

Culture

Flourishing with little or no care, the plant is drought-tolerant and suffers from over-watering. In greenhouse experiments, it has been found highly responsive to light. Under high light intensity, it can be kept erect and compact; under low light, it grows higher, with ascending stems and the leaves are larger and thinner.

Season

In Jamaica, the plant blooms in June and again in October and November; fruits mature in March and October.

Food Uses

The fruits are generally stewed or preserved with sugar, or made into jam. Young shoots and leaves are cooked and eaten as greens. In rural Brazil, they are important as food for humans and livestock.

Food Value Per 100 g of Edible Portion

	Fruit	*Leaves*
Moisture	91.4 g	
Protein	1.0 g	
Fat	0.7 g	6.8-11.7 g
Carbohydrates	6.3 g	
Fiber	0.7 g	9.1-9.6 g
Ash	0.6 g	20.1-21.7 g
Calcium	174 mg	2.8-3.4 mg
Phosphorus	26 mg	1.8-2.0 mg
Iron	Trace	
Vitamin A	3,215 I.U.	
Thiamine	0.03 mg	
Riboflavin	0.03 mg	
Niacin	0.9 mg	
Ascorbic Acid	2 mg	
Magnesium		1.2-1.5 mg
Amino acid per 100 g Protein:		

Arginine	5.00-5.36 g
Histidine	2.49-2.54 g
Isoleucine	3.78-4.23 g
Leucine	6.99-8.03 g
Lysine	5.32-5.43 g
Methionine	1.72-2.03 g
Phenylanine	5.06-5.08 g
Threonine	3.09-3.60 g
Valine	4.78-5.52 g

Studies of the leaves in Brazil show a protein content of 17.4-25.5% and a mean digestibility of 85.0%.

Protein, lysine, calcium, phosphorus and magnesium levels are higher than in cabbage, lettuce and spinach.

Other Uses

In Israel, the flowers are said to be of great value in apiculture.

Medicinal Uses: In Brazil, the leaves are valued for their emollient nature and are applied on inflammations and tumors.

Cress, Upland

Winter cress, Scurvy grass, Belle Isle cress, Spring cress, Yellow rocket, Toi

Cruciferae *Barbarea vulgaris* R. Br., *B. verna* (Mill.) Aschers.

Source: Magness et al. 1971

These cresses, related to water cress and horse-radish, are cultivated sparingly for winter salads and pot herbs. Plants are naturalized in many parts of the U.S. Plants are hardy biennials. Leaves are generally entire but notched, and smooth. As grown under cultivation, leaf exposure and general culture are similar to those of spinach and turnips for greens. Portion of the plant consumed is the leaves.

This is a cool season, slightly spreading grass found throughout the Western States--particularly on alkaline soils. It is a tall, coarse grower, sometimes reaching to 10 feet. It is relatively low in palatability and is not planted commercially but affords emergency summer or winter pasturage where present.

Bayberry

Myrica cerifera L.; *M. carolinensis* Mill.

Other common names.—(1) Southern waxmyrtle, waxberry, tallow berry, candleberry, tallow shrub, candleberry myrtle; (2) northern bayberry, small waxberry.

Figure 13.—Northern bayberry (*Myrica carolinensis*)

Habitat and range.—The bayberry is native in sandy swamps or wet woods from New Brunswick south to Florida. *Myrica cerifera* is found as far west as Texas and Arkansas while M. carolinensis is common in bogs in northern New Jersey and Pennsylvania.

Description.—The southern waxmyrtle is a shrub or slender tree up to 40 feet high. The leaves are from 1 to 4 inches long, narrow, wedge-shaped, entire or with a few teeth, and have a fragrant odor when crushed. The flowers appear from March to May, according to locality, generally before the leaves are fully expanded. Male and female flowers are borne on separate trees, the male flowers in cylindrical yellow clusters and the female flowers in green somewhat shorter clusters. The fruit, which remains on the tree for several years, consists of clusters of round, 1-seeded, somewhat berrylike nuts covered with a whitish wax. Northern bayberry is a shrub 8 feet high or less, with broader and blunter leaves.

Part used.—The bark of the root, collected in late autumn. After thorough cleansing and while still fresh the bark is loosened and removed by heating the root. The wax obtained from the berries, used for making bayberry candles, is also an article of commerce.

Bean

Leguminosae *Phaseolus* sp., *Vigna* sp., *Vicia* sp., *Dolichos* sp., *Glycine* sp.

Source: Magness et al. 1971

Beans of several genera and species, and numerous varieties, are important food crops and are of some importance as feed crops in many countries. All are annuals, grown from seeds. The fruits are pods in which the seeds are contained. In green or snap beans, also termed 'string', pods are harvested before ripening, and both pods and the immature seeds are consumed, mainly as pot vegetables. In some kinds, the seeds when near full grown, but while still immature, are threshed from the pods and frozen or canned. In dry or field beans pods and seeds are allowed to ripen, then threshed and seeds only are consumed. Plants may be "bush," non-climbing and reaching a height of 15 to 30 inches; or "vine" or "pole," vining types reaching 10 or more feet in length.

Bean, Broad, Favabean or Fava

Fava bean,Faba bean, Horse bean, English bean, Windsor bean, Haba, Tick bean, Cold bean, Silkworm bean

Leguminosae *Vicia faba* L.

Source: Magness et al. 1971

This type of bean is very important as a cool-season crop in Mediterranean areas and in cool regions of Europe, but is grown to only a limited extent in the U.S. Plants are erect annuals reaching 2 to 4 feet and very leafy. Pods are large and thick, 2 inches up to a foot or more in length. Seeds are large and flat. They are used as green-shell, the seeds removed from the pod before maturity, or as dry beans. They are also used as feed for livestock.

Season, planting to harvest: 4 to 5 months. Pod set to harvest, 30 to 60 days.

Production in U.S.: No data; very limited.

Use: Cooked vegetables and stock feed.

Part of plant consumed: Seeds for food; immature pods as snap-beans and whole plant for feed.

Bean

Common, Kidney, Pea, Navy, Habichuela as dry or field beans.

Leguminosae *Phaseolus vulgaris* L. Tepary bean. P. *acutifolius* A. Gray.

Source: Magness et al. 1971

These are beans that ripen prior to harvest and are threshed dry from the pods. Only the ripe seeds are marketed. Four main types are grown as follows: (1) Medium type includes Pinto, Great Northern, Sutter, Pink Bayo, and Small Red or Mexican Red; (2) Pea or Navy; (3) Kidney; and (4) Marrow. Seeds vary in size from about 1/3 inch long in the pea or navy bean to 3/4 inch in the Kidney. All plants are of bush type. They are usually cut or pulled when most pods are ripe, then vines and pods are allowed to dry before threshing.

The Tepary bean *P. acutifolius*, is native to southwestern U.S. and Mexico and long grown by the Indians there. It is highly heat and drought resistant, but eating quality is less desirable than *P. vulgaris*. Culture is similar to that of other dry or field beans.

Season, bloom to harvest: 3 to 3.5 months.

Production in the U. S.: 900,000 tons.

Use: Commercially canned, soup, cooked in homes.

Part of plant consumed: Seed only.

Beech nuts

Fagaceae: *Fagus* sp.

American beech: *F. grandifolia* Ehrh

European beech: *F. sylvatica* L.

Source: Magness et al. 1971

The seeds of these beech species are sometimes gathered from native trees, or from trees planted for other purposes, and used as food. The seeds are formed in prickly burrs, about 0.75 to 1 inch in diameter, which remain closed until ripe, then partially open. The angular seeds or nuts are up to 0.75 inch long. The seed coat must be removed from the kernel before eating. In general, beech nuts are similar to small chestnuts. The trees are not cultivated for the purpose of nut production.

Ewart, L.C. 1993. New bedding plants. p. 604-608. In: J. Janick and J.E. Simon (eds.), New crops. Wiley, New York.

New Bedding Plants

Lowell C. Ewart

New floricultural crops have been defined by Roh and Lawson (1990) as "a newly discovered genera or species; newly introduced cultivars of plants grown in earlier years, but forgotten or without complete cultural information; plants that are cultivated in foreign countries but have not been introduced in the United States; or crops that can be produced with new production technologies that can enhance crop quality and shorten the total production time." If this classification is followed, new bedding plants fit the definition of new crops very well.

There has been a renewed interest to bring new bedding crops to market in the last five years. The trend is to introduce new perennial, bulb, and wildflower plants in addition to annuals for the bedding plant and landscape industries. This trend will likely continue well into the next century, especially with bedding plants and garden plants leading all other floriculture crops with a wholesale value of $971 million in 1990 (Agr. Stat. Board 1991). This represents an 8% gain over 1989, and reflects a yearly increase that has remained unbroken for over 10 years.

NEW CROPS FOR CONSIDERATION

The following taxa selections are either under evaluation or have recently been released for bedding plant sales. Additional new bedding plants are listed in Table 1.

Begonia

Begonia MSB-1 is a hybrid derived from inbreds developed from crossing *Begonia* x *semperflorens-cultorum* Hort. with *Begonia schmidtiana* Regel. The purpose was to develop material suitable for hanging basket production from seed rather than from cuttings. The plants grow fast, have a nice spreading, branched habit, and the flower color is a bright red. Evaluations have been excellent.

Canna

Canna x 'Tropical Rose' is an All-America Selections Flower Award Winner for 1992, the first canna ever to receive this award. 'Tropical Rose' is an improved dwarf canna that can be sold as young potted plants from seed sown 6 to 8 weeks prior to selling and which reaches heights of 76 cm (Sutherland 1991). Usually, cannas are grown from rhizomes rather than from seed. The soft rose-colored blooms appear the first of July and continue the rest of the summer in the Midwest.

Catharanthus

Catharanthus roseus (L.) G. Don still commonly known as vinca, has had several new additions due, in great part, to the work of R.D. Parker of the University of Connecticut. The cultivars 'Parasol' and 'Pretty In Rose' are both 1991 All-America Selections Bedding Plant Award Winners, and 'Pretty in White' is a 1992 All-American Selections Award Winner in this category.

'Parasol' improves on the cultivar 'Little Bright Eye' for flower size and flower quality. The large 4 to 5 cm blooms are pure white with a red center. The blooms have overlapping petals creating a full round flower. 'Parasol' exhibits heat and drought tolerance, and is an excellent landscape subject.

'Pretty in Rose' is a new deep rose, almost purple, color now available for the first time in vinca; whereas, 'Pretty in White' is a beautiful white with a small cream-colored eye. Both of these cultivars bloom all summer long and perform best in full sun. In combination with other annuals, they are perfectly suited to hanging baskets, planters, or patio urns.

These cultivars were derived from species and escaped 'wild' accessions (R.D. Parker pers. commun.). The collection, which began in 1978, contains material principally from Madagascar and Mauritius, but also contains material collected in Brazil, India, Mexico, Portugal, and South Africa.

Craspedia

Craspedia x 'Drumstick' is new to horticultural cultivation. This native from Australia is easily grown from seed. It is a green pack item and blooms approximately 170 days from seeding. The 3 cm globular flowering heads of golden yellow are held atop long, wiry stems about 60 cm tall. The excellent cutting stems rise from compact rosettes of ground level foliage. The flowers have very good durability either fresh or dried.

Gomphrena

Gomphrena x 'Strawberry Field' is the first true strawberry-red red gomphrena and is a beautiful, continuous blooming annual. The 3.5 cm blooms are borne in profusion on 60 cm stems, and they are delightful in bouquets either fresh or dried. It is a green pack item and starts to bloom approximately 90 days from seeding and will bloom all summer.

Hosta

Hosta selection MSH-1 (Fig. 1) was found growing among what appeared to be a variable group of seedlings in an old abandoned garden. The plants are very dwarf, early flowering with 26 cm flower stalks with light purple flowers. The plant silhouette is on the order of *Hosta lancifolia* Engl., but much smaller. The plants, in regular perennial fashion, bloom the second year from seed in early June in the Midwest and are excellent as a rock garden subject.

Iris

Dwarf bearded iris (*Iris pumila* L.) (Fig. 2) are beautiful in the spring and are usually purchased as rhizomes in late summer. They can now be produced as a spring sales, pot plant item (E.J. Holcomb pers. commun.) by storing potted rhizomes at 7°C for 8 weeks. There are many cultivars with various colors that bloom in about 25 days after storage and produce more flowering stalks per pot if the plants are grown under high pressure sodium lighting. These dwarf iris are excellent for rock garden or edging use, blooming in late April to early May. They are best grown in full sun in a well drained location.

Kalanchoe

Kalanchoe MSK-20, a selection developed for hanging basket production, was derived from crossing *Kalanchoe* x 'Jingle Bells' with *Kalanchoe manginii* Hamet. & Perr. B, and can be produced from cuttings or from seed. The plants need 5 weeks of short days to induce flowering. The critical photoperiod is 12 h, but the optimum is 9 h. The habit of the plant is more like *K. Manginii*, only larger. The 2.5 cm long, trumpet shaped, red flowers are borne in profusion on the ends of the branches. The natural flowering time is December through March in the United States.

Kalanchoe MSK-1 (Fig. 3), 2, and 4, selections from crosses within *Kalanchoe blossfeldiana* Poelln., are produced from seed and are intended for mass market sales. The plants require short days for flower induction. The colors of MSK-1, 2, and 4 are orange scarlet, hot pink, and apricot-yellow, respectively. The individual flowers have a spread of 17 mm, and the natural flowering time is December through April in the United States.

Rhodohypoxis

Rhodohypoxis bourii (Bak.) Nel., known as the Starlet Flower, is native to South Africa and hardy only into zone 8. Grown from rhizomes, it has been used as a rock garden plant. It is suitable as an attractive spring pot plant, ready for sale 5 to 6 weeks from potting. The flower colors range from white, pale pink to red, and the flowers, each comprising 6 petals, meet at the center with no eye. The slender stems produce a succession of 2 cm flowers. The plants can be enjoyed as a patio subject or planted out in the garden, but should be removed before freezing temperatures are experienced. The rhizomes can reflower after 8 to 10 weeks of storage at 4°C (Bay City Flower Co. pers. commun.). Production of this crop is still somewhat hampered by the limited number of rhizomes available each year.

Salvia

'Lady in Red' salvia, an All-America Selections Flower Award Winner for 1992, is derived from *Salvia coccinea* Juss. ex J. Murr., sometimes called Texas sage. The bright red flowers, which attract humming birds and butterflies, are borne in loose whorls along a spike above the foliage. Mature plant height is 60 cm. 'Lady in Red' can be produced as a flowering bedding plant, using the same culture as for *Salvia splendens* F. Sellow ex Roem. & Schult (Sutherland 1991). Crop time from sowing to initial bloom is about 10 to 12 weeks, and the plants will flower all summer long.

Steirodiscus

Steirodiscus x 'Gold Rush' has a beautiful yellow, daisy-like flower about 2.5 cm in diameter. In full bloom, the flowers cover the entire plant which grows to 12 to 18 cm in height (Hamrick 1989). It is produced from seed and will grow well at 15° to 21°C. The plants, however, require a cool night temperature of 2° to 5°C and 15°C days to flower. Temperatures over 26°C will result in poor growth and shorten the bloom period. In general, the crop time is 12 weeks (American Takii Inc. pers. commun.).

Trillium

A double flowered form of *Trillium grandiflorum* (Michx.) Salisb. ('Flore Pleno') (Fig. 4) is quite rare as a commercial item. The single flowered type at one time was forced as a pot plant, but went out of style. Now, with the renewed interest in wildflowers in the landscape, such items have become popular again. The plants, however, are now protected in some states and cannot be dug from the wild. The double flowering form can be propagated vegetatively, but at a premium price. Potted up during the summer previous to spring sales and stored overwinter, this plant sells itself when in bloom at a garden center outlet. The double flowers have a good 2 to 3 weeks duration time which adds to their value for spring sales. The plants can be enjoyed best, however, if planted as soon as possible into the landscape.

Viola

Violet MSV-1 (Fig. 5) is of hybrid derivation from within the wild *Viola* stemless, blue, cut-leaved group. In the spring, the plants are covered with blue flowers that are held above the foliage forming a beautiful blue carpet. Propagation is by seed or division. Violets are photoperiodic (Mastalerz 1977), producing conspicuous clasmogamous flowers under short day, and inconspicuous clestogamous flowers under long day conditions. It should be possible to keep the plants flowering year-round by manipulating photoperiod and temperature. This should allow sales of flowering plants for landscape use from spring through most of the summer.

Zinnia

The most economic important garden zinnia (*Zinnia elegans* Jacq.) is very susceptible to several leaf diseases. *Zinnia angustifolia* HBK, however, is virtually disease free. Until now only the orange flowered cultivar 'Classic' was available. A new white flowered cultivar 'Star White' (Fig. 6) has been introduced. The single, daisy-like flowers measure about 2.5 cm and appear in mass on plants reaching 35 cm. The plants thrive in hot, dry conditions and carry the same disease resistance found in *Z. angustifolia* (Burpee pers. commun.). The plants bloom all summer and are propagated from seed.

CONCLUSION

The plants highlighted represent an interesting and colorful group of new plants that should find a home in the garden for years to come. They are an example of what new crops can do for increasing the interest of color and diversity in the landscape.

Table 1. Examples of other new cultivars and species that show potential for bedding plant sales.

Taxa	Comments
Annuals	
Calandrinia x 'Bogota'	Very dwarf, heat tolerant, violet rose color
Centaurea x 'Blue Midget'	Dwarf, free flowering
Gaillardia x 'Red Plume'	Dwarf, heat tolerant, excellent flower production
Gaillardia x 'Yellow Sun'	Dwarf, heat tolerant
Impatiens x 'Spectra'	Dwarf New Guinea-type from seed
Lisianthus x 'Blue Lisa'	Dwarf, deep blue
Nasturtium x 'Tip Top'	Dwarf, in single colors or as a mix
Sanvitalia x 'Double Sprite Yellow'	Double flowers, heat tolerant
Perennials	
Claytonia verginica L.	Wildflower
Dicentra Cucullaria (L.) Bernh.	Wildflower
Lychnis x 'Molten Lava'	Dwarf, deep red
Platycodon x 'Sentimental Blue'	Dwarf, large flowered

Oregon Hollygrape

Berberis aquifolium Prursh.

Other common names.—Oregon grape, Rocky Mountain grape, hollyleaved barberry, California barberry, trailing mahonia.

Figure 81.—Oregon hollygrape (*Berberis aquifolium*)

Habitat and range.—This shrub is native in woods in rich soil among rocks from Nebraska to the Pacific Ocean, but it is especially abundant in Oregon and northern California.

Description.—Oregon hollygrape is a low-growing shrub from 2 to 5 feet in height, resembling the holly of the Eastern States. The leaves are divided like those of an ash; the five to nine leaflets from 2 to 3 inches long and about 1 inch wide are evergreen, thick, leathery, smooth, and shining on the upper surface with marginal spines. The numerous small yellow flowers appear in April and May and are borne in erect clusters. The fruit consists of a cluster of blue berries. The rootstock and roots are more or less knotty, about an inch or less in diameter, with tough yellow wood and brownish bark.

Other species.—The roots of *Berberis nervosa* Pursh, which is found in the same region, are sometimes collected with that of Oregon hollygrape.

Part used.—The bark, collected in autumn.

Brazil nut

Butter nut, Cream nut, Para nut

Myrtaceac *Bertholletia excelsa* Humb. & Bonpl.

Source: Magness et al. 1971

The tree is very large, up to over 100 feet. It is a tropical evergreen, native to northern Brazil, with large leathery leaves, 2 feet long and 6 inches wide. The tree forms forests along the Amazon and Rio Nigro Rivers. Large quantities of nuts are gathered from such trees, but they are little cultivated. The fruits are round, about 6 inches in diameter, with a hard shell near 0.5 inch thick, which contains 18 to 24 of the 3-sided angular nuts. The shell of the individual nut is woody, rather thin, and completely filled with the white, creamy kernel. Brazil nuts are not produced commercially in the U.S., but large quantities are imported.

Big bluegrass

Gramineae *Poa ampla* Merr.

Source: Magness et al. 1971

This is a strong-growing perennial bunchgrass native in Western United States. Plants are up to 4 feet tall, with numerous basal leaves 8 to 16 inches long by 0.375 inch wide and a deep, fibrous root system. Stands are generally not dense, but the high production of palatable forage make this a very valuable range grass. It starts growth early in the spring and continues into fall. It is very useful for regrassing farm and depleted range lands. Mixed plantings of big bluegrass and legumes as alfalfa have produced high yields of excellent forage. It is easily injured by overgrazing. Seed is large in size and produced readily. Propagation is by seeding.

Last update February 18, 1999 by ch

Big trefoil

Leguminosae *Lotus pedunculatus* Cav.

Source: Magness et al. 1971

In general appearance big trefoil resembles birdsfoot trefoil, but its range of adaptation is quite different. It is much less winter hardy so is adapted only to humid areas with mild winters. It is grown mostly in western Oregon but also is promising for the Southeastern States. It tolerates submergence and grows well on wet, poorly drained soil. It spreads by underground stems. The root system is shallow. It can be grown in combination with sod-forming grasses, competing well with them. It is high in palatability, both as pasturage and as hay. Seed inoculation is important in establishing plantings. While less important nationally than birdsfoot trefoil, it is a valuable crop for special areas.

Betula lenta L.

Betulaceae
Cherry birch, Sweet birch, Black birch

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

A beer is made from birch bark. Fernald et al., (1958) quote an old English recipe for the beer:

"To every Gallon of Birch-water put a quart of Honey, well stirr'd together; then boil it almost an hour with a few Cloves, and a little Limon-peel, keeping it well scumm'd. When it is sufficiently boil'd, and become cold, add to it three or four Spoonfuls of good Ale to make it work...and when the Test begins to settle, bottle it up . . . it is gentle, and very harmless in operation within the body, and exceedingly sharpens the Appetite, being drunk ante pastum."

According to Grieve (1931), Kamschatka natives drink the sap without previous fermentation. In Spring, the inner bark can be cut up into noodle-sized strips and cooked as birch "noodles." Like maple sap, the sap can be used for honey, syrup, or sugar after boiling down. Wood used by cabinet makers. The oil distilled from the wood is insectifugal and can be used to preserve furs.

Sweet Birch oil is used as a counter irritant for arthralgia and neuralgia, usually in balms, liniments, and ointments. It is used to impart a wintergreen flavor in such things as baked goods, candies, chewing gums, dairy desserts, gelatins, puddings, and root beer, rarely constituting as much as 0.1% of candy (Leung, 1980). Used in cosmetic shampoos (List and Horhammer, 1969–1979), and in the sugar industry for flavoring and in perfumery. Birch tar oil, distilled from the wood and bark of Betula pendula Roth is used for eczema, psoriasis, and other skin diseases.

Folk Medicine

According to Hartwell (1967–1971), the birch species are used in folk remedies for abdominal and mammary cancers and carcinomas and warts. Reported to be alterative, anodyne, antiseptic, counterirritant, deobstruent, depurative, diaphoretic, diuretic, parasiticide, pectoral, stomachic, and vulnerary, sweet birch is a folk remedy for burns, chafing, cold, cough, dandruff, dysentery, dysmenorrhea, gout, gravel, lumbago, rheumatism, scalds, sciatica, and sores (Duke and Wain,1981; List and Horhammer, 1969–1979; Erichsen-Brown, 1979). The bark has been used as an astringent, antiseptic, antipyretic, and antirheumatic. Cherokee chewed the leaves for dysentery and used the bark tea for colds, dysentery, milky urine, and stomach ailments. Delaware used the bark decoction as cathartic or emetic. Iroquois used it for colds, fever, soreness, and venereal diseases. Ojibwa used bark as diuretic. In the days of Milspaugh, much of the so-called oil in wintergreen was made instead from young birch, there being little variance between oil of wintergreen and oil of birch (Duke,1983c).

Chemistry

Per 100 g, the leaves are reported to contain, on a zero-moisture basis, 28.1 g protein, 8.6 g fat, 55.6 g total carbohydrate, 16.9 g fiber, and 7.7 g ash (Miller, 1958). Hager's Handbuch lists 3% monotropitoside (Salicylic-acid primvercoside, gaultherin, $C_{19}H_{26}O_{12}$) and 0.23–0.6% essential oil, 99.8% of which is methysaliclate. Buds contain 4–6% essential oil containing betulol. According to Morton (1977), the distilled oil contains 97–99% methyl salicylate (List and Horhammer, 1969–1979).

Toxicity

Very toxic orally, methyl salicylate can be absorbed through the skin, resulting in human fatalities. As little as 4, 700 mg can be fatal in children (Leung, 1980).

Description

Aromatic tree with brown, exfoliating bark on young stems, twigs glabrous. Leaves ovate or elliptic, 2.7–10 cm long, 1.5–6 cm wide, pubescent on the veins beneath, apically acute or acuminate; sharply serrate, base cordate, rounded or cuneate; petioles usually pubescent, 0.8–1.9 cm long. Pistillate catkins cylindric or oblong, 1.2–3.4 cm long, 0.6–1.2 cm broad; bracts glabrous; samaras obovoid, 2.5–3.5 mm broad, apically winged, glabrous (Radford et al, 1968).

Germplasm

Reported from the North American Center of Diversity, cherry birch, or cvs thereof, is reported to tolerate heath balds, frost, shade, and slope. ($2n = 28$).

Distribution

Southern Maine to southern Ontario, southern to eastern Ohio and Delaware, along the mountains to Alabama and Georgia.

Ecology

Estimated to range from Cool Temperate Moist to Wet through Boreal Moist to Wet Forest Life Zones, and to tolerate annual precipitation of ca 6 to 15 dm, annual temperature of 5 to 12°C, and pH of 4.5 to 7.5. Farther south in rich woods and heath balds.

Cultivation

For the oil, birch is usually harvested from the wild. Birch seeds do best if stratified, or can be sown after collection in late summer or fall. Seed is broadcast and covered very lightly (2–5 mm) keeping the seedbed moist if possible. Epigeal germination is usually complete 4–6 weeks after spring sowing. Seedlings require light shade during their first summer.

Harvesting

Midrange this flowers from April to May, fruits ripening from August to September, the seeds dispersing from September to November (Agriculture Handbook 450). Birch seed is collected by picking or stripping the cones while they are still green (to prevent shattering). Ripe cones, on the other hand, are placed in, bags to prevent loss of seed. Seedling densities of 250–475 m^2 are suggested.

Yields and Economics

Most sources indicate that birch oil, which replaced wintergreen oil, has been largely replaced by synthetic methyl salicylate. Salicylic acid is now synthesized and selling at ca $2.50 to $3.00 per kilo. Salicylic acid in technical form is used as a coupling agent dye intermediates, in the foundry industry as a curing agent in the production of shell moulding compounds, as an agent for retarding the vulcanization process in rubber, as a preservative for glues and leather goods, and in alkyl/alkyd resins and latex paints (CMR, Dec. 13, 1982).

Energy

According to the phytomass files (Duke, 1981b), annual productivity ranges from 3 to 12 MT/ha in various species of birch, standing biomass 2–220 MT/ha. Rather lower productivity and standing biomass are reported by Cannell (1982). If there were a decent market for the oil of the bark and wood, then most of the aerial biomass could be an energetic byproduct.

Biotic Factors

Browne (1968) lists the fungi *Melampsoridium betulinum* and *Nectria galligena* and hymenoptera *Heterarthrus nemoratus* affecting cherry birch. Agriculture Handbook No. 165 lists the following as affecting this species: *Comandra umbellata* (seed plant parasitic on roots), *Cryptospora betulae* (on dead branches), *Cryptospora humeralis, Dermea molliuscula* (on dead twigs), *Diatrypella betulina* (on dead branches), *Fomes applanatus* (white-mottled heart rot), *F. connatus* (white spongy heart rot), *F. pinicola* (brown crumbly heart rot), *F. robustus* (white sapwood and heart rot),.*Gloeosporium betularum* (leaf spot), *Hymenochaete agglutinans* (trunk canker), *Melanconis acrocystis, M. stilbostoma, Microsphaera alni* (powdery mildew), *Nectria coccinea* (on branches), *Phyllactinia corylea* (powdery mildew), *Poria laevigata* (white spongy rot, trunk canker), *Poria obliqua* (white spongy rot, trunk canker), Septoria betulicola (leaf spot), *S. microsperms, Steganosporium piriforme* (on twigs), *Taphrina* sp. (leaf blister), and *Torula ligniperda* (red stain of heartwood).

Birdsfoot trefoil

Leguminosae *Lotus corniculatus* L.

Source: Magness et al. 1971

Birdsfoot trefoil is a perennial, fine-stemmed, leafy legume that has become of increased importance in American agriculture in recent years. Introduced by chance from Europe, strains selected in this country are now of major importance as pasture and hay crops. It is hardy and adapted to areas of ample moisture supply from the Ohio and Potomac Rivers north into Canada and west to the edge of the Great Plains, also in humid parts of the Pacific States. The leaves are sessile along the stems, each with 5 linear to oval leaflets. Stems are decumbent unless in fairly dense stands, reaching 20 to 40 or more inches in length. The plant has a deep, branched root system and tolerates both wet and moderately dry conditions. It is unusual among legumes in that it does not cause bloat in cattle. Both as pasture and as hay it is highly palatable and nutritious. Harvested seed increased 6-fold from 1949 to 1959, and in the latter year was sufflcient to plant about 300,000 acres, according to census data.

Bitter Nightshade

Solanum dulcamara L.

Figure 15.—Bitter nightshade (*Solanum dulcamara*)

Other common names.—Bittersweet, dulcamara, nightshade, climbing nightshade, woody nightshade, amara dulcis, fevertwig, violet-bloom, blue bindweed, felonwort, poisonberry, poisonflower, pushion-berry, morel, snakeberry, wolfgrape, scarlet berry, tether-devil, dwale, skawcoo.

Habitat and range.—This plant occurs in low damp grounds and moist banks of rivers from New Brunswick to Minnesota and south to New Jersey and Kansas.

Description.—Bitter nightshade has a climbing, somewhat woody, branched stem about 2 to 8 feet long. The leaves are from 2 to 4 inches long, some entire and others having one to three lobes at the base. The purplish flowers, which resemble those of the potato, are produced from about May to September in compound clusters. The berries, which ripen in autumn, are oval, red, juicy, and contain numerous seeds. The plant has a handsome appearance in autumn with its colored berries, and is often planted as an ornamental.

Part used.—The young branches from plants only 1 or 2 years old, collected after the leaves have fallen.

Neglected Crops: 1492 from a Different Perspective. 1994. J.E. Hernándo Bermejo and J. León (eds.). Plant Production and Protection Series No. 26. FAO, Rome, Italy. p. 149–163.

Andean tubers

The authors of this chapter are C. Arbizu and M. Tapia (CIP. Lima, Peru).

Oca (*Oxalis tuberosa*)

Botanical name: *Oxalis tuberosa* Molina

Family: Oxalidaceae

Common names. English: oca, oxalis; Quechua: oqa, ok'a; Aymara: apilla; Spanish: oca (Peru, Ecuador), oca, ibia (Colombia), ruba, timbo, quiba (Venezuela), papa roja, papa colorada, papa extranjera (Mexico)

Oxalis tuberosa is a crop native to the Andes. Together with the potato. the domestication of this and other Andean tubers in the central region of Peru (lat. 10°S) and northern Bolivia (lat. 20°S), where the greatest diversity both of cultivated and wild forms is found, is thought to have given rise to agricultural activity in the higher agro-ecological areas of the Andes. The migrations of pre-Columbian communities extended its cultivation to lat. 8°N in Venezuela and lat. 25°S in northern Argentina and Chile. Its cultivation was introduced into Mexico about 200 or 300 years ago and, nowadays, it is grown relatively extensively in the region of the Transverse Neovolcanic Axis. Oca was introduced into Europe in the last century and, even though it was produced as a new vegetable, it did not become established as a permanent crop. It is known to have existed in New Zealand since 1860 and its cultivation seems to have gained popularity in the last 20 years.

The oca is sown together with the ullucu, mashwa and native potatoes on plots from 30 to approximately 1000 m^2. It is therefore difficult to tell what its cultivated area and production is. However, it is estimated that 20000 ha are sown annually in Peru, with an average production of 3 to 12 tonnes per hectare, although some experimental selections and treatments have produced as much as 97 tonnes per hectare.

Uses and nutritional value

Oca is first sun-dried to make it sweeter and then parboiled, roasted or prepared as *pachamanca* (meat roasted in a hole in the ground).

The dried, frozen tuber is called *khaya*. If it is washed after freezing, a whiter product called *okhaya is* obtained which is considered to be of superior quality. The flour of the latter is used to make porridges and desserts. Oca is first and foremost a good source of energy; its protein and fat content is low.

Botanical description

O. tuberosa is an annual, herbaceous plant that is erect in the first stages of its development, and decumbent or prostrate towards maturity. The tubers are claviform-ellipsoid and cylindrical, with buds on the whole surface, and variegated in colour: white, yellow, red and purple.

The leaves are trifoliate, with petioles of varying length (2 to 9 cm). The inflorescences consist of four or five flowers. The calyx is formed by five pointed, green sepals. The corolla has five purple-striped, yellow petals; ten stamens in two groups of five; and a pistil that is shorter or longer than the stamens. Propagation is almost exclusively by the tubers. The flower structure has an efficient mechanism which facilitates cross-pollination.

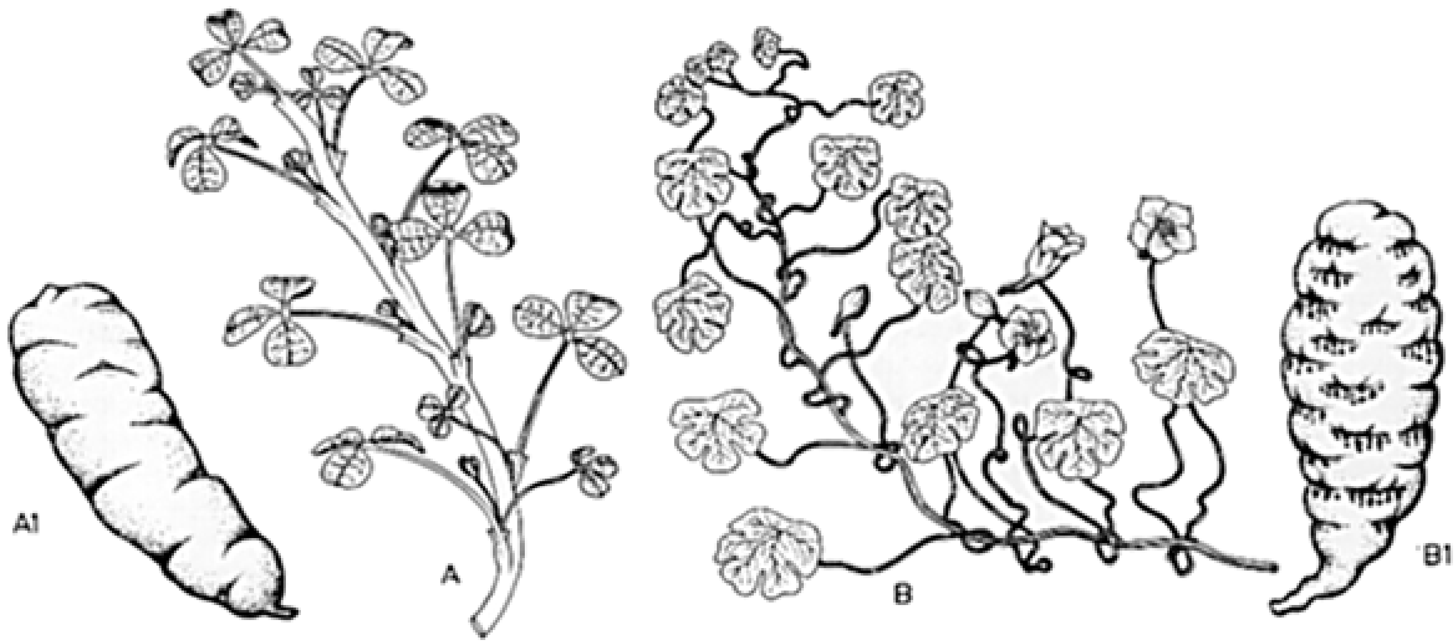

Figure 15. Andean tubers: A) oca (*Oxalis tuberosa*); A1) tuber; B) mashwa (*Tropaeolum tuberosum*); B1) tuber

Ecology and phytogeography

Oca is grown from 3000 to 4000 m, from Colombia to Chile. However, the greatest concentration is found between 3500 and 3800 m, in the suni agro-ecological zone (mountain slopes).

Wild species of the genus *Oxalis* are found on the low ridges of the Peruvian coast, or growing sympatrically with cultivated oca in the Andes and on the edges of forests.

Genetic diversity

The basic number of chromosomes has been established as x = 11. There are reports of ocas that are close to pentaploid (2n = 2x = 58) and hexaploid (2n = 2x = 66) and also of hexaploid cultivated ocas. The frequency of diploids, triploids, tetraploids, pentaploids and hexaploids as well as those that are not exactly euploid should be clarified. The role of the 2n gametes in the formation of the polyploid complex and the nature of the F_1 and F_2 material needs to be studied.

The pattern of variability in the oca seems to be fairly complex. In fact, cultivated forms have hitherto been grouped together into a single species which includes several shapes and colours of tuber.

The self-incompatibility system present in the oca and consequent cross-pollination, together with the aesthetic selection made by Andean farmers, must have had an influence on the existence of the wide variety of tuber colours and shapes. as well as the number and depth of "eyes" or "buds".

The wide variability found in the colour of the tubers suggests a continual variation, since colours range from white to black, with various hues of yellow. pink and red in between. Flesh colour also seems to undergo continual variation, although less than skin colour does. Ocas have been seen with ivory-yellow and violet-purple flesh in several hues. There are a great many shapes in the vascular ring pigmented with the same colouring as the skin, followed in colour intensity by the medulla.

Oca collections in South America

Over the past ten years, expeditions have been made to Peru, Ecuador and Bolivia to collect cultivated oca. Field collections in Peru are being maintained and evaluated at the Universities of Cuzco, Huancayo, Ayacucho, Cajamarca and Puno, and at INIAA, where there are over 1000 accessions with sufficient duplications. Most of this material is kept in vitro at the Biotechnological Laboratory of the Universidad Nacional Mayor San Marcos in Lima. The collection of Ecuadorian oca is kept as a field collection at the Santa Catalina station in Quito.

Cultivation practices

The three Andean tubers (oca, mashwa and ullucu) are grown in the same agro-ecological zone and their soil requirements and cultivation practices are very similar to those of the potato: for this reason they are dealt with together.

In the northern area of the Peruvian sierra. the traditional form of cultivation is on *melgas:* after cultivation of the potato, the land is divided into three to five plots, each of which is sown with one of the Andean tubers.

On the high plateau of Puno and in the agro-ecological zone of the semi-humid puna, a mixture of tubers is sown. By contrast, in the quechua agro-ecological zone, the oca and ullucu are planted together with maize. These crops show a high response to agricultural work such as fertilization, earthing up, hoeing and, above all, the control of pests and diseases; their production increases to levels of 40 to 50 tonnes per hectare, which are comparable to the highest potato yields.

Prospects for improvement

The prospects for this crop lie in the possibility of increasing its yield and in its use as an alternative source of flour to wheat.

The following aspects should be taken into account:

- The oca has to compete for ground (cultivation areas) with potatoes; as a result, its expansion could be limited; research carried out in southern Peru seems to confirm this.
- Attacks by pests, such as weevils, may cause the loss of an entire crop; studies on the integrated control of these pests, through cultivation practices, biological control using the fungus *Beauveriabrogniartii*, postharvest management and the use of resistant varieties would need to be carried out; bitter ocas show a degree of resistance to the various weevils.
- **Presence of viral diseases:** Although just one virus has been identified in the oca, it seems that others exist which damage the crop: the purity of commercial varieties and genetic materials must be established as standard practice, as virus-free varieties would give higher yields.

- The extensive growing period of seven to eight months exposes the crop for a longer time to attack from biotic and abiotic factors. and oca cultivation is consequently being gradually replaced by early varieties of potato (with a growing period of four to five months), the short duration of the tuber also affects its propagation.

The high yields in dry matter obtained from this crop and the possibilities of attaining up to 6 or 7 tonnes of flour per hectare are factors that ought to be dealt with in an agro-industrial research programme.

Mashwa (*Tropaeolum tuberosum*)

Botanical name: *Tropaeolum tuberosum* Ruíz & Pavón

Family: Tropeolaceae

Common names. English: mashwa; Spanish: mashwa, mashua (Peru, Ecuador), isaño, añu (Peru, Bolivia), maswallo, mazuko, mascho (Peru) and cubio (Colombia)

Tropaeolum tuberosum apparently originates from the central Andes (lat. 10° to 20°S). Its cultivation is thought to have been spread by pre-Columbian migrations to Colombia (lat. 8°N) and northern Argentina and Chile (lat. 25°S). In spite of its hardiness, there are no references to its introduction into other countries, possibly because the tuber's flavour is not very pleasant when eaten for the first time.

Grown together with ullucu, oca and native potatoes on plots from approximately 30 to 1000 m^2, it is difficult to ascertain its cultivated area and production. However, it is estimated that around 6000 ha are sown annually in Peru, with an average yield of 4 to 12 tonnes per hectare. Under experimental conditions, up to 70 tonnes per hectare have been obtained.

From an agronomic point of view, mashwa is very hardy because it grows on poor soil, without the use of fertilizers and pesticides. Even under these conditions, its yield can be double that of the potato. Its cultivation together with ullucu, oca and native potatoes could be accounted for by the nematicide and insecticide control properties that the plant has.

Since the time of the Incas, who included them in their soldiers' rations, the tubers have had anaphrodisiac properties attributed to them. Today, it is known that testosterone levels are significantly reduced in male rats that are fed mashwa.

Uses and nutritional value

Mashwa is important for meeting the food requirements of resource-poor people in marginal rural areas of the high Andes. It is prepared in the form of a stew, as a roast or in the form of *thayacha*. For the latter preparation, the tubers are exposed overnight to frost and are eaten the following day accompanied by sugar-cane syrup.

Botanical description

T. tuberosum is an annual herbaceous plant of erect growth when it is young and it has prostrate stems with compact foliage when mature. This enables it to compete advantageously with weeds. At first sight, the tubers may be confused with oca tubers, but they can be distinguished by their conical shape, dark markings and a greater concentration of buds on the distal part, as well as by their sour taste.

The growing cycle of this species varies between 220 and 245 days. Unlike oca and ullucu, mashwa produces a great quantity of viable seeds.

Ecology and phytogeography

Mashwa is cultivated from Colombia to Bolivia, from 3000 to 4000 m, with a greater concentration between 3500 and 3800 m. In spite of the poor-quality soils, extreme temperatures, radiation. variation in precipitation and the winds of the Andes, the plant grows quickly, managing to repel insects and nematodes, suppress weeds and maximize photosynthesis. The proportion of dry matter transferred to the tubers can be as high as 75 percent.

Genetic diversity

The genus *Tropaeolum* has a wide geographical distribution and seems to be very variable. There are an estimated 50 species in Mexico and Central and South America. Wild species of mashwa in Peru can be found on the low ridges of the Peruvian coast, on the edges of forests or growing sympatrically with cultivated mashwa in the Andes.

Ornamental *Tropaeolum* can be found in gardens on the coast and in the Andes. Weed forms of mashwa, called kite añu, are sporadic in the maize or tuber fields of the sierra. *T. edule, T. polyphyllum* and *T. patagonicum* have also been described as producers of tubers in the Andes of Chile and Argentina, but they apparently have no economic use.

As in the case of the oca, the crossability groups are not known, in other words the situation of the mashwa's gene stock is unknown.

Chromosome calculations have established the basic number as $x = 13$. Cultivated forms are clearly tetraploids ($2n = 4x = 52$). The frequency of diploids, triploids and tetraploids is not known and nor is the possible gene flow.

Cross-pollination and the tendency towards self-fertilization, together with aesthetic selection, must have influenced the appearance of various morphotypes. It can be said that the diversity of the mashwa is less than that of the oca, and slightly less than that of the ullucu. However, variation has been found in tuber colour, shapes, bud characteristics and flesh colour. The tuber's skin colour varies from ivory to very dark-purplish violet, with several hues of yellow, orange and purplish violet in between. Pink or purple speckles or stripes may occur on the skin at the apex and under the buds. Tuberization in the buds is more frequent in clones of shortened conical tubers than elongated and ellipsoid conical tubers. The greatest variation in tuber colours and shapes is found in the region between central Peru and northern Bolivia.

Mashwa collections in South America

Cultivated mashwa, just like ullucu and oca, has been collected extensively in Peru, Ecuador and Bolivia during the last ten years. The field collections of Peru. stored and evaluated in the gene banks of Ayacucho, Cajamarca, Huancayo, Cuzco and Puno, exceed 300 accessions. Many of the accessions are kept *in vitro* in the biotechnological laboratory of the Universidad Nacional Mayor San Marcos in Lima. The field collection of Ecuadorian mashwa is stored and evaluated at the Santa Catalina experimental station in Quito.

Cultivation practices

Mashwa cultivation practices are the same as those described for the oca.

Prospects for improvement

Because of its flavour, the mashwa could have a better chance of more extensive use in animal feeding. In this connection. certain clones with a protein content of up to 11 percent show good prospects.

An investigation into the factors limiting mashwa production. carried out by the CIP in the Peruvian Department of Cuzco (1989). elicited the following answers from the peasants: scarcity of suitable land (28 percent): low crop yields (17 percent): and scarcity of seed (17 percent).

The rise in population and consequent pressure on the land would seem to be a limiting factor not only in Cuzco but also in other parts of the Andes. Low crop yields would not be a serious limiting factor. since the mashwa responds well to good soil management. Seed scarcity is a problem that can be solved.

The main lines of research are as follows:

- the function of undesirable substances:
- the long cultivation period:
- tuber storage:
- the selection of varieties for the various agro-ecological conditions:
- consumption patterns in rural and urban populations.

Bitter Potatoes (*Solanum* x *juzepczukii*), (*Solanum* x *curtilobum*)

Botanical names: *Solanum* x *juzepczukii*, *Solanum* x *curtilobum*

Family: Solanaceae

Common names. English: bitter potato; Aymara: luki; Quechua: ruku; Spanish: choquepito, ococuri

It seems that the domestication of bitter potatoes began some 8000 years ago and that, as cultivated domesticated species, they have been used extensively for at least 3000 years.

Acosta, one of the first Spanish chroniclers to describe the agricultural resources of the Andes, mentions that bitter potatoes that had been exposed to the cold overnight and then pressed and dried were transformed into what was known as *chuño* and were used as bread is in Europe. A century later, the priest Bernabé Cobo reported that. on the high plateau, there were wild potatoes and bitter potatoes which the Aymaras called aphus and which could only be eaten when processed as *chuño*: this food constituted the main staple in the high plateau region between Peru and Bolivia.

In spite of their importance for the agro-ecological zones of the puna. where frosts during the growth period limit food production, these crops were not studied during the time of the settlement, nor at the start of the Republic. During the 1920s, the Russian expedition organized by Vavilov and undertaken with his students Juzepczuki and Bukasov made a detailed description of these species on the basis of collections gathered on the high plateau around Lake Titicaca.

Several studies have been carried out on bitter potatoes during the past 50 years, including their origin, description and an evaluation of their nutritional capacity.

The area cultivated at present varies greatly from one year to the next, depending on whether an adequate amount of seed is available. However, there are an estimated 15000 ha in Peru and around 10000 ha on the high plateau of Bolivia, on peasants' plots ranging from 300 to 500 m^2 and over more extensive areas on land under sectoral rotation. There are further potential areas for cultivation, the inclusion of which could easily double the current production.

Uses and nutritional value

If bitter potatoes are to be eaten, they must first undergo processing to remove the glycoalkaloids. Traditional processes in the upper Andean area. described in various works, consist of exposing the tubers to several night frosts and drying them in strong sunlight at altitudes of 4 000 m to obtain black *chuño*. Larger bitter potatoes are preferably used to prepare white *chuño*, also called *tunta* (Aymara) or *moraya* (Quechua). Freezing is followed by the peeling, hydrating for up to 30 days and drying.

Black *chuño* is produced up to the edge of the forest where it keeps very well because of its characteristics as a dehydrated product. White *chuño* is preferably eaten on feast days. It fetches a high price at town markets where it is an ingredient of various regional dishes. Both white *chuño* and black *chuño* are very rich in energy.

The potential of bitter potatoes lies precisely in their ability to withstand low temperatures and yield a surplus. thus constituting an important food reserve. It has been calculated that, between August and March, black *chuño* can account for 70 percent of the food of rural populations of the Peruvian and Bolivian high plateau.

Botanical description

Solanum x *juzepczukii* measures 30 to 50 cm and has a semi-rosette growth habit, long, straight leaves. short petioles and a small, blue corolla.

S. x *curtilobum* is distinguished by its more coriaceous leaves and its corolla, which is bigger and purple with very short lobules and a pointed end.

The tubers vary in size and shape, ranging from rounded (Piñaza) to elliptical, oblong or elongated-oblong (Luki), and in colour. Clones of Ococuri have purple and white tubers.

The growing cycle varies greatly between five and eight months. The clone Piñaza is one of the earliest, taking 150 days; Ruki clones are the latest, taking up to 195 days.

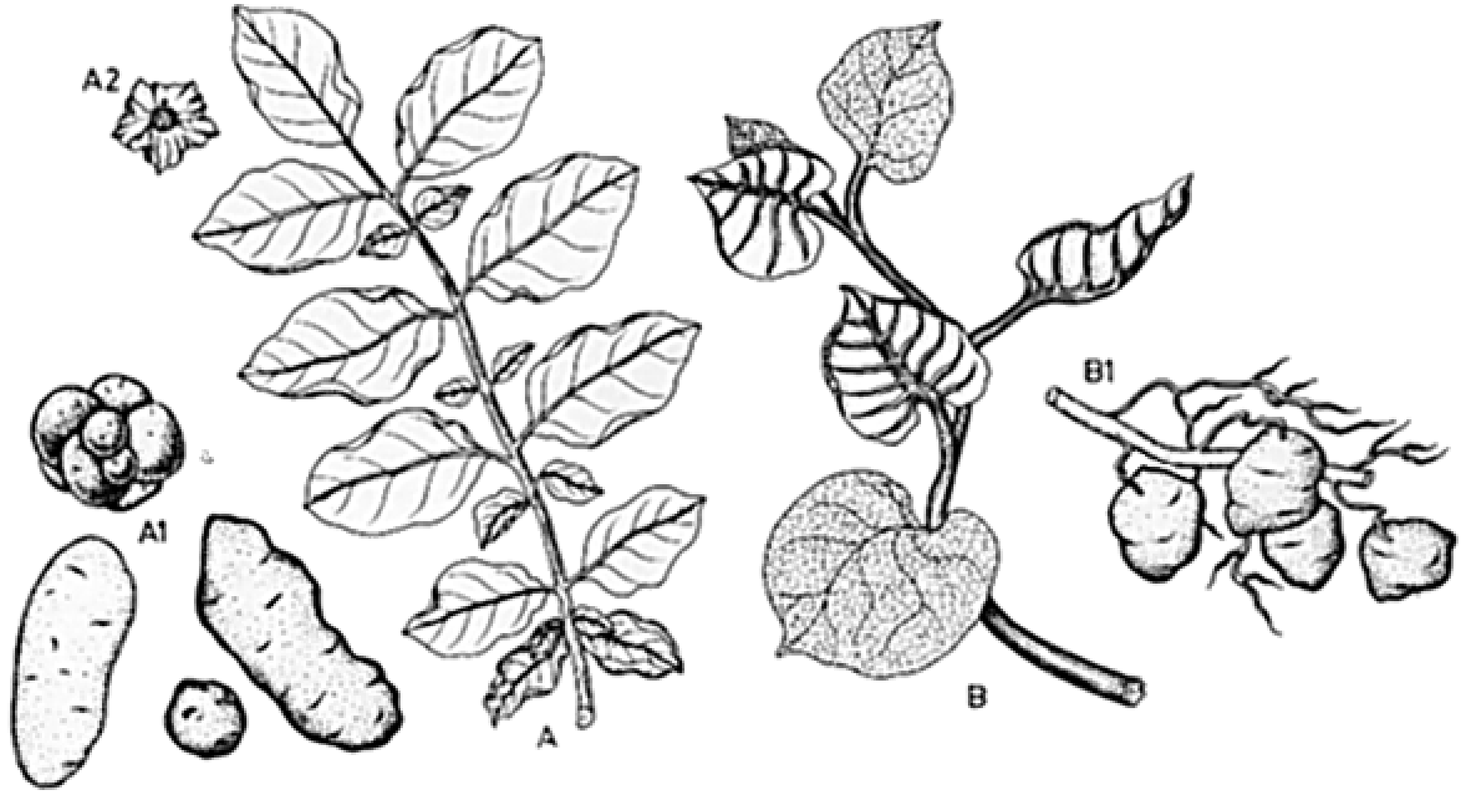

Figure 16. Andean tubers: A) bitter potatoes; A1) tubers; A2) flower; B) ullucu (*Ullucus tuberosus*); B1) tubers

Ecology and phytogeography

Bitter potatoes are cultivated at altitudes between 3000 and 4300 m, in the agro-ecological zones of the humid puna and suni, which are characterized by mean growth period temperatures of between 6 and 14°C, with precipitations which vary according to the region and year between 400 and 1400 mm, are spread over five to six months and which coincide with the summer period in the Southern Hemisphere (October-May).

Frosts may occur during the growth stage, with the temperature dropping to -5°C in some years. A greater incidence of low temperatures is observed in the dry period and these affect production heavily, with damage varying according to the species. Recently, in an area of Peru with frosts and temperatures of -5°C, the reduction in the harvest was 5 percent in the case of *S.* x *juzepczukii*, 30 percent in the case of *S.* x *curtilobum* and 40 percent in the case of the common potato.

The cultivation of bitter potatoes requires soils which have sufficient organic matter (3 to 5 percent) and which have had a period of fallow or adequate rotation. The best yields are obtained on soils which have lain tallow for three to four years and have had 2 to 3 tonnes of manure applied.

Bitter potatoes predominate on land where the main production is livestock and where there is natural pasture and thus little pressure on the land. Because of this, land can be put under a rotational system of crops with canihua (*Chenopodium pallidicaule*) or fodder plants such as barley or oats. including a prolonged period (up to six years) of fallow during which the natural vegetation covers the soil again. In areas which have a very broken topography and where the puna zone is very close to the suni or quechua (valley) zones, rotation includes other crops suited to these conditions, with tubers such as oca (*Oxalis tuberosa*) and ullucu (*Ullucus tuberosus*) or mixtures of these species.

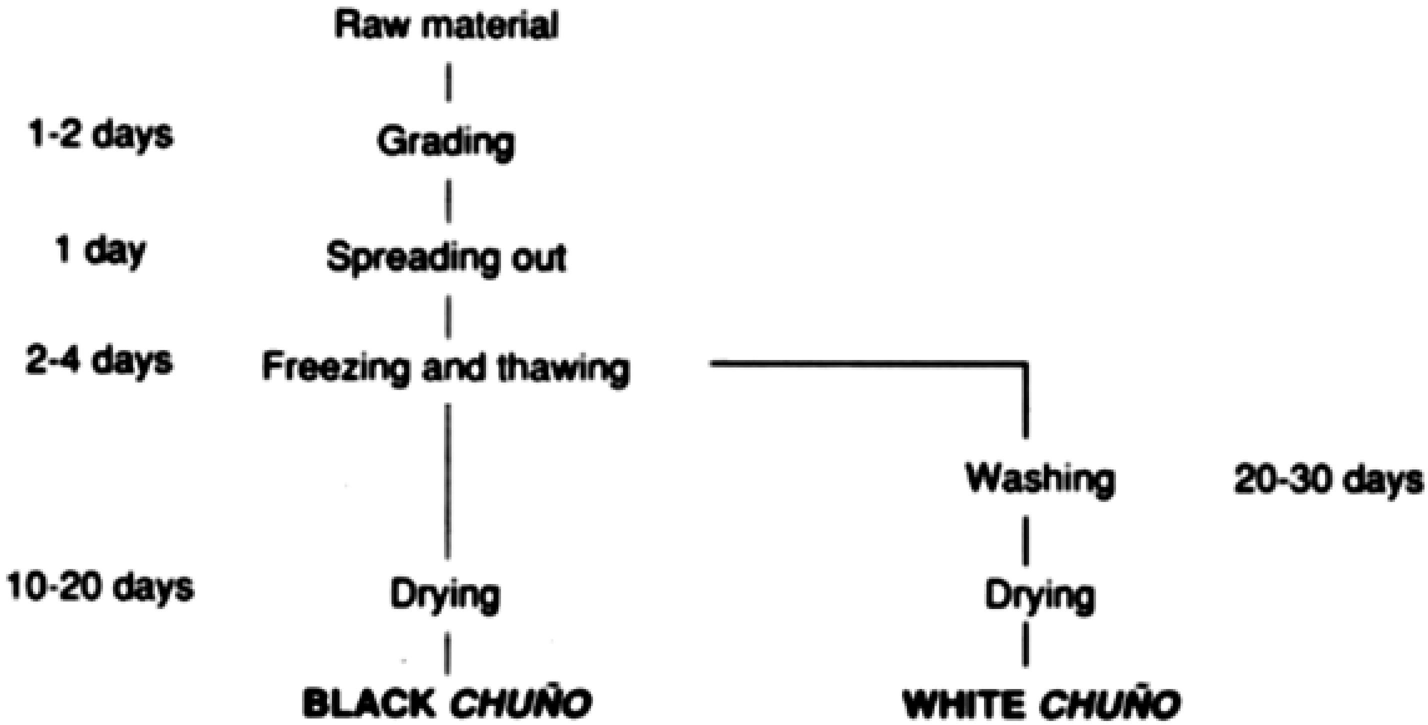

Figure 17. Diagram of *chuño* processing

Genetic diversity

In the southern region of Peru and on the Bolivian high plateau, there are a great number of varieties which have been bred by the peasants over centuries and which are suited to various ecological conditions in the highest region of the Andes.

Bitter potatoes belong to two species: *S.* x *juzepczukii* triploids and *S.* x *curtilobum* pentaploids. Because of their ploidy. which is caused by a high degree of sterility. it is difficult to use the characteristics of bitter potatoes in improvement programmes. The origin of bitter potatoes would seem to be due to various crossings derived from wild species such as *S. acaule.*

There is greater variability in the species S. x *juzepczukii*, the main cultivated varieties being Ruki, Luki, Piñaza, Parina, Locka, Parko, Keta and Kaisallu, with white or purple tubers.

In the species *S.* x *curtilobum*, we may distinguish those of the Choquepito group and the so-called Ococuri, which are characterized by a lower glycoalkaloid content than *S.* x *juzepczukii*.

There is an extensive collection of bitter potatoes in Cuzco and Puno in southern Peru, while a collection from the Bolivian high plateau is maintained at the experimental station of Patacamaya.

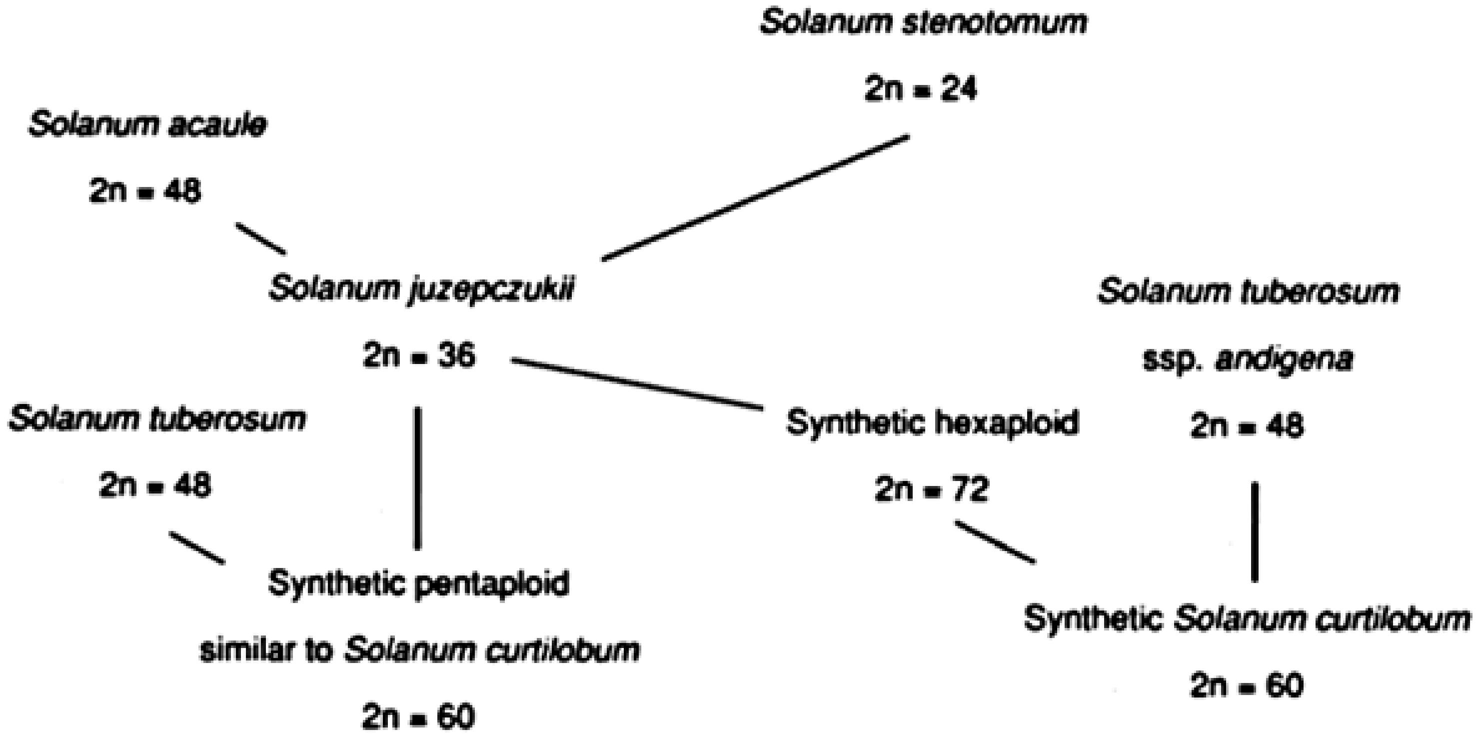

Figure 18. The origin of bitter potatoes

Cultivation practices

The soil is generally prepared with local implements, such as the *chakitakllla* or foot-plough, with the entire peasant family taking part in the operation. since it involves plots located in isolated places.

The sowing period of bitter potatoes is very much conditioned by the presence of rain, since the cap is grown under rain-fed conditions. The period extends from September to November, depending on whether the rains begin early or late. the tradition being to stagger sowing on two or three dates as a means of reducing the climatic risk. The crop needs to be earthed up once or twice when the plants reach a height of 30 to 30 cm. The start of tuberization coincides with the start of flowering, approximately seven to nine weeks after emergence, and lasts for about four weeks, during which time the absence of humidity and severe frosts is vitally important. In this respect there is a differentiation between early, intermediate and late ecotypes, which may mature between four to six months, hence a wide range is available for improvement programmes.

Fertilization is limited to sheep manure. However, there have been positive responses to the addition of chemical fertilizers in intermediate doses. The var. Piñaza responds better to fertilization than the var. Ruki, but the latter has a higher dry matter content.

The varieties of *S.* x *juzepczukii* are better suited to shallow soils than S. x *curtilobum*, which has deeper roots.

On account of their prostrate habit, bitter potatoes are susceptible to nematodes *(Naccobus aberrans*), to the Andean weevil (*Premnotrypes* spp.) and also to wart fungus (*Synchytrium endobioticum*).

Prospects for improvement

The tolerance of bitter potatoes to low temperatures is considered to be their main advantage and there is considerable scope for making selections from current populations. The existence of several varieties also enables cultivation to be extended to the different soil conditions in the highest area of the Andes. Bitter potato genes have been used more for the improvement of so-called sweet varieties than for their own improvement.

The main limitation is their glycoalkaloid content which gives them a bitter taste. In addition to solanine and chaconine, this includes tomatine, mysine and solamargine. However, since there is wide variability in this characteristic. varieties with a low content of this chemical substance can be selected. Although the current process to remove the bitter taste is fairly suited to local conditions and utilizes the climatic characteristics of the puna effectively, with its severe night frosts and intense daytime solar radiation, it is very labour-intensive (working conditions are very hard): it takes between 14 and 28 days to produce white *chuño*.

Ullucu (*Ullucus tuberosus*)

Botanical name: *Ullucus tuberosus* Loz.

Family: Basellaceae

Common names. English: ullucu, oca quina; Quechua: ulluku, ullus; Aymara: ulluma, illako; Spanish: michurui, michuri, miguri, micuche, ruba, rubia, timbo, tiquiño (Venezuela), chigua, chugua, rubas, hubas, camarones de tierra (Colombia), melloco (Ecuador), olluco, ulluco, lisa, papalisa (Peru), lisa, papalisa (Bolivia) and olloco, ulluca, ulluma (Argentina)

The ullucu is a plant native to the Andes. Ancient in origin, it is likely that its cultivation extended from the Andes of Venezuela (lat. 10°N) to northwestern Argentina and northeastern Chile (lat. 25°S) in pre-Hispanic times. However, the exact region of its domestication is not known. Ceremonial vessels of the Robles Moqo style of the Wari culture (the centre of which was Ayacucho between AD 400 and 700) are decorated with multicoloured representations of Andean plants, including the ullucu. It also appears on *qero* ceremonial vessels of the post-Incan era. The oldest vestige is the presence of starch among 4000-year-old plant remains from Ancon and Chilca on the Peruvian coast.

The ullucu's wide distribution in the Andes and its age are also revealed in the profusion of regional names.

Uses and nutritional value

Of the three Andean tubers, the ullucu is the most popular and has become established on the tables of both the rural and urban population in Ecuador, Peru and Bolivia. Traditional preparations include *mellocos* soup (Ecuador); *olluquito con charqui* (*ullucu* with meat—Peru); *chupe* (potato, meat, egg and cheese stew) and *ají de papalisas* (ullucu pepper—Bolivia and Peru). It is also suitable for use in contemporary dishes such as salads. Some varieties contain a greater quantity of mucilage and need to be preboiled before preparation to remove it. The Andean tubers perish easily, which explains why ancient Andean peoples attempted to store surpluses by freezing and drying, processes used also for the ullucu. The product obtained is called *lingli* in Peru; its average protein content is 1.7 percent in the edible tuber, while the carbohydrate and energy content is slightly less than that of most tubers.

Botanical description

The ullucu is an erect, compact plant which reaches a height of 20 to 50 cm. At the end of its growth it is prostrate. Tuber shapes vary from spherical to cylindrical and colours range from white, yellow, light green, pink and orange to purple. On very rare occasions, it forms fruit; the seed then has the form of an inverted pyramid, with very prominent angles and a corrugated surface.

Ecology and phytogeography

The origin and development of the ullucu in the cold climates of the Andes suggest that it is one of the crops most suited to the complex agro-ecology of areas between 3000 and 4000 m. Although the precise role of hybridization, introgression and mutation in the ullucu is not known, these must have acted—along with natural and human selection pressure—to favour the plant's distribution and adaptation to the various types of Andean climate and soils.

Genetic diversity

The wild ullucu would seem to indicate a sympatric distribution with the cultivated ullucu, since up to now it has been found from the Andes of La Libertad in Peru (lat. 8°S) to northwestern Argentina (lat. 25°S). This would appear to indicate a smaller geographical range of habitats than that of the cultivated ullucu. However, collecting expeditions have been orientated towards cultivated material, which is harvested in dry periods when there is no opportunity to collect wild material. It is probable that in the geographical distribution area of the wild ullucu—which seems to be wide—ullucus may be found with interesting characteristics that will help to extend our knowledge of its domestication.

Cultivated ullucus are diploid and triploid, with a basic number of 12. The presence of polyploids in the wild ullucu has also been demonstrated. Nevertheless, the frequency of diploids, triploids and probably tetraploids needs to be determined. In the wild, triploids are generally formed by hybridization between diploids and tetraploids, or by the fusion of a normal gamete and another that has not been reduced between diploid parents. Triploids are generally sterile and the only way of propagating them is vegetatively. Their great vigour allows them to prosper and occur in profusion over a wide distribution area.

The study of meiosis in the cultivated diploid ullucu shows a regular meiotic pairing with the formation of 12 bivalents. Meiosis of the triploids is within expectations, i.e. defective and with the presence of univalents and trivalents. Meiotic pairing of artificial diploid hybrids would need to be researched, provided the combinations are possible.

Ullucu collections in South America

Cultivated and wild ullucus did not arouse much interest among plant explorers in the past. In spite of the fact that the collections of Bukasov and Juzepczuki in South America between 1925 and 1928 were followed by several expeditions to gather cultivated and wild plants, ullucu does not seem to have been collected, even within the same South American countries. Three stages could be distinguished in the collection of ullucu and the formation of gene banks. The first occurred in the 1920s with the work of Bukasov and Juzepczuki; the second covers the work of León through the establishment of the then greater collection of ullucu germplasm at the IICA, with material from Colombia, Ecuador, Peru and Bolivia. Later, collections of wild ullucus were made in northeastern Argentina and Bolivia by Brucher. The third stage began in the 1970s with small local collections at the Universities of Cuzco, Huancayo and Ayacucho, and likewise in the 1980s. Thanks to very positive help from the IBPGR. FAO, CIID and IICA/OAS they were continued more intensively with national programmes such as those of the IBTA in Bolivia, INIAP in Ecuador and INIAA and the Universities of Puno, Cuzco and Ayacucho in Peru. Under these programmes, gene banks are produced annually. These banks suffer from the following shortages which limit the knowledge and promotion of the ullucu:

- **Scant geographical representation:** While the Andes of Ecuador and Peru were explored. few or no collections were made in the Andes of Colombia, Venezuela, the eastern area of Peru, southern Bolivia and northwestern Argentina.
- **Duplication of accessions:** In clonal propagation crops such as the ullucu, there is a high probability of repeatedly collecting one and the same clone in different localities: also. the exchange of germplasm between national programmes without identifying data has meant that one and the same clone can be recorded under different numbers in various banks.
- **Incomplete documentation:** No standardized. internationally accepted descriptors exist for the characterization of the ullucu; there is a lack of specimens from herbaria such information would be very useful in the event of living collections being lost.
- **A lack of wild plant collections:** There is an almost total absence of wild material, such material would help to understand the variation patterns of the cultivated forms and could provide valuable characteristics for improvement.

Cultivation practices

Ullucu cultivation practices are the same as those described for the oca.

Prospects for improvement

Although the ullucu is a hardy plant that is suited to the difficult conditions of the Andes, viral diseases seem to constitute one of its most serious problems. Viral infections in gene banks affect up to 80 percent of samples. This is a particularly serious problem, not only for gene banks, but also for the crop's management.

Viruses may form viral complexes of up to four different particles in a single plant, causing loss of vigour, deformation and leaf mottling. Moreover, they are far more difficult to eliminate than bacterial or fungal pathogens. Eradication in commercial varieties and selected genetic material is an urgent requirement, although the number of viruses which affect the ullucu is not known. Studies at the CIP have revealed at least four viruses, but the number may be higher.

Another limiting factor is the prolonged cultivation period. While modem commercial varieties of potato are harvested after four or five months in the Andes, the ullucu takes seven or eight months to mature. In other words, ullucu plants are exposed longer to drought, frost, pests, diseases and other adverse factors which are frequent in the Andes. Productivity in terms of time and space is consequently low. It seems to be one of the causes of marginalization, so that ullucu cultivation is gradually being replaced by varieties of early high-yielding potatoes.

The biggest advantage of the ullucu is that it is firmly established among rural and urban people in areas where its supply is almost continuous throughout the year.

American Bittersweet

Celastrus scandens L.

Figure 2.—American Bittersweet (*Celastrus scandens*

Other common names.—False bittersweet, climbing bittersweet, shrubby bittersweet, fevertwig, fever-twitch, staff tree, climbing staff tree, staff vine, waxwork, Roxbury waxwork, yellowroot, climbing orange-root, Jacob's-ladder.

Habitat and range.—This woody vine or climbing shrub is found in woods and thickets, growing in rich damp soil from Ontario to Manitoba and south to North Carolina and New Mexico.

Description.—American bittersweet is a woody and shrubby climber, growing over trees or fences. It has smooth thin leaves 2 to 4 inches long and about half as wide. The small greenish-white or greenish-yellow flowers are produced in June in short clusters. The fruit is a roundish, orange-yellow capsule which opens in autumn, disclosing the scarlet-colored seed. The seed capsules remain on the plant well into the cold season.

Part used.—The bark of the plant and root, but especially that of the root.

Black Cherry

Prunus serotina Ehrh.

Figure 16.—Black cherry (*Prunus serotina*)

Synonym.—*Prunus virginiana* Mill., not of Linnaeus.

Other common names.—Wild cherry, wild black cherry, cabinet-cherry, black choke, rum cherry, whisky-cherry, Virginian prune-bark.

Habitat and range.—The black cherry occurs in woods or open places and is most abundant in the Southeastern States, but its range extends from Nova Scotia to Florida, westward to Texas, and north through Oklahoma, the eastern portions of Kansas, Nebraska, and South Dakota.

Description.—This tree sometimes reaches a height of 90 feet and a maximum trunk diameter of 4 feet. The trunk is straight and covered with rough black bark, but the young branches are smooth and reddish. The smooth shining leaves are about 2 to 5 inches long. The long drooping clusters of small white flowers are borne at the ends of the branches, usually during May. The cherries, which ripen about August or September, are round, black, or very dark purple, about the size of a pea, and have a sweet, slightly astringent taste.

Part used.—The bark, collected in autumn. The outer layer is removed, and the bark is then carefully dried and preserved. Young thin bark is preferred and that from very young or very old branches should not be used. Black cherry bark should not be kept longer than one year, because it deteriorates with age.

Black grama

Gramineae *Bouteloua eriopoda* (Torr.) Torr.

Source: Magness et al. 1971

Black grama is a major native grass of the semiarid to arid areas from West Texas westward to California. The stems, when in contact with soil, form roots at the nodes to form other nearby plants. Stems are slender and wiry, up to 2 feet. Plants are leafy and highly palatable with good feeding value both summer and winter. They are highly drought resistant.

Blackhaw

Viburnum prunifolium L.

Other common names.—Sloe, sloe-leaved viburnum, stagbush, shonny.

Figure 17.—Blackhaw (*Viburnum prunifolium*)

Habitat and range.—The blackhaw occurs in dry woods and thickets and on rocky hillsides from Connecticut to Florida and west to Michigan and Texas, but is found in greatest abundance in the South.

Description.—This shrub or small tree, from 10 to about 20 feet in height, has rather stout, spreading branches. The smooth bright-green, finely toothed, broadly or roundish oval leaves are 1 to 3 inches long. The numerous stemless flower clusters are from 2 to 4 inches broad, composed of numerous white flowers appearing from April to June. The fruit, which is sweet and edible, is about half an inch long, bluish black, covered with a bloom, and ripens in early autumn. It contains a somewhat flattened stone.

Another species.—The sweet viburnum (*Viburnum lentago* L.), known also as nannyberry and sheepberry, is collected with *V. prunifolium*. It grows in rich soil from Canada south to Georgia and Kansas. Its fruit matures in October, becoming sweet and edible, and sometimes remaining on the shrub until the following spring.

Part used.—The bark of both species, collected in autumn.

Black Sapote

Diospyros digyna Jacq.

Diospyros obtusifolia Humb. & Bonpl. ex Willd.

The black sapote is not, as might be assumed, allied to either the sapote *(Pouteria sapota* H.E. Moore & Stearn) or the white sapote *(Casimiroa edulis* Llave & Lex.). Instead, it is closely related to the persimmon in the family Ebenaceae. For many years it has been widely misidentified as *Diospyros ebenaster* Retz., a name confusingly applied also to a strictly wild species of the West Indies now distinguished as *D. revoluta* Poir. The presently accepted binomial for the black sapote is *D. digyna* Jacq. (syn. *D. obtusifolia* Humb. & Bonpl. ex Willd.).

In Spanish, it is known variously as sapote, *sapote negro*, *zapote, zapote negro, zapote prieto, zapote de mico, matasano* (or *matazano) de mico,* or *ebano.* It has been called black persimmon in Hawaii.

Description

Plate LXI: BLACK SAPOTE, *Diospyros digyna*

The tree is handsome, broad-topped, slow-growing, to 80 ft (25 m) in height, with furrowed trunk to 30 in (75 cm) in diameter, and black bark. The evergreen, alternate leaves, elliptic-oblong to oblong-lanceolate, tapered at both ends or rounded at the base and bluntly acute at the apex, are leathery, glossy, 4 to 12 in (10-30 cm) long. The flowers, borne singly or in groups of 3 to 7 in the leaf axils, are tubular, lobed, white, 3/8 to 5/8 in (1-1.6 cm) wide, with persistent green calyx. Some have both male and female organs, large calyx lobes and are faintly fragrant; others are solely male and have a pronounced gardenia-like scent and a few black specks in the throat of the corolla. The fruit is bright-green and shiny at first; oblate or nearly round; 2 to 5 in (5-12.5 cm) wide; with a prominent, 4-lobed, undulate calyx, 1 1/2 to 2 in (4-5 cm) across, clasping the base. On ripening, the smooth, thin skin becomes olive-green and then rather muddy-green. Within is a mass of glossy, brown to very dark-brown, almost black, somewhat jelly-like pulp, soft, sweet and mild in flavor. In the center, there may be 1 to 10 flat, smooth, brown seeds, 3/4 to 1 in (2-2.5 cm) long, but the fruits are often seedless.

Origin and Distribution

The black sapote is native along both coasts of Mexico from Jalisco to Chiapas, Veracruz and Yucatan and in the forested lowlands of Central America, and it is frequently cultivated throughout this range. It was apparently carried by the Spaniards to Amboina before 1692, and to the Philippines long before 1776, and eventually reached Malacca, Mauritius, Hawaii, Brazil, Cuba, Puerto Rico and the Dominican Republic. In 1919, seeds from Guadalajara, Mexico, were sent to the Bureau of Plant Industry of the United States Department of Agriculture; cuttings and seeds were received from the Isle of Pines, Cuba, in 1915; seeds arrived from Hawaii in 1916 and 1917; others from Oaxaca, Mexico, in 1920. Numerous seedlings have been grown in southern California but all have been killed by low temperatures. The tree does very well in southern Florida, though it has been grown mainly as a curiosity. Outside of its homeland, the fruit has not achieved any great popularity. In Mexico, the fruits are regularly marketed.

Varieties

Certain trees tend to bear very large, seedless or nearly seedless fruits maturing in summer instead of winter as most do, but no varietal names have been attached to them in Florida.

Climate

The black sapote is not strictly tropical inasmuch as it is hardy as far north as Palm Beach County, Florida, if protected from frost during the first few years. Trees that have become well established have withstood occasional brief exposures to 28º or 30º F (-2.22º or-1.11º C). In Mexico, the tree is cultivated up to elevations of 5,000 or even 6,000 ft (1,500-1,800 m).

Soil

The tree has a broad adaptability as to terrain. In Mexico it grows naturally in dry forests or on alluvial clay near streams or lagoons where it is frequently subject to flooding. Nevertheless, it thrives on moist sandy loam, on well-drained sand or oolitic limestone with very little top-soil in southern Florida. It is said to flourish on all the soils of Cuba.

Propagation

The black sapote is usually grown from seeds, which remain viable for several months in dry storage and germinate in about 30 days after planting in flats. Vegetative propagation is not commonly practiced but the tree has been successfully air-layered and also shield-budded using mature scions.

Culture

Seedlings are best transplanted to pots when about 3 in (7.5 cm) high and they are set in the field when 1 to 2 years old, at which time they are 1 to 2 ft (30-60 cm) in height. They should be spaced at least 40 ft (12 m) apart. Most begin to bear in 5 to 6 years but some trees may take somewhat longer. The tree is naturally vigorous and receives little or no cultural attention in Florida though it has been noted that it benefits from fertilization.

Season

In Mexico, the fruits are common in the markets from August to January. Most black sapotes in Florida ripen in December, January or February. Certain trees, especially the large-fruited types, regularly come into season in June, others in July and August.

Harvesting

It is difficult to detect the slight color change of mature fruits amid the dense foliage of the black sapote tree. Many black sapotes ripen, fall and smash on the ground before one has the chance to pick them, and this is one reason why .the tree is not favored for landscaping in urban areas. An experienced picker can harvest the fruits at the green-mature or olive-green stage with a cutting pole equipped with a cloth sack.

Yield

No yield figures are available but the tree is noted for bearing well. In 1899, the annual crop in Mexico was valued at $27,000, a considerable sum at that time.

Keeping Quality

Fruits picked when full-grown but unripe (bright-green) have ripened in 10 days at room temperature. Therefore it is at this stage that they must be picked for marketing and shipping. Firm, olive-green fruits will ripen in 2 to 6 days. Fruits displayed on markets in Mexico are somewhat shriveled and wrinkled. The black sapote is very soft when fully ripe. Though it may remain fit for eating if held for a few days in cold storage, it is too soft to stand handling.

Food Uses

Unkind writers have employed unflattering phrases in describing the flesh of the black sapote and have probably hindered its acceptance. This seems quite unreasonable because the color and texture of the pulp closely match stewed prunes, to which there seems to be no aesthetic objection. In the Philippines, the seeded pulp is served as dessert with a little milk or orange juice poured over it. The addition of lemon or lime juice makes the pulp desirable as a filling for pies and other pastry. It is also made into ice cream. In Mexico, the pulp may be mashed, beaten or passed through a colander and mixed with orange juice or brandy, and then served with or without whipped cream. Also, they sometimes mix the pulp with wine, cinnamon and sugar and serve as dessert. Some Floridians use an eggbeater to blend the pulp with milk and ground nutmeg. A foamy, delicious beverage is made by mixing the pulp with canned pineapple juice in an electric blender. In Central America, the fermented fruits are made into a liqueur somewhat like brandy.

Food Value Per 100 g of Edible Portion*	
Moisture	79.46-83.1 g
Protein	0.62-0.69 g
Carbohydrates	12.85-15.11 g
Fat	0.01 g
Ash	0.37-0.6 g
Calcium	22.0 mg
Phosphorus	23.0 mg
Iron	0.36 mg
Carotene	0.19 mg
Thiamine	
Riboflavin	0.03 mg
Niacin	0.20 mg
Ascorbic Acid**	191.7 mg

*According to analyses in Mexico and Guatemala.

**The ascorbic acid content is said to be about twice that of the average orange.

Toxicity

Unripe black sapotes are very astringent, irritant, caustic and bitter, and have been used as fish poison in the Philippines.

Other Uses

Wood: The wood is yellowish to deep-yellow with black markings near the heart of old trunks; compact and suitable for cabinetwork but little used. Reports of dark wood utilized for furniture are probably the result of confusion with other species of *Diospyros.*

Medicinal Uses: The crushed bark and leaves are applied as a blistering poultice in the Philippines. In Yucatan, the leaf decoction is employed as an astringent and is taken internally as a febrifuge. Various preparations are used against leprosy, ringworm and itching skin conditions.

Note: The rare, wild relative *D. revoluta* Poir., mentioned at the beginning, has not only been included with the black sapote under the erroneous *D. ebanaster,* but has also been dealt with as *D. nigra* Perr. and under at least 8 other binomials. In Puerto Rico, the Dominican Republic, Montserrat, Dominica and Guadeloupe it is variously called black apple, *barbara*, *bambarat, barbequois, bois noir*, *bois negresse*, *ebene*, *guayabota*, *plaqueminier*, and *zapote negro*. It has smaller, thicker leaves and smaller fruits than the black sapote and the calyx is square. Little, Woodbury and Wadsworth say the fruits are poisonous and, with the bark, used as fish poison.

Juglans nigra L.

Juglandaceae

Eastern black walnut

Black Willow

Salix nigra Marsh.

Other common names.—Swamp willow.

Figure 19.—Black willow (*Salix nigra*)

Habitat and range.—This tree is found in low ground and along streams from New Brunswick to western Ontario and in North Dakota, Florida, and Texas.

Description.—This willow is a tree attaining a height of 120 feet and a trunk diameter of 3 feet, with narrow lance-shaped leaves 2 1/2 to 5 inches long and up to three-quarters of an inch wide, finely toothed and hairy when young. Male and female flowers are borne in separate catkins which expand with the leaves the male catkins l to 2 inches and the female catkins 1 1/2 to 3 inches long.

Part used.—The bark and buds.

Blessed Thistle

Cnicus benedictus L.

Synonyms.—*Carduus benedictus* Steud., *Carbenia benedicta* Adans.

Figure 20.—Blessed thistle (*Cnicus benedictus*)

Other common names.—Holy thistle, St.-Benedict's-thistle, Our Lady's thistle, bitter thistle, spotted thistle, cursed thistle, blessed cardus, spotted cardus.

Habitat and range.—The blessed thistle is a weed which is found sparingly in waste places and stony, uncultivated localities from Nova Scotia to Maryland and the Southern States, also on the Pacific coast.

Description.—This plant, which scarcely exceeds 2 feet in height, has a coarse, erect, branched, and rather woolly stem. The leaves are 3 to 6 inches long, more or less hairy, with margins lobed and spiny. The yellow flower heads which appear from about May to August are borne at the ends of the branches, almost hidden by the upper leaves, and are about 1 1/2 inches long. Surrounding the flower heads are leathery scales, tipped with long, branching, yellowish-red spines. The herb has a rather disagreeable odor which is lost in drying.

Part used.—The leaves and leafy flowering tops, gathered preferably just before or during the flowering period.

Carambola or Star Fruit

Jalea

Oxalidaceae *Averrhoa carambola* L.

Blimbe

Grosella china, Cucumber tree, Bilimbe

***A. bilimbi* L.**

Source: Magness et al. 1971

The carambola tree attains a height of 35 feet. Its fruits are star-shaped when cut across, ovoid to ellipsoid, yellow, 4 to 5 inches in length and are acutely 5-angled. The fruit is crisp, juicy, and aromatic. The ripe fruits are used for preserves, jams and jellies. The half ripe fruit is used as pickles.

The blimbe tree attains a height from 20 to 60 feet. The mature fruit resembles small cucumbers and range from 2 to 3 inches in length. They are smooth, thin, green, rind sometimes faintly 5-angled. Fruits of blimbe are candied as a preserve. The pulp also is used to make a refreshing drink.

Blue Cohosh

Caulophyllum thalictroides (L.) Michx.

Other common names.—Caulophyllum, papoose root, squawroot, blueberry root, blue ginseng, yellow ginseng.

Habitat and range.—Blue cohosh is found in the deep rich loam of shady woods from New Brunswick to South Carolina and westward to Nebraska, being abundant especially throughout the Allegheny Mountain region.

Figure 22.—Blue cohosh (*Caulophyllum thalictroides*)

Description.—Blue cohosh is from 1 to 3 feet in height and hears at the top one large almost stemless leaf which is divided into three divisions, each of which is again divided into three divisions consisting of three leaflets each. The latter have from three to five lobes. During its early growth the plant is covered with a bluish-green bloom which gradually disappears. The small greenish-yellow flowers are borne in small heads during April and May. The small round seeds, which ripen in August, are borne on stout stalks and resemble dark-blue berries. The thick, crooked rootstock is covered with a mass of matted roots.

Part used.—The rootstock with roots, collected in autumn.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Last update Friday, March 13, 1998 by aw

Blueflag Iris

Iris versicolor L.

Figure 23.—Blueflag iris (*Iris versicolor*)

Other common names.—Iris, flag lily, liver lily, snake lily, poison flag, water flag, American fleur-de-lis or flower-de-luce.

Habitat and range.—Blueflag iris delights in wet, swampy localities, making its home in marshes, thickets, and wet meadows from Newfoundland to Manitoba and south to Florida and Arkansas.

Description.—This well-known plant is from 2 to 3 feet hl height With an erect stem, sometimes branched near the top, and sword-shaped leaves, shorter than the stem, from one-half to 1 inch in width and showing a slight grayish bloom. The flowers, which appear from May to July, are large and handsome, each stem bearing from two to six or more. They have a peculiar form, consisting of six segments, the three outer ones turned back and the three inner ones erect and much smaller. They are purplish blue, the narrow base of the segments variegated with yellow, green, or white and marked with purple veins. Blueflag has a thick, fleshy, horizontal, branched rootstock producing many long, fibrous roots. It is poisonous and has caused poisonous effects in persons who mistook the plant for sweetflag which it resembles greatly when not in flower.

Part used.—The rootstock, collected in autumn. demand.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Last update Friday, March 13, 1998 by aw

Blue grama

Gramineae *Bouteloua gracilis* (HBK) Lag. ex Steud.

Source: Magness et al. 1971

Blue grama is a long-lived native perennial grass that grows throughout the Great Plains. It is low growing, up to 18 inches, with small leaves, not over 6 inches long and 0.125 inch or less in width. It is found on all soil types, but thrives best on upland, rather beavy soils. It is drought resistant. Growth is late starting in spring. It is relished as pasture by all classes of livestock. It is one of the more important range grass species, standing heavy grazing well. It is readily established by seeding.

Last update February 18, 1999 by ch

Introduced Panicgrasses

Gramineae *Panicum* sp.

Source: Magness et al. 1971

Three species of*Panicum*, one introduced from India and two from Africa, are of some importance in parts of the United States.

Blue panicgrass, *P. antidotale* Retz., native to India, was introduced via Australia in 1912. It has a coarse, vigorous root system and is sodforming. Forage yields are high on fertile, well drained soils. It is important in parts of southwestern United States, both for dry-land and irrigated pastures. It is not winter hardy in northern locations.

Kleingrass, *P. coloratum* L., is a complex of grasses which includes both bunch and sod-forming types. It was introduced from Africa. Adapted to moist, heavy soil, it is used for pasture, hay and silage - mainly in South Texas. Plants have slender stems up to 4 feet, with abundant dark green leaves.

Guineagrass, *P. maximum* Jacq., is a warm-season, spreading grass from Africa used to a limited extent for pastures and silage in Florida and other southern areas. It is a tall, coarse grower with high nutritive value when leafy and green. It is not cold hardy. Propagation is by sod pieces.

Last update February 18, 1999 by ch

Blue Vervain

Verbena hastata L.

Other common names.—Verbain, false verbain, wild hyssop, simpler's-joy, ironweed.

Figure 24.—Blue vervain (*Verbena hastata*)

Habitat and range.—Vervain is found in moist fields, meadows, and waste places from Nova Scotia to British Columbia and Florida, Nebraska, and Arizona.

Description.—This rather rough, finely haired herb has an erect, straight 4-sided stem, 4 to 7 feet high, usually branched above with broadly lance-shaped sharply toothed leaves. The small, usually blue, flowers are densely clustered in numerous slender panicled spikes 2 to 6 inches long.

Part used.—The herb.

Blue wild-rye

Gramineae *Elymus glaucus* Buckl.

Source: Magness et al. 1971

This wild-rye is a perennial bunchgrass native throughout the Western States.
It grows in small tufts, reaching up to 5 feet. Leaves are broad and flat, up to 12 inches long. It is abundant on moist soils but will tolerate drought. The coarse leaves are relished by cattle, particularly while succulent. It is shade tolerant and gives high yields of pasturage or of good hay if cut early. It is propagated by seeds but has not been widely planted.

Last update February 18, 1999 by ch

Blueberry

Huckleberry

Ericaceae *Vaccinium* sp.

Highbush blueberry *V. corymbosum* L.

Lowbush blueberry *V. angustifolium* Ait.

Rabbiteye blueberry *V. ashei* Reade

Source: Magness et al. 1971

Several species of blueberries are native in the U.S., and fruits of many are gathered from the wild. The three species listed are the ones in commercial culture. The lowbush is not commercially planted, but thousands of acres of natural stands are pruned, sprayed and harvested. The highbush varieties, produced by breeding during the past half century, are now widely grown. The rabbiteye is increasing in importance in the Southeast.

Plants of all are woody shrubs, varying from 2 to 3 feet in the lowbush to 10 or more feet in the highbush and rabbiteye, but in cultivation held to 5 to 6 feet by pruning. Fruit is smooth skinned with a waxy coating or bloom. Individual berries are borne in clusters, are round to oblate in shape. Size up to 0.75 inch diameter in cultivated varieties; 0.25 to 0.5 inch in natives.

Season, bloom to harvest: 2 to 4 months.

Production in U.S.: About 27,000 tons.

Use: Fresh, frozen, canned, jam, culinary.

Part of fruit consumed: All.

Last update February 18, 1999 by ch

Bluegrasses

Gramineae *Poa* sp.

Source: Magness et al. 1971

Some 200 species of *Poa* are distributed throughout the cool, temperate regions of the world, with 65 species recognized in the United States. They are valuable for pasturage, hay and lawns. They are considered the most palatable of range and pasture grasses. The more important agricultural species follow.

Big bluegrass

Texas bluegrass

Bulbous bluegrass

Canada bluegrass

Mutton bluegrass

Kentucky bluegrass

Sandberg bluegrass

Roughstalk bluegrass

Last update February 18, 1999 by ch

Bulbous bluegrass

Gramineae *Poa bulbosa* L.

Source: Magness et al. 1971

This is a cool-season bunchgrass believed native to Southern Asia and the Mediterranean Area. It is now found in nearly all temperate and subtropical regions. In this country it is grown mainly in the Pacific Area, especially Southern Oregon and Northern California. Its distinctive feature is that it forms small, true bulbs at the base and small bulblets in the panicle. It rarely forms true seeds but is propagated by planting the bulblets, which can be handled in harvesting and planting much as though they were seed. The stems reach to 18 inches high. Growth starts in the fall and continues through winter and spring in mild climates. It ceases when the bulblets form about mid-May.

Index | Search | Home

Canada bluegrass

Gramineae *Poa compressa* L.

Source: Magness et al. 1971

This grass, like Kentucky bluegrass, is native to Europe but is extensively naturalized in Northern States. The foliage is a distinctive bluegreen in color. It spreads by underground rhizomes. It is adapted to open, rather poor, dry soils and under these conditions may be better than Kentucky blue for pastures or lawns. Forage is highly palatable and nutritions. Seed production is good, and propagation is by seeding.

Last update February 18, 1999 by ch

Poa pratensis L.

Syn: *Phalaris japonica* Steud.

Gramineae

Kentucky bluegrass

We have information from several sources:

Cool-Season Grass Seed Production: Alternative Field Crops Manual, University of Wisconson Cooperative Extension Service, University of Minnesota Extension Service, Center for Alternative Plant & Animal Products

Food and feed crops of the United States Magness, J.R., G.M. Markle, C.C. Compton. 1971

Mutton bluegrass

Gramineae *Poa fendleriana* (Steud.) Vasey

Source: Magness et al. 1971

This grass is native from the Great Lakes westward to the Cascade Mountains and south into Mexico. It is a perennial bunchgrass with erect stems up to 24 inches tall. It develops tillers at the base and rarely produces short rhizomes. Leaves are mainly basal, are rather firm and stiff. They are folded or inrolled, rarely flat. The species grows under a wide range of conditions including elevations to near the top of the Rocky Mountains. It is also found among sagebrush and in open timber stands. It is well adapted to dry slopes and is found on clay loam as well as sandy or gravelly soils. It is drought resistant, palatable and nutritious, and starts growth very early. Even the dry growth is grazed well. These characteristics make it a valuable range crrass. The name reflects the value sheepmen place on the grass for sheep feed.

Last update February 18, 1999 by ch

Roughstalk bluegrass

Gramineae, Poaceae *Poa trivialis* L.

Source: Magness et al. 1971

This bluegrass generally resembles Kentucky blue but differs in that it does not have rhizomes. It is native to Europe and is more important there as a pasture grass than in this country. It is used in this country for pasture on wet soils and for lawns in shaded areas. It is not adapted to droughty conditions. Although highly palatable, its restricted areas of adaptation Iimit its general agricultural importance.

Last update July 1, 1996 bha

Sandberg bluegrass

Gramineae, Poaceae *Poa secunda* Presl

Source: Magness et al. 1971

This is a native bluegrass occurring generally throughout the Northern Plains and Western States. It is a bunchgrass reaching to 24 inches under optimum conditions. Leaves are rather sparse. The grass starts growth early in spring and matures and dries in midsummer. While green, and even after drying, the foliage is quite palatable, so it is a valuable range grass. Seed germination is usually low. Sandberg is usually seeded in combination with later growing grasses to obtain maximum pasturage over a long season.

Last update June 28, 1996 bha

Texas bluegrass

Gramineae, Poaceae *Poa arachnifera* Torr.

Source: Magness et al. 1971

This is a vigorous sod-forming perennial native in the Southeastern and Southern Plains States. Plants grow up to 3 feet on strong soil, with numerous leaves 6 to 12 inches long and 0.25 inch wide. The grass grows throughout the winter producing abundant, nutritious pasture which is highly palatable. This is a valuable species where native, but seeding is difficult. The species is dioecious, with male and female plants. It produces only limited quantities of seed which is covered with woolly hairs that are difficult to remove. Consequently, establishment of stands for agricultural use is limited.

Last update June 27, 1996 bha

Caucasian bluestem

Gramineae *Bothriochloa caucasica* (Trin.) C.E. Hubb.

Source: Magness et al. 1971

This bunchgrass bluestem from Russia shows promise as a pasture and hay grass for the Central and Southern Great Plains. The plant is leafy with fine stems and reseeds readily. It is palatable while succulent but ripens early so is less useful for late pasture than the native bluestems. It is especially useful for erosion control and is also used for pasture and hay. It thrives best on medium- to fine-textured soils but will also grow on sandy soil.

Last update February 18, 1999 by ch

Diaz bluestem

Gramineae *Dichanthium annulatum* (Forsk.) Stapf in Prain

Source: Magness et al. 1971

This is a warm season bunchgrass from South Africa, useful for pasture in South Texas. Stems are slender, erect to semi-decumbent, up to 5 feet in height. In one variety stems are leafy and have stiff leaves at the nodes. Plants reseed aggressively. The grass is palatable both as pasture and hay. Plants are drought tolerant, somewhat alkali tolerant, and well adapted to range seeding on heavy soils.

Last update February 18, 1999 by ch

Little bluestem

Gramineae *Schizachyrium scoparium* (Michx.) Nash

Source: Magness et al. 1971

This is a vigorous, long-lived native bunchgrass, widely distributed over the United States; but most prevalent in the Central and Southern Great Plains. It is usually found associated with big bluestem grass. It is more drought resistant that big bluestem, and a smaller plant - reaching not over 3 feet. Leaves are up to 8 inches long, and not over 0.25 inch wide. It furnishes dependable grazing and cured hay, but is not highly palatable. It is especially valuable for erosion control.

Last update February 18, 1999 by ch

Yellow bluestem

Gramineae *Bothriochloa ischaemum* (L.) Keng.

***Dichanthium aristatum* (Poir) C.E. Hubb.**

Source: Magness et al. 1971

These bluestems are both native to Central or Southern Asia. Yellow bluestem is used for pasture through the Southern Great Plains. *D. aristatum* appears not to have a common name, but varieties are known as Angleton and Gordo. They are used as pasture and hay in the humid Gulf Coastal Plain in Texas. Both of these species are warm season, semiprostrate bunchgrasses, leafy or medium leafy. In palatability *D. aristatum* appears superior to yellow bluestem but both furnish good pasturage and good hay if cut early.

Last update June 26, 1996 bha

Blumea lacera: Useful Plant

Pankaj Oudhia
Society for Parthenium Management (SOPAM)
28-A, Geeta Nagar, Raipur - 492001 India
pankaj.oudhia@usa.net
www.celestine-india.com/pankajoudhia

Copyright © 2001. All Rights Reserved. Quotation from this document should cite and acknowledge the contributor.

Blumea lacera L., Compositae, is one of the common rabi weeds of India (Oudhia and Tripathi 1999a). It is an annual herb, with a strong odor of turpentine. Stem is erect, ash colored, densely glandular, pubescent. Leaves are often incised or lyrate. There are many flower heads in single plant, arranged in axillary cymes or terminal panicle. Pappus is white. Fruits is an achene, oblong and not ribbed. Flowering time January to April (Agharkar 1991).

The plant occurs throughout the plains of India from the north-west ascending to 2,000 ft in the Himalayas. It is a common roadside weed in Ceylon and Malaya. It is distributed to the Malay Islands, Australia, China and Tropical Africa. *Blumea* consists of about 80 species (Caius 1986). *Blumea lacera* competes with rabi crops such as linseed, chickpea, and wheat for light, food and moisture (Oudhia, 1997) and harbors diseases and insects such as *Euplexia dolorosa*, *Eublemma trifasiciata* (Lefroy, 1909). *Blumea lacera* is described as a valuable medicinal plant in many popular systems of medicine including *Ayurveda*, homoeopathy, and unani. Stimulatory allelopathy of different parts of *B. lacera* on many agricultural crops has also been reported (Oudhia 1996). Not much work has been done on various utility aspects of *B. lacera*. In many parts of India, *Blumea* is cultivated for its green leaves and roots. *Blumea* is late kharif crop in these parts (Oudhia and Tripathi 1999b)

Reported Uses

Blumea is described in *Ayurveda* as bitter, astringent, acrid, thermogenic, errhine, anti-inflammatory, styptic, opthalmic, digestive, anthelmintic, liver tonic, expectorant, febrifuge, antipyretic, diuretic, deobstruant, and stimulant (Warner et al. 1996). The root kept in the mouth is said to cure disease of the mouth. In the Konkan region of India, the plant is used to drive away fleas and other insects. It is prescribed as an antiscorbutic in West Africa (Caius 1986). Essential oil from *Blumea* has been shown analgesic, hypothermic, and tranquilizing activities (Anonymous 1972). Campestrol has been isolated from aerial parts and 5-hydroxy-3, 6, 7, 3',4'- pentamethoxy flavone, 5,3',4' trihydroxy flavone and an unidentified flavone have been isolated from leaves (Rastogi and Mehrotra 1991). *Blumea lacera* is considered a valuable homoeopathic drug (Oudhia et al. 1998a) useful in case of enuresis, neuralgia, headache, cold borne cough. A tincture is useful in case of bleeding piles (Ghosh 1988). Natives of Chhattisgarh use this weed for treating health problems (Oudhia et al. 1998b). There is a heavy demand of different parts (fresh and dry both) of this weed in national and international drug markets (Oudhia and Tripathi 1999c). Farmers can earn extra income after selling various parts of *Blumea* with the help of co-operatives (Oudhia and Traipathi 1999d). Fresh leaves of *Blumea* are the most valuable part.

Stimulatory allelopathy of *B. lacera* on many agricultural crops such as rice has been reported (Oudhia et al. 1997b, 1998c,d) including rabi and kharif obnoxious weeds such as *Echinocloa colonum*, *Ageratum conyzoides* (Oudhia et al., 1998c), *Chenopodium album*, *Melilotus indica*, *Phalaris minor*, *Cirsium arvense*, and *Spilanthes* (Oudhia et al. 1997a)

Cultivation

Blumea is a late kharif crop. Standard agrotechniques have not been developed. Seeds are generally sown in late August on prepared land with good tilth; fertilizers are not used. Leaves are harvested at time of 50% flowering. Blumea leaf beetle (*Chrysolina madrasae* Jackoby) is the main insect pest (Oudhia 1989, 1997, 1999a,b,c,d; Oudhia & Thakur 1996).

Boer lovegrass

Gramineae *Eragrostis chloromelas* Steud.

Source: Magness et al. 1971

This is a warm-season bunchgrass, introduced from South Africa in 1932. It is adapted to semidesert areas of the Southwestern States. The grass is palatable, drought resistant, and fairly long lived. It lacks hardiness for more northern areas. Seed of improved varieties is available.

Punanrnava or Santhi (*Boerhaavia diffusa*)

Scientific Name: *Boerhaavia diffusa* Linn. Syn. *B. repens; B. repens* var. *diffusa*
Family: Nyctaginaceae
Family Name: Hog weed, Horse Purslane
Common Indian Names
Gujarati: Dholia-saturdo, Moto-satoda.
Hindi: Snathikari
Canarese: Kommegida
Marathi: Tambadivasu
Sanskrit: Punarnava, Raktakanda, Shothaghni, Varshabhu
Bengali: Punurnava
Tamil: Mukaratee-Kirei
Telugu: Punernava

Habitat: Grows as common weed.

Botanical Description: Please see Table 1

Useful Parts: Root, leaves and seeds.

Medicinal Uses: According to Ayurveda, Punarnava is bitter, cooling, astringent to bowels, useful in biliousness, blood impurities, leucorrhoea, anaemia, inflammations, heart diseases, asthma, alternatives etc. The leaves are useful in dyspepsia, tumours, spleen enlargement, abdominal pains. According to Unani system of medicine, the leaves are appetizer, alexiteric, useful in opthalmia, in joint pains. Seeds are tonic expectorant, carminative, useful in lumbago, scabies. The seeds are considered as promising blood purifier.

Traditional Medicinal Uses: In many parts of India, different parts of Punarnava are used as folk medicine.

Ayurveda Properties: Punarnavastaka, Punaravataila, Punarnavaleha etc.

Chemical Constituents: Punarnava contains b-Sitosterol, a-2-sitosterol, palmitic acid, ester of b-sitosterol, tetracosanoic, hexacosonoic, stearic, arachidic acid, urosilic acid, Hentriacontane, b-Ecdysone, triacontanol etc.

Table 1. Major differences between *B. diffusa* and *Boerhaavia elegans*

Characters	*Boerhaavia diffusa*	*Boerhaavia elegans*
Plant	A perennial herb from a fusiform root	An erect glabrous shrub
Stem	Prostrate, decumbent or ascending, 4-10 dm long, rather slender, divaricately branched	Annual, woody below, glabrous above, thinly pubescent near the base, terete
Leaves	Opposite or sub-opposite, two of a node unequal, broadly ovate or suborbicular, obtuse to rounded or subcordate at the base.	Linear-oblong or oblong-lanceolate, obtuse and often mucronulate at the apex
Flowers	In penduncculate, glomerulate clusters arranged in slender, long stalkcked, axillary or terminal corymbs	In large, lax, much branched, leafless, glabrous compound cymes above the leaves
Fruit	Obovoid or sub-ellipsoid, rounded above, slightly cuneate, below, broadly and bluntly 5-ribbed, very glandular throughout	
Flowering and Fruiting	Throughout the year in Indian conditions	September to December in Indian conditions

Bogbean

Menyantheas trifoliata L.

Other common names.—Buck bean, bog myrtle, bog hop, bog nut, brook bean, bean trefoil, marsh trefoil, water trefoil, bitter trefoil, water shamrock, marsh clover, moonflower, bitterworm.

Figure 25.—Bogbean (*Menyanthes trifoliata*)

Habitat and range.—The bogbean is a northern marsh herb occurring in North America as far south as Pennsylvania, Minnesota, and California.

Description.—This herb arises from a long, black, creeping, scaly rootstock, the leaves being produced from the end of the same on erect stems measuring about 2 to 10 inches in height. The leaves consist of three somewhat fleshy, smooth leaflets 1 1/2 to 3 inches long. The flower cluster is produced from May to July on a long, thick, naked stalk arising from the rootstock. It bears from 10 to 20 flowers each, with a funnel-shaped tube terminating in five segments which are pinkish purple or whitish on the outside and whitish and bearded on the inside.

Part used.—The leaves, collected in the spring.

Erythrina fusca Lour.

Syn.: *Erythrina glauca* Willd.
Fabaceae
Gallito, Coral bean, Bois immortelle

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Occasionally planted as a hedge and as a support for the betel vine in Assam and Bengal. Young leaves are eaten, raw or boiled, as a vegetable in Java. In Puerto Rico, trees have been planted in pastures and along fences and roads as ornamental shade trees. Elsewhere, they are used for cacao and coffee shade and living fence posts. Heartwood is light yellow to yellowish-brown and moderately soft. The lightweight wood is weak, not durable, and scarcely suitable for lumber.

Folk Medicine

According to Hartwell (1967–1971) seeds are used in folk remedies for cancer in Annam. Reported to have the same medicinal attributes as *Erythrina indica*, whose bark is used for fever, hepatosis, malaria, rheumatism, toothache, also for boils and fractures. Perry (1980) cites many more uses for *Erythrina indica*. The bark is used for poulticing fresh wounds in Malasia. Boiled roots are taken internally or externally for beri-beri. Grated wood used for hematuria (Perry, 1980). The root is used for rheumatism. Bark and leaves serve as a vermifuge (List and Horhammer, 1969–1979).

Chemistry

Per 100 g, the leaves are reported to contain 60 calories, 81.5 g H_2O, 4.6 g protein, 0.8 g fat, 11.7 g total carbohydrate, 4.1 g fiber, 1.4 g ash, 57 mg Ca, 40 mg P, 1.8 mg Fe, 2,300 μg β-carotene equivalent, 0.24 mg thiamine, 0.17 mg riboflavin, 4.7 mg niacin, and 3 mg ascorbic acid (Leung et al, 1972). Leaves contain (ZMB): 325 calories, 24.9 g protein, 4.3 g fat, 63.3 g total carbohydrate, 22.2 g fiber, 7.6 g ash, 308 mg Ca, 222 mg P, 5.2 mg Fe, 0.91 mg thiamine, 0.52 mg riboflavin, 6.54 mg niacin, and 78 mg ascorbic acid (Duke, 1981b). Seeds contain the alkaloid erythraline. Erysodine, erysonine, erysopine, erysothiopine, eryso- thiovine, crysovine, erythraline, erythramine, erythratine, and hypaphorine are also reported (List and Horhammer, 1969–1979). The similarity in alkaloid and amino acid patterns in *E. fusca* and *E. glauca* were considered by Krukoff (1972) in rendering these species synonymous.

Description

Deciduous armed tree, 10–20 m tall; to 1 m dbh; outer bark grayish, coarse, branches glabrous, sparsely armed with short prickles. Leaves trifoliolate; stipules caducous; petioles 8–18 cm long; rachis 4–8 cm long; petiole and rachis with 2 apical glands; leaflets ±ovate, ±rounded or acute at apex, glabrous above, with white appressed trichomes below; terminal leaflet 8–14 cm long, 7–12 cm wide; lateral leaflets smaller. Flowers thick, mostly 3 per node, in large, terminal, somewhat pendent racemes; pedicels stout, turned away from apex, ca 2 cm long; flowers showy, pale orange; stamens diadelphous, green, gradually arched, about halfway exserted. Legumes 15–20 cm long, 2 cm wide, densely brown-tomentose, pointed at apex, weakly ribbed on margins; seeds several, ellipsoid, dark brown, ca 12 mm long (Croat, 1978).

Germplasm

Reported from the Indochina-Indonesian and Central American Centers of Diversity (Croat, 1978), bois immortelle, or cvs thereof, is reported to tolerate waterlogging. Apparently it will not tolerate shade. ($2n = 42$)

Distribution

Mascarene Islands, from Northeastern India to Java, Polynesia and Sri Lanka. Near sea coasts, along rivers, and in places where soil conditions exclude the true "high evergreen forest" (Burkill, 1966). According to Croat, the species (as *E. fusca*) is widespread in the Old World tropics, while in the Americas (as *E. glauca*), it ranges from Guatemala throughout the Amazon Basin. In Panama, it is known only from Tropical Moist Forest, often forming pure stands in freshwater marshes, in the Canal Zone, Bocas del Toro, Cocle, Darien, and Panama (Croat, 1978). This is the most widespread species in the genus, and the only one occurring (on three continents, undoubtedly dispersed by marine currents (Krukoff, 1972).

Ecology

Estimated to range from Tropical Dry to Wet through Subtropical Dry to Wet Forest Life Zones, this coral bean is estimated to tolerate annual precipitation of 10 to 40 dm, annual temperature of 20 to 28°C, and pH of 6 to 8. According to Krukoff (1972) the species thrives in variety of conditions, seeming to prefer lowlands (seashores, swamps with outlets, low overflow lands, river banks, shores of lakes, etc.).

Cultivation

According to Martin and Ruberte (1975), this is one of the easiest species of *Erythrina* to grow. Like most *Erythrinas*, this probably roots readily from large fence-post sized cuttings. Seeds germinate rather rapidly.

Harvesting

For those risking them as vegetables, the young buds and leaves are probably at their tenderest when leafing out, often in tandem with the commencement of the rainy season.

Yields and Economics

No data available.

Energy

With no hard data available to me, I have no reason to suspect that this species would be any less productive than *E. poeppigiana*, which probably returns ca 25 MT/ha/yr in monoculture, 10 MT/ha in intercropping scenarios. Nitrogen fixing nodules are reported in Hawaii (Allen and Allen, 1981).

Biotic Factors

Croat suggests that hummingbirds pollinate the species, said to produce a copious nectar.

Boneset

Eupatorium perfoliatum L.

Synonym.—*Eupatorium connatum* Michx.

Other common names.—Thoroughwort, thorough-stem, thoroughwax, wood boneset, teasel, agueweed, feverwort, sweating plant, crosswort, vegetable antimony Indian sage, wild sage, tearal, wild isaac.

Figure 26.—Boneset (*Eupatorium perfoliatum*)

Habitat and range.—Boneset is a common weed in low, wet ground, along streams, on the edges of swamps, and in thickets from Canada to Florida and west to Texas and Nebraska.

Description.—This plant is easily recognized by the peculiar arrangement of the leaves, which are opposite each other and joined at the base, making it appear as though they were one with the stem passing through the center. It is erect, growing rather tall, from 1 to 5 feet in height, with rough, hairy, stout stems. The crowded, flat-topped clusters of flowers are produced from about July to September and consist of small heads of tubular white flowers.

Part used.—The leaves and flowering tops, collected when the plants are in flower, and stripped from the stalk.

Selection of *Boronia* for Essential Oils and Cut Flowers*

Julie A. Plummer, Joanne M. Wann, John A. Considine, and Z.E. (Ted) Spadek

Several species of *Boronia* (Rutaceae) are endemic to the southwest of Western Australia. They grow in wet or seasonally wet low-lying areas and are usually associated with jarrah (*Eucalyptus marginata* Sm.) forests, paperbark (*Melaleuca parviflora* Lindl.) flats, and creeks. Two species are commercially exploited; *B. megastigma* Nees. (brown boronia) for its essential oils and *B. heterophylla* F. Muell. (red boronia, kalgan) for cut flowering stems (Plummer 1995). In the past total production was from plant material harvested from natural stands. With increasing demand and the need to improve quality these industries have shifted to harvesting cultivated plants.

B. megastigma plants bear a profusion of strongly scented bell-like flowers (Fig. 1). Petals are yellow on the inside, while outer petal color varies from yellow (cv Lutea) through red to dark brown. Outer petal color may be solid or in vertical red (cv Harlequin) or brown stripes (Plummer 1995). Essential oils are extracted from the flowers with hexane to yield about 0.4%-0.8% concrete. Concrete is washed with alcohol or distilled to yield 60% boronia absolute (Guenther 1949; Penfold and Willis 1954). Boronia absolute is valued at between US$4,000 to $10,000/kg, depending on quality and purity. It can be used in perfumes, cosmetics, and as a food flavoring where it enhances most fruit essences (Davies and Menary 1984; Weyerstahl et al. 1994). There are over 150 compounds in boronia concrete. ß-Ionone is by far the most important, but other compounds such as dodecyl acetate enhance the perfume. The monoterpene hydrocarbons, α-pinene, ß-pinene, and limonene detract from the aroma. Three cultivated genotypes have been shown to have a high degree of variability in their essential oil components (Davies and Menary 1984) but the diversity within the species has not been examined.

Cut flowering stems of *B. heterophylla* have been exported from Australia to Japan for 7 years and markets are growing in southeast Asia, Europe, and Canada. *B. heterophylla* is an upright shrub which produces a spectacular display of vibrant pink bell-shaped flowers each about 1 cm long in early spring. Cultivated plants can yield 8-12 stems 12-15 months from planting, 20-30 stems in the third year, and 30-60 stems in the fourth year with a commercial life of 5-6 years. Stems are usually 60 cm long and are picked with >50% of the flowers open (Plummer 1995). Although demand currently exceeds supply, the limited flowering season (1-2 weeks) and lack of flower color options are obstacles to future expansion.

Demand for both boronia absolute from *B. megastigma* and cut flowering stems of *B. heterophylla* is increasing. The export market potential is substantial and is likely to continue its rapid growth. Exports from Western Australia alone are expected to increase by 20% per annum. Boronia exports from Western Australia were valued at US$46,000 FOB (freight on board) in 1992/93 while the total value of boronia exports from Australia was US$180,000 FOB in the same year (Anon. 1994). Current wholesale prices for *B. heterophylla* range from US$2.00 to $3.50 per bunch, depending on supply. Wholesale prices for *B. megastigma* blossom for essential oil production range from US$10 to $15/kg.

Commercial production of both species is dependent on a few cultivars and selection of superior genotypes would be beneficial. The aim of this study was to investigate variation in the content of essential oil components of *B. megastigma* within and between populations, and over different seasons, and to extend the color range and production period of *B. heterophylla*.

METHODOLOGY

Boronia megastigma

For plant sampling in Aug. to Sept. 1993 *B. megastigma* flowers were collected from plants in 13 natural populations and from a yellow flowering selection growing in cultivation. In Aug. to Sept. 1994 flowers were collected from 16 natural populations. Flowers from 25 randomly selected plants were collected from the majority of populations, but where numbers of flowering plants were limited, fewer plants were sampled (n = 24 for the Walpole-2 and Palgarup-1 populations; n

= 20 for the Yallingup population; n = 22 for the Barlee population).

Details of flower color, plant age, and plant vigor were collected for all plants. Plant age was determined using the number of years since the last fire or major soil disturbance as an approximate age. Seedlings were determined as less than 1 year old, young plants 1-2 years, mature plants 2 to 6 years and old plants greater than 6 years. Plant vigor was determined by the density of leaves and flowers on each plant. Weak plants had few flowers and little foliage, average plants had moderate amounts of foliage and flowers, and vigorous plants had abundant flowers and lush green foliage. Oil component contents within each category were compared using analysis of variance and means were separated using Fisher's PLSD. The amount of shading by surrounding vegetation was determined for 273 of the plants sampled in 1993 using a Model-A forest densiometer (Lemmon 1957).

Seven to 10 plants from 12 natural populations initially sampled in 1993 were re-sampled in 1994 in order to investigate the quantity of oil components produced by individual plants over successive years. Comparisons were made using paired 2-tailed t-test.

For oil analysis 12 flowers collected from each plant were extracted with absolute ethanol (10 ml). Collection vials were weighed before and after flower collection and the difference used to determine flower fresh weight. Flowers were extracted for at least 24 h before oil analysis. An aliquot (4 ml) of the extract was analysed without further purification or concentration using a gas liquid chromatograph (Hewlett Packard 5890A) fitted with dual columns (50 m length, 0.25 mm internal diameter BPX70 from SGE International and 50 m length, 0.2 mm internal diameter ULTRA1 from Hewlett Packard) connected to a single injection port and twin ionization detectors. The injector and detector temperatures were set at 275°C. An initial oven temperature of 60°C was held for 5 minutes and then increased at a rate of 8°C min^{-1} to a final temperature of 260°C which was held for 10 min. Ethyl un-decanoate (1 µg ml^{-1}) was used as an internal standard. The quantity (µg g^{-1} fresh weight of flowers) of α-pinene, ß-pinene, limonene, α-ionone, ß-ionone, and dodecyl acetate was determined using the areas produced by the ULTRA 1 column. The BPX70 column was used to confirm the presence or absence of α-ionone, ß-ionone and dodecyl acetate. α-Pinene, ß-pinene, and limonene co-eluted with the solvent peak on this column.

Principal components analyses were performed on the oil data. The first analysis used the oil data from all individuals sampled to plot the orthogonal factor scores and determine the relationship between the different oil components. The second analysis used the mean data for each oil component from each population to determine the relationship between different populations in terms of the 5 oil components.

Boronia heterophylla

New populations of *B. heterophylla* were sought in 1994. Plants were tagged and their flowering period, flower density, flower color, and plant vigor were determined. Cutting material was taken from plants to assess their ease of propagation and subsequent growth and flowering in cultivation.

RESULTS

Boronia megastigma

The 29 *B. megastigma* populations identified cover most of the remaining natural range of the species however, much of this region is now agricultural land (Fig. 2). Flowers from all plants contained ß-ionone. α-Ionone was either absent or present in undetectable amounts and was therefore excluded from further analysis. ß-Pinene was absent from half of the plants, α-pinene from about a quarter of plants and limonene and dodecyl acetate were absent from only a few plants. Oil contents were used to rank each oil component (Table 1). Ranking was determined by a fixed percentage of plants whose oil component quantity fell within the stated range. The extremely high ß-ionone producers (those in the top 5%) contained 803 to 1787 μg g^{-1} of ß-ionone. ß-Ionone was the major essential oil component, followed by dodecyl acetate. α-Pinene and limonene were often present in similar quantities, and ß-pinene was usually the least abundant of the oil components examined.

The mean quantity of oil components varied considerably between populations. α-pinene, ß-pinene and limonene were commonly absent from individual plants, but each of these compounds was present in at least one plant in each population. Location had some influence on the content of the monoterpene hydrocarbons. Southeastern populations had quite high concentrations of α-pinene, ß-pinene, and limonene, while northern populations all had low concentrations. Location was not always a good indicator of the content of oil components. In the Jarrahwood area, Jarrahwood-3 produced more than twice the amount of α-pinene and ß-pinene as Jarrahwood-2 and Jarrahwood-4, even though the three populations are only a short distance apart. Location did not influence ß-ionone and dodecyl acetate. The highest mean ß-ionone content for a population was 736 μg g^{-1} at Albany-1 and the lowest was 227 μg g^{-1} at Porongurup-1.

The quantity of oil components from plants within populations varied considerably. The Walpole-1 population sampled in 1993 was typical of the variation in ß-ionone content within populations. ß-Ionone concentration ranged from very low (175 μg g^{-1}) to extremely high (1342 μg g^{-1}).

The relationship between oil components based on their quantitative presence in plants was investigated using principal components analysis. Results indicated that ß-ionone and dodecyl acetate were closely related and quite distinct from the monoterpene hydrocarbons. The was also a close relationship among the monoterpene hydrocarbons. α-Pinene and ß-pinene, and to a lesser extent, limonene were closely related.

Principal components analysis was also used to investigate the relationship between *B. megastigma* populations based on the mean content of oil components at each site. Results failed to show any distinct relationships between populations. However, among the populations sampled in each year there were certain populations which were closely related in terms of the mean content of the 5 oil components. Some populations in close proximity to each other were similar in oil composition, but others were distinct. Boyup Brook, Palgarup-1 and Palgarup-2 were within 33 km of each other and were closely related (1993 data). Jarrahwood-2 and Jarrahwood-4 were closely related, but Jarrahwood-3 was quite distinct (1994 data).

Canopy cover above *B. megastigma* plants affected concentrations of the monoterpene hydrocarbons but not ß-ionone ($y = 0.6x + 365$; $r^2 = 0.005$) and dodecyl acetate ($y = 0.8x + 273$; $r^2 = 0.009$). Plants shaded by higher densities of canopy cover produced lower concentrations of -pinene ($y = -3x + 267$; $r^2 = 0.09$), ß-pinene ($y = -2.2x + 156$; $r^2 = 0.09$), and limonene ($y = -2.1x + 160$; $r^2 = 0.09$).

Plant age, plant vigor, and flower color each affected the concentration of at least one of the five essential oil components investigated. Similar trends occurred in both years but only 1993 data is presented. Age affected four essential oil components (Table 2). Young plants contained less alpha-pinene and limonene than mature plants and less ß-pinene than seedlings, mature and old plants. Old plants had the most dodecyl acetate. Seedlings had more ß-pinene and limonene, and less ß-ionone and dodecyl acetate than older plants but, due to the low sample size of seedlings, the differences were not significant. Vigorous plants tended to produce more ß-pinene and limonene than weak plants (Table 3). Red flowers contained the lowest concentrations of ß-ionone and dodecyl acetate (Table 4). There was a tendency for red/brown flowers to have less ß-ionone and dodecyl acetate than brown flowers. Yellow flowers contained no ß-pinene.

In plants sampled in both years ß-ionone and dodecyl acetate content differed between the 1993 and 1994 sampling. The mean quantity of ß-ionone and dodecyl acetate was higher in 1994 than 1993, while α-pinene, ß-pinene and limonene content did not differ (Table 5). The mean quantity of the majority of oil components for each population sampled in 1994 was the same as for 1993. Where differences did occur, they could be attributed to either large differences in an individual plant, or numerous small differences in several plants within the population.

Twenty six plants were found to have no α-pinene in at least 1 of the years sampled. Of the plants found to have no α-pinene present in either the 1993 or 1994 analysis, 69% were found to have no α-pinene in both years. No ß-pinene was found in 53 plants in at least 1 of the years sampled. Of these plants, 85% had no ß-pinene in both years. Of the plants lacking limonene, only 21% had no limonene in both years. Many plants consistently had two or more of the hydrocarbon monoterpenes absent, and several were lacking all three.

Boronia heterophylla

Seven populations of *B. heterophylla* were located. A number of known sites no longer contained boronias or they had been recently burnt out by fires. Plants bearing flowers with a wide range of pink tones were identified but white flowers proved elusive. Most petals had solid color but some presented either vertical or horizontal bands of deeper color. Some populations had uniform plants with consistent pink colored flowers whilst others showed considerable variation in both plant form and petal color. Flowering period was very uniform with nearly all plants flowering in early Sept. (early spring, southern hemisphere). The exceptions were one plant which flowered two weeks earlier and others which flowered up to several weeks later than the general population. Some plants proved easier than others to propagate from cuttings. The resulting plants will be assessed in cultivation during their first flowering season in Sept. 1996.

DISCUSSION

Considerable diversity was identified both within and between populations of *B. megastigma* and *B. heterophylla*. In *B. megastigma* flowers, ß-ionone was the major oil component followed by dodecyl acetate. These two compounds impart much of the desirable perfume of boronia absolute and their close association following principle components analysis is promising for the selection of genotypes with very high yields of both compounds. The monoterpene hydrocarbons, α-pinene, ß-pinene, and limonene are undesirable in boronia absolute. These components were also linked but were quite distinct from ß-ionone and dodecyl acetate. These relationships indicate that selection of genotypes which produce very high quality oil with abundant ß-ionone and dodecyl acetate and little or no monoterpenes is possible.

The relationships between ß-ionone and dodecyl acetate and α-pinene, ß-pinene, and limonene is supported by the work of Bussell et al. (1995) on volatile oil ontogeny in *B. megastigma*. The stigma, stamen, and staminode tissue contained dodecanol, ß-ionone, dodecyl acetate, and heptadecene among the principal components. ß-Ionone and dodecyl acetate concentrations were highest in the stigma extracts. Extracts of the combined ovary, nectary, and receptacle tissue contained primarily α-pinene, ß-pinene, and limonene. The petal tissue contained relatively low concentrations of all of the above-mentioned volatile compounds.

The recorded characteristics of *B. megastigma* and *B. heterophylla* varied considerably between populations. Although current populations were quite isolated from one another, this is likely to be a recent event due to a number of factors, such as over-picking, frequent fires, and land clearing for agriculture. Boronia flowers are pollinated by an unidentified small moth (Bussell et al. 1995). It is possible that as populations have become more isolated, the movement of pollinators could be restricted to individual populations or a few close populations. This would result in distant populations becoming more genetically isolated over time. For example *B. megastigma* populations in the southeastern area of their range had quite high concentrations of α-pinene, ß-pinene, and limonene while northern populations all had low concentrations.

Populations in close proximity may remain genetically similar not only due to pollen transfer but also water flow which could wash seeds down river from one population to another. Populations within the same water catchment area, e.g. (*B. megastigma*) Jarrahwood-2 and Jarrahwood-4, appeared closely related, while nearby populations located within different catchment areas e.g. Jarrahwood-3 were occasionally quite distinct. However, location did not always explain the differences between populations. There are many environmental factors which may affect flower color, oil content, and plant vigor.

Canopy cover was used as a crude measure of shading levels. In open conditions with little canopy cover and shade, *B. megastigma* produced high amounts of α-pinene, ß-pinene, and limonene. In dense forest where canopy cover and shade levels were high, monoterpene hydrocarbons were produced in lower quantities. A number of essential oil species have decreased yields when they are grown under shade. In peppermint (*Mentha piperita*) high oil yield, including the production of limonene, results from high light intensity (Clark and Menary 1980). Reduced oil production occurs under low radiation in Japanese mint (*Mentha arvensis*) (Duriyaprapan and Britten 1982). In contrast to our results, experiments by Bussell (1996) showed that 70% shade cloth (30% of ambient light) had no effect on α-pinene and limonene concentrations (ß-pinene was not tested) in three clones of *B. megastigma* and ß-ionone and dodecyl acetate concentrations increased. Although the genetic material used by Bussel (1996) was different, the shade levels much higher and the plants grown under cultivation, these differences highlight the need to further investigate the influence of shading. Light may also affect flower color in *B. heterophylla*. Anthocyanins contribute to red flower color and anthocyanin production in many species is modified by light quality and intensity. Flowers of *B. heterophylla* are known to fade during senescence (Plummer 1995) but the influence of light on pigment intensity remains unknown.

Plant age, vigor, and flower color affected the concentration of oil components in *B. megastigma*. Unfortunately concentrations of oil components produced by seedlings was not a good indication of production in the adult plant. This reduces the possibility of screening seedling material for high quality oil in a breeding program. Red-flowering plants are unlikely to be used in commercial production of oil as they produced low amounts of the favorable compounds, ß-ionone and dodecyl acetate. Plants with yellow flowers produced very little limonene and no ß-pinene but relatively high levels of ß-ionone and dodecyl acetate. Bussell (1996) also found ß-pinene to be absent from yellow flowering *B. megastigma*. Apart from these trends flower color does not appear to be a useful tool in selecting plants with high oil quality.

Some differences in oil content were detected between 1993 and 1994. The concentrations of the undesirable oil components, α-pinene, ß-pinene, and limonene were fairly consistent which permits genetic selection for low or no production. The change in ß-ionone and dodecyl acetate content was only marginal but offers the possibility of environmental manipulation, such as site selection, to increase yield.

Boronia heterophylla plants with a range of solid and striped flower colors, and plants which flower outside the usual two-week flowering period were identified. Most of these plants could be propagated successfully. Plants will need to be examined in cultivation to determine if these characteristics are genetically controlled. Plants will also need to be assessed for their ability to produce numerous high quality stems and withstand the substantial pruning at harvest. Selected plants with these attributes will increase the colour range and harvest period.

Although many of the original populations of *B. megastigma* and *B. heterophylla* no longer exist much variation exists in the remaining plants. Natural pollination of boronias requires the presence of a pollinator moth and her movements tend to ensure out-crossing. Thus the remaining plants probably contain most of the original genetic diversity. Boronias can be manually self and cross pollinated (Plummer and Considine 1995) and a breeding program has commenced. *B. megastigma* plants with high yields of ß-ionone and dodecyl acetate and low or no monoterpene production were identified. Collection from natural stands is inadequate to meet demand and expansion of cultivation is underway. Currently boronia absolute is only used in the food flavoring sector and development of new uses will require expanded production. *B. heterophylla* plants with a range of pink flower tones and different flowering periods were identified. Although these characteristics will need to be confirmed under conditions of commercial cultivation they show promise for the improvement of product quality and the expansion of production of these new crops.

Side-oats grama

Gramineae, Poaceae *Bouteloua curtipendula* (Michx.) Torr.

Source: Magness et al. 1971

This is a long-lived native grass, widely distributed, but most abundant in the Central and Southern Great Plains. It produces short rhizomes and tends to a bunch-type growth. The leaves are about 6 inches long and under 0.25 inch wide. Flower stems may reach to 3 feet. It produces an abundance of leafy forage well liked by all classes of livestock. Hay of good quality is produced if mowed sufficiently early. It is adapted to wide ranges of soil and climate. Seedling vigor is good, and stands are readily established by seeding. Generally, side-oats grama is seeded in mixtures with other grasses. Several varieties of superior local adaptation are in the trade.

Grama grasses

Gramineae *Bouteloua* sp.

Source: Magness et al. 1971

Some 18 species of *Bouteloua*, the grama grasses, are native in the United States, mainly throughout the Great Plains and Western States. They are summer growers, and the amount of growth produced is dependent on available moisture. Most species cure naturally, so growth from a previous season is palatable for livestock. They are prized as forage producers on range and pasture land. The three most valuable species are side-oats grama, black grama, and blue grama.

Mimosa scabrella Benth.

Syn.: *Mimosa bracatinga*
Mimosaceae
Bracatinga

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Regarded as a useful living fence post or ornamental avenue tree. Useful for reforestation. It sheds copious leaves forming a good humus. Makes an excellent fuel wood. Though its pulp is inferior to *Eucalyptus saligna* it is promising for printing and writing papers (fibers average 1.1–1.2 mm long). Used for coffee shade in Guatemala, where Standley and Steyermark (1946) say, "The coffee plantations shaded by bracatinga are very handsome, for the trees are uniform in height, their crowns far above the coffee bushes... The bracatinga has been much advertised in tropical America in recent years as a tree suitable for reforestation...until better trees could take its place."

Folk Medicine

No data available.

Chemistry

I find no data on this species. *Mimosa hostilis* reportedly contains the hallucinogen N,N-dimethyltryptamine, and is used in making a beverage which translates "Wine of Jurema." Interestingly, this species is called catinga instead of bracatinga.

Description

Unarmed tree to 15 m tall, 40 cm in diameter, with sparse broad crown, the trunk branching shortly above the base; bark whitish, young branchlets lepidote. Leaves bipinnate; the pinnae mostly 5–7 pairs; leaflets 25–35 pairs, oblong-linear, obtuse, stellate, subterminal peduncles ca 1.5 cm long, the heads about 7.5 mm in diameter. Sepals glabrous, ca 1.2 mm long. Corolla 4-lobed, stellate tomentose, ca 3.5 mm long. Stamens 4. Pods sessile, oblong-linear, obtuse, verrucose-tomentose 20–25 x 5–6 mm 2–4-jointed. Seeds castaneous, 3–4 mm long.

Germplasm

Reported from the South American Center of Diversity, bracatinga, or cvs thereof, is reported not to tolerate wet soils which tend to stunt its growth.

Distribution

Native to the cool subtropical Parana plains of Southeastern Brazil although Standley and Steyermark (1946) have reported its introduction into Guatemala. Small plots have been established in Argentina, Colombia, Ethiopia, Guatemala, Jamaica, Mexico, Portugal, El Salvador, Senegal, Spain, Venezuela, and Zaire.

Ecology

Estimated to range from Tropical to Subtropical Moist Forest Life Zones. Grows in many types of well-drained soils. Grows at 2,400 m in Guatemala.

Cultivation

Easily planted by seed, 3–4 seed sown in depressions 3–4 cm deep. Spaced at 2–3 m. Readily cultivates in plantations, even at exceptionally close spacings (NAS, 1979).

Harvesting

Some plantations have been harvested on rotations of only 3 years.

Yields and Economics

May attain 15 m tall in 3 years, 8–9 m in 2 years, and 5 m in 14 months.

Energy

Before the advent of the diesel, bracatinga was grown to fuel Brazilian railroads. Although the plant is reported to fix nitrogen, Allen and Allen (1981) do not cite it as a nodulated species.

Biotic Factors

Agriculture Handbook No. 165 lists the following diseases for *Mimosa* spp.: *Cylindrosporium* sp. (leaf spot), *Lipocystis caesalpiniae* (rust), *Meliola bicornis* and *Meliola denticulata* (black mildew), *Phymatotrichum omni-vorum* (root rot), *Ramularia mimosae* (leaf spot), *Ravenelia dysocarpae* (rust), and *Ravenelia fragrans* (rust). Golden (p.c. 1984) reports the nematode *Meloidogyne incognita acrita.*

Proso millet

Broomcorn millet, Hog millet, Hershey millet

Gramineae, (Poaceae)

***Panicum miliaceum* L.**

Source: Magness et al. 1971

Proso millet is the only millet grown as a grain crop in the United States. Other millets as foxtail, Japanese or barnyard, and pearlmillet or cattail are grown mainly for forage or pasture and are listed under Grass Forage and Pasture Crops.

Proso millet is probably grown on not more than 150,000 acres in the United States, though actual data are unavailable. Most production is in the Northern Plains and other short-growing season areas. In Asia, Africa and Russia, grain millet is an important food crop, but is less important than formerly as other adapted grains are more desirable. Since proso millet will mature a grain crop in from 60 to 75 days after seeding, and is low in moisture requirement, it will produce some food or feed where other grain crops would fail.

Millets have been grown in Asia and North Africa since prehistoric times, and little is known of their origin. They probably came originally from Eastern or Central Asia. They were important in Europe during the middle ages before corn and potatoes were known there. Today they are of minor importance in Western Europe.

Proso millet grows up to four feet with stout, erect stems which may spread at the base. Stems and leaves are hairy. The panicle or flower head is rather open, like oats, and drooping. In different varieties it may be spreading, one-sided, or erect. The branches in the panicle bear spikelets only toward the tips. Each spikelet has two unequal glumes and a single flower. The flower consists of the lemma and palea, enclosing the stamens and pistil. As in oats, the lemma and palea adhere to and are a part of the threshed grain. The ripened seed is small (about 2 mm. wide and 2.5 mm. long), ovate and rounded on the dorsal side. Seeds range in color from white or cream to yellow, brown or nearly black. The seeds do not mature uniformly and shattering of those first ripe often occurs before others are mature. For this reason the crop is usually mowed and cured in the swath or windrow prior to combining.

As food in Old World countries, millet is used as a meal for making baked foods, as a paste from pounded wet seeds or as boiled gruel. As feed the grain is eaten readily by livestock, and is equal to or superior to oats in feed value. It should be ground for livestock feed. It is also used in poultry and bird seed mixes.

A related species is brown top millet, *P. ramosum* L.,-*Brachiaria ramosa* (L.) Stapf., which is sometimes seeded for game bird pasturage in the Southeastern States.

Potential of Fanweed and Other Weeds as Novel Industrial Oilseed Crops*

Patrick M. Carr

Diversification has been suggested as a possible strategy for improving the financial condition of United States crop producers (Jolliff and Snapp 1988; Jolliff 1989). Agricultural production of industrial feedstocks, for example, would open additional markets to farmers who typically grow only food and feed crops. In some instances, farm production of industrial feedstocks could be quite profitable since high-value specialty chemicals are contained in the seeds of some plants (Hinman 1986).

While crambe, (*Crambe abyssinica* Hochst.), ironweed [*Vernonia galamensis* (Cass.) Less.], and several other plant species have been identified as promising industrial crops (Princen 1983), few studies have evaluated the potential of present weed species as sources of high-value specialty chemicals and industrial feedstocks (Clopton and Triebold 1944; Shultz et al. 1983). There are several weeds that are well adapted to growing conditions in different regions of the United States and could be grown as sources of industrial chemicals if domesticated. While a plant may contain desirable chemicals or have valuable properties, it is unknown if these plant species could be developed for field production. The objective of this research was to evaluate the agronomic potential of four weeds occurring in the Northern Great Plains: fanweed [*Thlaspi arvense* (L.)], black mustard [*Brassica nigra* (L.) Koch], wild mustard [*Brassica kaber* (DC.) Wheeler], and hare's ear mustard [*Conringia orientalis* (L.) Dumort]. These four weeds were studied since previous work indicated that each contained valuable specialty chemicals (Appelqvist 1971), or were related to other plant species which were sources of valuable chemicals. The potential of *Euphorbia lagascae* Spreng., as a field crop was also considered since past research indicates it may have potential as an industrial crop (Krewson and Scott 1966), even though this plant species is neither native to, nor naturalized in, the United States.

METHODOLOGY

1990

A field evaluation was conducted under dryland management at the Carrington Research/Extension Center (47°30' N, 99°7' W) in central North Dakota. Seed samples of a single accession of black mustard, hare's ear mustard, and *Euphorbia lagascae* were obtained from the USDA/ARS National Center for Agricultural Utilization Research in Peoria, Illinois, while seed of wild mustard and fanweed were collected from wild stands. Seed of each species along with crambe, an industrial crop which is grown in North Dakota, was planted in nonreplicated 1.4 m^2 plots on May 17. The agronomic potential of each species was rated on the basis of its ease of establishment, rate of growth, initiation and duration of flowering, susceptibility to lodging and pests, seed development (determinate or indeterminate), susceptibility of seeds to shatter, and other factors. Height of 10 plants of each species was measured prior to harvest. A 0.7 m^2 area was harvested by hand for determination of dry matter, grain yield, and seed weight.

1991

The six plant species included in the 1990 field experiment were each planted in 8.2 m^2 plots in a randomized complete block design with four replicates. The agronomic potential of each plant species was evaluated as described. A sunfleck ceptometer (Decagon Devices, Inc., Pullman, WA) was used to quantify the amount of photosynthetically active radiation (PAR) that was intercepted by the plant canopy in plots of two replicates on selected dates during the growing season. Plants in a 1.9 m^2 area from the central portion of each plot were harvested for determination of dry matter, grain yield, and seed weight. Seed oil content and fatty acid distribution of the oil were determined for a representative sample of each species by mass spectroscopy at the Food and Cereal Science Laboratory at North Dakota State University, in a manner previously described (Riveland 1991).

RESULTS AND DISCUSSION

Fanweed

Fanweed (*syn*. stinkweed, field pennycress, pennycress) was rated as having excellent potential as a new crop if established in the fall (Table 1). Poor germination of spring-sown fanweed seed was a problem. As a result, yield of fanweed was low when planted in the spring. Metzger (1990) reported that exposure to temperatures of 0° to 10°C for 3 to 6 weeks can break the dormancy of fanweed seed. Dormancy can be broken if seed is scarified by scratching the seedcoat (Best and McIntyre 1975), although this was not true for spring-sown seed in this study. Broadcast planting rather than seed drilling is desirable, since exposure to light seems to enhance seed germination. Overwintering fanweed plants were in full-flower by mid-May, while other plant species were still seedlings. Hence, seed production by most fanweed plants was completed prior to the relatively hot, dry conditions which developed by mid-July during 1990 and 1991.

Seeds, contained in pods, tended to shatter as plant moisture levels declined; however, plants could be swathed to minimize harvest loss from shattering and to promote uniform seed maturation. If swathed, fanweed could be harvested in mid-June in the Northern Great Plains, possibly enabling a second crop to be planted in the field during the same growing season. Double cropping would likely be possible in more southern portions of its range in North America.

Individual fanweed plants established in the fall produced an average of 1,600 seeds, translating into an estimated yield of about 1,500 kg/ha for both years. This yield is similar to that reported in Montana during the 1940s when fanweed was experimentally grown under irrigated management (Clopton and Triebold 1944), and to seed production estimates of wild stands in Canada (Best and McIntyre 1975). Seed yields in excess of 1,300 kg/ha are not unusual when seed from wild fanweed stands is grown in the northern United States.

Fanweed demonstrated potential as an industrial crop on the basis of seed oil content and composition (Table 2). Fanweed seed contained about 26% oil by weight; the oil, in turn, was close to 40% erucic acid (22:1). Erucic acid is an unusual fatty acid with several industrial applications (Van Dyne et al. 1990). While the level of erucic acid in the seed produced by crambe was greater than that produced by fanweed, consideration of pests, crop rotations, and other factors could make fanweed a promising candidate for new crop development.

Black Mustard

Black mustard was rated as having very good to excellent agronomic potential. Plants were easy to mechanically sow and manage. Growth was vigorous and large plants developed (Table 1). Seed production was underway by early July; the seeds which developed were contained in pods from 1.3 to 1.9 cm long which tended to shatter as plant moisture levels declined. Plants would probably need to be swathed prior to harvesting. Black mustard may fit as a short season crop in some crop rotations in the Northern Great Plains.

Black mustard produced relatively large amounts of seed (>1,200 kg/ha) during 1990 and 1991 (Table 1). In 1991, close to 1,900 kg/ha of seed was produced, making black mustard the highest yielding species evaluated. By comparison, yield of crambe averaged 1,820 kg/ha in 1991. Unlike fanweed, seed dormancy was not a serious problem with black mustard, so relatively good plant stands were fairly easy to establish in the spring.

Black mustard produced seed that was 32% oil (Table 2). Of this, roughly 40% was erucic acid. As with fanweed, black mustard demonstrated potential as an industrial crop, even though crambe seed contained greater amounts of erucic acid.

Wild Mustard

Wild mustard (charlock, kaber mustard) was considered to have very good to excellent agronomic potential. Plants were easy to mechanically sow and manage, and seeds appeared to lend themselves to mechanical harvesting methods. As with fanweed and black mustard, seeds of wild mustard were susceptible to shattering so plants would probably be swathed prior to harvesting the seed if grown on a field-scale.

Wild mustard produced roughly 2,000 kg/ha of seed during 1990 and 1991 (Table 1). Individual plants produced an average of 2,076 seeds which were contained in pods approximately 2.5 cm in length. The seed contained about 26% oil but failed to be comprised of a high percentage of highly valued fatty acids (Table 2). For this reason, wild mustard was considered to have low potential as an industrial crop.

Hare's Ear Mustard

Hare's ear mustard (*syn*. hare's mustard) was considered to have moderate agronomic potential. Plants were generally easy to mechanically sow and manage. However, about 15% of the stand was destroyed by an unknown pathogen in 1991. Plants were short (<40 cm) and some seed pods were less than 10 cm above the soil surface (Table 1). This could present difficulties in the mechanical harvesting process. Seed could be harvested without first swathing the plants since seed pods were not susceptible to shattering.

Hare's ear mustard produced relatively low quantities of seed in 1990 and 1991 field evaluations; yields averaged 901 kg/ha in 1990 and only 549 kg/ha in 1991 (Table 1). Individual plants produced an average of 590 seeds which were contained in seed pods about 5 cm in length.

Hare's ear mustard produced seed containing about 30% oil, with close to 30% of the oil being comprised of erucic acid (Table 2). Other research indicates that the oil contains additional fatty acids with industrial applications (Appelqvist, 1971). It seems that further consideration of hare's ear mustard as an industrial crop is warranted.

Euphorbia lagascae

Euphorbia lagascae was considered to have the lowest agronomic potential of all plant species. Seed development was indeterminate and fruits containing the seed burst violently as the seed approached maturity. Still, this plant species was agronomically attractive in several respects. The seed was large and easy to mechanically sow. Seedlings grew rapidly and were easy to manage.

Grasshoppers and other insect pests did not appear to feed on *Euphorbia lagascae*. Improvements in seed retention are needed.

Euphorbia lagascae produced an abundance of seed in 1990 and 1991 field evaluations, but much of the seed could not be collected due to seed shattering. Hence, harvested seed only amounted to about 200 kg/ha during 1990 and 150 kg/ha during 1991 (Table 1). Further studies are needed to assess seed yields when plants are swathed prior to harvesting.

Euphorbia lagascae produced seed which contained over 50% oil by weight. Past research determined that the oil contained over 50% vernolic acid (K. Carlson 1991 pers. commun.), making it a promising candidate for new crop development if genetic improvements and/or management practices could enhance the mechanical harvestability of seed.

Weed Control

Weeds were a problem and had to be removed by hand throughout the growing season. Effective weed control strategies must be developed for each plant species. The plant canopy produced by crambe intercepted more than 90% of the incident PAR after June 13 in the 1991 field evaluation (Fig. 1). Only small amounts of PAR could penetrate the canopy after this date and reach weed seedlings which were developing underneath. This may explain why weed pressure was much greater in hare's ear mustard than in crambe plots, since more than 50% of the incident PAR reached weed seedlings developing under a canopy of hare's ear mustard through most of the growing season.

SUMMARY

Fanweed, black mustard, hare's ear mustard, and *Euphorbia lagascae* contain fatty acids with important industrial applications. These plants have varying degrees of potential as novel industrial crops. Fanweed is adapted to growing conditions in the Great Plains and seems suited to field production methods. Approximately 1,500 kg/ha of seed was produced in 1990-91 field evaluations in North Dakota. This seed contained about 180 kg/ha of erucic acid, an unusual fatty acid with several industrial uses. Black mustard and hare's ear mustard also produced seed containing erucic acid, but these weed species appeared to have less potential than fanweed as industrial crops when agronomic factors were considered. Seed harvesting difficulties with *Euphorbia lagascae* and failure of wild mustard seed oil to contain high-value fatty acids presently limit their potential as industrial crops.

Choy Sum, Chinese Cabbage

Cruciferae *Brassica parachinensis* Bailey

Source: Magness et al. 1971

This oriental vegetable is very similar in growth habit and culture to Chinese cabbage, which see. However, it is grown for the flowering stalk. The entire plant with the flowering stalk may be harvested and marketed. In exposure of edible parts daring growth the plant is comparable to sprouting broccoli.

Conservation of Medicinal and Aromatic Plants in Brazil

Roberto F. Vieira*

THE BRAZILIAN VEGETATION

Approximately two thirds of the biological diversity of the world is found in tropical zones, mainly in developing countries. Brazil is considered the country with the greatest biodiversity on the planet, with nearly 55,000 native species distributed over six major biomes (Fig 1): Amazon (30,000); Cerrado (10,000); Caatinga (4,000); Atlantic rainforest (10,000), Pantanal (10,000) and the subtropical forest (3,000).

The Brazilian Amazon Forest (tropical rainforest) covers nearly 40% of all national territory, with about 20% legally preserved. This ecosystem is rather fragile, and its productivity and stability depend on the recycling of nutrients, whose efficiency is directly related to the biological diversity and the structural complexity of the forest (Anon. 1995). Giacometti (1990) estimated that there are about 800 plant species of economic or social value in the Amazon. Of these, 190 are fruit-bearing plants, 20 are oil plants, and there are hundreds of medicinal plants (Berg 1982).

The "Cerrado" is the second largest ecological dominion of Brazil, where a continuous herbaceous stratum is joined to an arboreal stratum, with variable density of woody species. The cerrados cover a surface area of approximately 25% of Brazilian territory and around 220 species from cerrado are reported as used in the traditional medicine (Vieira and Martins 1998).

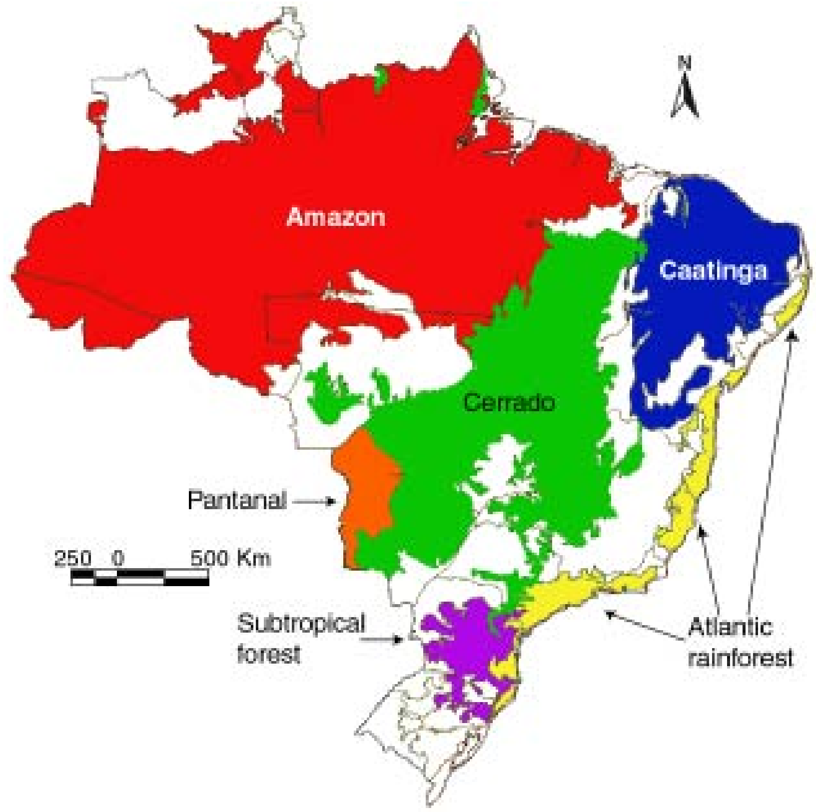

Fig. 1. Major biomes of Brazil, source: Embrapa, Cenargen.

The "Caatinga" extends over areas of the states of the Brazilian Northeast and is characterized by the xerophitic vegetation typical of a semi-arid climate. The soils that are fertile, due to the nature of their original materials and the low level of rainfall, experience minor runoff (Anon. 1995). Various fruit species and medicinal plants have their centers of genetic diversity in this region, and the use of local folk medicines is common. Several important aromatic species are reported for this region (Craveiro et al. 1994), such as *Lippia* spp. and *Vanillosmopsis arborea*.

The Atlantic Forest extends over nearly the whole Brazilian coastline, and is one of the most endangered ecosystems of the world, with less than 10% of the original vegetation remaining. The climate is predominantly hot and tropical, and precipitation ranges from 1,000 to 1,750 mm. The land is composed of hills and coastal plains, accompanied by a mountain range (Anon. 1995). Several important medicinal species are found in this region, such as *Mikania glomerata, Bauhinia forficata, Psychotria ipecacuanha*, and *Ocotea odorifera*.

The territory of the Meridional Forests and Grasslands includes the mesophytic tropical forests, the subtropical forests, and the meridional grasslands of the states of southern Brazil. The climate is tropical and subtropical, humid, with some areas of temperate climate. The naturally fertile soils, associated with the mild climate, allowed a rapid colonization during the last century, mainly by European and, more recently, by Japanese immigrants (Anon. 1995). Several medicinal plants, such as chamomile (*Matricaria recutita*), calendula (*Calendula officinalis*), lemon balm (*Melissa officinalis*), rosemary (*Rosmarinus officinalis*), basil (*Ocimum basilicum*), and oregano (*Origanum vulgare*), were introduced and adapted by immigrants.

The Pantanal is a geologically lowered area filled with sediments which have settled in the basin of the Paraguay River. Pantanal flora is formed by species from both Cerrado and Amazon vegetation. More than 200 species useful for human and animal consumption as well as for industrial use have been recorded in this region (Anon. 1995).

GERMPLASM CONSERVATION

In the last decade, serious efforts to collect and preserve the genetic variability of medicinal plants have been initiated in Brazil. The National Center for Genetic Resources and Biotechnology—Cenargen, in collaboration with other research centers of Embrapa (Brazilian Agricultural Research Corporation), and several universities, has a program to establish germplasm banks for medicinal and aromatic species (Table 1).

Table 1. List of institutions, germplasm collections of medicinal and aromatic plants, accessions, curator, and contact.

Institution	Major germplasm collections	No. accessions	Curator	Contact
Agronomic Institute of Paraná	*Pfaffia*	Unknown	P. Guilherme	www.pr.gov.br/iapar

Univ. of Paraná	*Maytenus*	78	M. Scheffer	Universidade Federal do Parana, Escola de Florestas, Departamento de Silvicultura e Manejo, Rua Bom Jesus, 650, Juveve, 80035-010, Curitiba, PR

The first step is to establish criteria to define a species priority, based on economic and social importance, markets, and potential genetic erosion. Vieira and Skorupa (1993) proposed the following criteria to define priority, as follows: (1) species with proven medicinal value including those containing known active substance(s) or precursor(s) used in the chemical–pharmaceutical industry with proven pharmacological action, or at least demonstrating pre-clinical and toxicological results; (2) species with ethnopharmacological information widely used in traditional medicine; and which are threatened or vulnerable to extinction; (3) species with chemotaxonomical affinity to botanical groups which produce specific natural products.

Conservation of threatened germplasm includes seed banks, field preservation, tissue culture, and cryopreservation. Seed storage is considered the ideal method; seeds considered orthodox can be dried and are able to be preserved at sub-zero temperatures (–20°C), while recalcitrant seeds, including most tropical species, lose their seed viability when subjected to the same conditions. Maintenance of the germplasm in field collections is costly, requires large areas, and can be affected by adverse environmental conditions. Tissue culture or cryopreservation techniques can be also considered in some cases.

The next step is to decide which germplasm conservation method will be applied: ex situ or in situ. In an ex situ procedure, the germplasm is collected from fields, markets, small farms, and other sites, in form of seeds, cuttings, underground systems, and sprouts. The collected samples should represent the original population with passport data and herbarium vouchers. In a long term, mutation can take place over the years in a cold chamber or in vitro conservation. In contrast, in situ conservation maintains population in its preserved natural area, allowing the evolutionary process to continue, although genetic reserves are subject to anthropogenic action and environmental effects. Most in situ conservation has focused in forest species, with some medicinal species included, such as *Pilocarpus microphyllus* and *Aniba roseodora*. The establishment of genetic reserves in Brazil has relied on National Parks and conservation areas established by the environmental protection agency of Brazil, Ibama.

There are now five forest genetic reserves in Brazil: one in the Amazon Tropical Rainforest, state of Para; one in the Caatinga, state of Minas Gerais; two in the Cerrado in the Federal District, and one in the Meridional Forest (Subtropical) in the state of Santa Catarina. Four other genetic reserves are being created; two in the Atlantic Forest in the states of Rio de Janeiro and Espirito Santo, one in the Caatinga in the state of Piaui, and another in the Tropical Humid Forest in transition with Cerrado in the state of Minas Gerais (Anon. 1995). These reserves aim to conserve the most endangered species and those of greatest economic interest, including medicinal and aromatic plants.

The Brazilian program on medicinal germplasm conservation has three foci: (1) ethnobotanical studies; (2) germplasm collection and characterization; and (3) in situ conservation. Ethnobotanic and phytogeographic studies on the medicinal flora of Cerrado have been able to identify and collect genetic material for conservation. About 110 species used in traditional medicine were reported in the Cerrado region (Vieira et al. 1998). Bibliography review and a herbaria search were carried out allowing an estimation of the medicinal potential of each species studied, their geographic distribution, and period of fruit maturation.

In 1994, a cooperative project between the Brasília Botanical Garden and Embrapa/Cenargen was established. An in vivo collection of medicinal plants from Cerrado, now contains 161 accessions (Dias et al. 1995). The collection has facilited phytochemical and pharmacological studies of this plant materials, and an anti-inflamatory agent has been identified on *Lychnophora salicifolia* (Miguel et al. 1997).

PRIORITY SPECIES

A few germplasm collections of medicinal and aromatic plants have been established in Brazil (Table 2). The following species, listed alphabetically, have been recognized as priority for germplasm conservation.

Table 2. List of medicinal and aromatic species with high priority for germplasm collection and conservation in Brazil.

Species	Common name	Habit	Active substance/pharmacological action	Region	Conservation form
Achyrocline satureioides L.	Macela	Herb	Hypotensive, spasmolytic	Cerrado	Field collection

Ageratum conyzoides L.	Mentrasto	Herb	Anti-inflammatory	Ruderal	Field collection
Aniba roseodora Ducke	Pau rosa	Tree	Linalool	Amazon forest	In situ
Astronium urundeuva (Fr. All.) Engl.	Aroeira	Tree	Anti-inflammatory, anti-ulceric	Cerrado	In situ, cold chamber
Baccharis trimera DC.	Carqueja	Herb	Hepatic disturbs	Ruderal	Field collection
Bauhinia forficata L.	Pata de Vaca	Tree	Diabetes	Atlantic forest	Cold chamber
Caryocar brasiliensis Camb.	Pequi	Tree	Anti-inflamatory	Cerrado	In situ
Copaifera langsdorffi Desf.	Copaiba	Tree	Oil, anti-inflamatory	Cerrado	In situ, cold chamber
Croton cajucara Benth.	Sacaca	Herb	Linalool	Amazon	Field collection
Croton zehntneri Pax et Hoff.	Cunha	Shrub	Anetol, eugenol	Caatinga	Field collection
Datura insignis B. Rodr.	Toe	Shrub	Escopolamina	Amazon forest	Cold chamber
Dimorphandra mollis Benth.	Faveiro	Tree	Rutin, anti-hemorragic	Cerrado	Cold chamber
Echinodorus macrophyllus (Kunth.) Mich	Chapeu de Couro	Herb	Diuretic	Cerrado	Field collection, cold chamber
Jatropha elliptica (Pohl) Baill.	Batat de Tiu	Shrub	Jatrophone	Cerrado	In situ, field collection
Lippia spp.	Alecrim pimenta	Shrub	Source of volatile oils, anti-microbial	Caatinga	Field collection
Lychnophora ericoides Mart.*; L. salicifolia* Mart.	Arnica do Cerrado	Shrub	Volatile oils	Cerrado	Field collection, in situ
Mandevilla vellutina Mart.		Shrub	Anti-inflamatory, bradykynin antagonist	Cerrado	In situ, field collection
Maytenus ilicifolia Mart. ex. Reiss; *M. aquifolium* Mart.	Espinheira Santa	Tree	Anti-ulceric	Meridional forest	Cold chamber, in situ

Mikania glomerata Spreng.	Guaco	Herb	Bronchitis, coughs	Atlantic forest	Field collection
Ocotea odorifera (Vell.) Rohwer	Canela Sassafraz	Tree	Safrol, metileugenol	Atlantic forest	In situ
Operculina macrocarpa (L.) Farwel	Batata de Purga	Herb	Purgative	Caatinga	Cold chamber
Piper hispidinervum DC.	Pimenta longa	Herb	Safrol	Amazon	Cold chamber, field collection
Pfaffia paniculata (Martius) Kuntze	Ginseng brasileiro	Herb	Antitumor compounds	Margins of Parana river	Cold chamber, field collection
Phyllanthus niruri L.	Quebra pedra	Herb	Hepatitis B, renal calculus	Ruderal	Cold chamber
Pilocarpus microphyllus Stapf.	Jaborandi	Shrub	Pilocarpine	Amazon forest	Cold chamber, in situ
Psychotria ipecacuanha(Brot.) Stokes	Ipecac	Herb	Emetin, cefaline	Amazon and Atlantic forest	Cold chamber, in situ
Pterodon emarginatus Vogel	Sucupira	Tree	Analgesic, antinoceptive, cercaricide	Cerrado	In situ, cold chamber
Solanum mauritianum Scopoli	Cuvitinga	Shrub	Solasodine	Ruderal, southeast and southern Brazil	Cold chamber
Stryphnodendron adstringens (Mart.) Coville	Barbatimao	Tree	Tannin, anti-inflamatory	Cerrado	In situ, cold chamber
Tabebuia avellanedae (Lor.) ex. Griseb.	Ipe roxo	Tree	Lapachol	Cerrado	In situ
Vanillosmopsis arborea (Aguiar) Ducke	Candeia	Shrub	Bisabolol	Caatinga	In situ, field collection

Maytenus ilicifolia Martius ex Reiss., Celastraceae (Espinheira Santa)

Espinheira santa is a small shrub evergreen tree reaching up to 5 m height. It is native to many parts of southern Brazil, mainly in Paraná and Santa Catarina states.

Leaves of *Maytenus* species are used in the popular medicine of Brazil for their reported antiacid and antiulcerogenic activity. The effects of a boiling water extract of equal parts of *M. aquifolium* and *M. ilicifolia* leaves have been tested in rats and mice. Attempts to detect general depressant, hypnotic, anticonvulsant, and analgesic effects were reported by Oliveira et al. (1991). The potent antiulcerogenic effect of espinheira santa leaves was demonstrated effective compared to two leading anti-ulcer drugs, Ranitidine and Cimetidine (Souza-Formigoni et al., 1991). Toxicological studies demonstrated the plant's safety.

Seeds of *Maytenus ilicifolia* can be classified as orthodox and stored at –20°C in long-term cold chambers (Eira et al. 1995). The Forestry Department of the University of Paraná began a project in 1995 to study the genetic variability of natural populations of *Maytenus ilicifolia* and 78 accession were collected in the states of Parana, Santa Catarina, and Rio Grande do Sul. Field collections are maintained at the university campus (Scheffer et al. 1998). Although cultivation of *M. ilicifolia* is the object of several studies in Brazil, a research focus on in situ conservation and sustainable systems of harvesting are required.

Pfaffia paniculata Martius, Amaranthaceae (Brazilian Ginseng)

Pfaffia is a large, shrubby ground vine, which has a deep root system. *Pfaffia* is well known in Central and South America with over 50 species growing in the warmer tropical regions of the area and has been exploited for more than 15 years. The species grow in the borders of Paraná river, but predatory collection has greatly reduced the natural populations.

In Brazil, *Pfaffia* is known as *para tudo,* which means "for all things" and also as Brazilian ginseng, since it is widely used like American and Asian ginseng (*Panax* spp.). The active substances are found in the roots.

This action is attributed to the anabolic agent, beta-ecdysterone as well as three novel ecdysteroid glycosides which are found in high amounts in *Pfaffia*. This species is such a rich source of beta-ecdysterone. The extraction methods employed to obtain it from this root is protected by a Japanese patent (Nishimoto et al. 1988).

The root of *Pfaffia* contains about 11% saponins. These saponins include a group of novel chemicals called pfaffosides as well as pfaffic acids, glycosides, and nortriperpenes. These saponins have clinically demonstrated the ability to inhibit cultured tumor cell melanomas and help to regulate blood sugar levels (Takumoto et al. 1983; Nishimoto 1984). The pfaffosides and pfaffic acid derivatives in *Pfaffia* have been patented as antitumor compounds in two Japanese patents (Japanese Patent 84184198, Oct. 19, 1984 by Rohto Pharmaceutical Co., Ltd.).

Few accessions of *Pfaffia* are available in any of the present field collections. This species requires an immediate recollection to preserve the plant. Due to its economic importance a germplasm collection and characterization of its chemical constituents, is fully warranted.

Phyllanthus niruri L., Euphorbiaceae (Quebra Pedra)

Quebra pedra is a small erect annual herb growing up to 30 to 40 cm. height. Although several species are recognized by this common name, *P. niruri* and *P. sellovianus* are the most scientifically studied. The antispasmodic activity of alkaloids in *Phyllanthus sellovianus* explained the popular use of the plant for kidney and bladder stones. The alkaloid extract demonstrated smooth muscle relaxation specific to the urinary and biliary tract which facilitates the expulsion of kidney or bladder calculi (Calixto 1984; Santos 1994, 1995)

Quebra pedra has gained world-wide attention due to its effects against Hepatitis B (Thyagarajan 1982; Mehrotra 1990; Yeh, et al. 1993; Wang 1995). Recent research on quebra pedra reveals that its antiviral activity extends to the human immunodeficiency virus (HIV). The HIV-1 reverse transcriptase inhibition properties of *P. niruri* can be obtained with a simple water extract of the plant (Qian-Cutrone 1996). There have been no side effects or toxicity reported in any of the clinical studies or in its many years of reported use in herbal medicine.

Several species, called quebra pedra, contain the same or similar active compounds. A germplasm collection to study the genetic and chemical variation, as well as the seed physiology of this species is necessary and warranted.

Pilocarpus microphyllus Stapf., Rutaceae (Jaborandi)

Jaborandi is an indigenous name (*ia-mbor-end*) of this species. *Pilocarpus microphyllus* contain the highest pilocarpine content in the leaves. The plant is an understory species, 6 to 8 m in height, of the pre-Amazonian rain forest in the states of Pará, Maranhão, and Piauí.

Pilocarpine is an imidazolic alkaloid that stimulates the secretions of the respiratory tract, the salivary, lachrymal, gastric and other glands, weakens the heart action, accelerates the pulse rate, increases intestinal peristalsis and promotes uterine contractions (Morton 1977). In the treatment of glaucoma, the alkaloid pilocarpine acts directly on cholinergic receptor sites, thus mimicing the action of acetylcholine. Intraocular pressure is thereby reduced, and despite its short-term action, pilocarpine is the standard drug used for initial and maintenance therapy in certain types of primary glaucoma (Lewis and Elvin-Lewis 1977). Recently, the US Food and Drug Administration approved pilocarpine for use to treat post-irradiation xerostomia (dry mouth) in patients with head and neck cancer (Pinheiro 1997).

The exploration of this product, due to its high economic value, has led to great scientific interest in research and development effects for domestication and conservation. Pinheiro (1997) reports that the price of jaborandi leaves has reached US$4.00/kg. The wild harvest or collection of leaves from wild *P. microphyllus* has been carrying out to such an extent that it has significantly reduced the natural populations, and this species is included in the official list of endangered plants from Brazilian flora (Anon. 1992).

In 1991, the Cenargen initiated a project for recollecting and conservation of the genetic variability of *Pilocarpus microphyllus* and related species. From 1991 to 1993, two collection expeditions were undertaken, covering the states of Pará and Maranhão. A total of 27 accessions were collected in form of seeds and seedlings (Vieira, 1993). A germplasm bank of Jaborandi was established at Maranhão State University, São Luis, and at Embrapa—Ocidental Amazon, Belém, Pará State.

Studies on the methodology of *P. microphyllus* conservation led to the conclusion that seeds of this species are considered orthodox. Seeds can be dried down to 6–8% moisture content and be conserved for a long period at –18°C and 5% relative humidity (Eira et al. 1993). A seed sample of all collected accessions is being maintained at Embrapa, Cenargen.

Native populations of *P. microphyllus* have suffered from anthropogenic activity, with plants of shorter size than normal due to intensive harvesting of leaves. It will be challenge to stimulate the management and cultivation of this species in its native habitat. Although seeds can be preserved for long periods, in situ conservation must be initiated and natural reserves established. This species can be only found in indigenous areas, and some private lands.

Psychotria ipecacuanha (Brot.) Stokes, Rubiaceae (Ipecac)

Psychotria ipecacuanha (Brot.)Stokes [= *Cephaelis ipecacuanha* (Brot.) A.Rich.] is a shrub, whose medicinal value relates to the production of emetine in the roots. Ipecac is found in the humid forests of Central America, Colombia, southern part of the Amazon Forest in the States of Rondônia, Mato Grosso, and Atlantic forest, in the States of Bahia, Espírito Santo, Minas Gerais, and Rio de Janeiro (Skorupa and Assis 1998).

Ipecac as a powerful emetic, is used in gastrointestinal diseases, diarrhea, and intermitent fevers. It is employed as an expectorant, in bronchitis, broncopneumonia, asthma and mumps, and also as a vasoconstrictor. In 1959, dihydroxi-emetine, an emetine analogue, was presented as an amoebicide due to its reduced toxic effect on cardiac muscle (Lewis and Elvin-Lewis 1977).

The global production of ipecac averages 100 t a year, originated mainly from Nicarágua, Brazil and India (Husain 1991). Considering the economic and medicinal values of ipecac, the deforestation of the areas of occurrence and the extrativist nature of its production, in 1988, Cenargen has began a program for the recollecting and conservation of the genetic variability of this species. From 1988 to 1991, five collecting expeditions were undertaken, covering the States of Rondonia, Mato Grosso, Pernambuco, Bahia, Espirito Santo, Rio de Janeiro, and Minas Gerais, and a total of 86 accessions were collected (Skorupa and Assis 1998) and now maintained in field germplasm banks at Embrapa—Ocidental Amazon, Belém, Para, and at Florestas Rio doce, Linhares, Espirito Santo. Recently, other germplasm collections was established at the University of North Fluminense, which contains 10 accessions originated from the Atlantic Forest area (states of Rio de Janeiro and São Paulo).

Solanum mauritianum Scop., Solanaceae (Cuvitinga)

The steroidal alkaloids of the Solanaceae are compounds of considerable pharmaceutical interest as starting materials for the synthesis of steroid compounds such as anticontraceptive steroids and corticosteroids. The world demand for steroid precursors continues to increase while some of the traditional sources of steroidal raw material, such as yams (*Dioscorea* spp.) of Mexico and Central America, are becoming rapidly depleted (Roddick 1986). Solasodine is a chemical analog of diosgenin, and may be a substitute for this drug.

There are around 1,100 species of *Solanum* in South America, and *S. mauritianum* is among the species with the highest solasodine content (Vieira and Carvalho 1993). *Solanum mauritianum* is a subtropical shrub which grow all over southern Brazil. The solasodine content of *S. mauritianum* was evaluated in green fruits of natural populations growing on two different soils. High contents of solasodine were found in both population of *S. mauritianum* (from 2% to 3.5% of total dry weight) (Vieira 1989). Germplasm collections are needed to continue the study of genetic and environmental variation of solasodine, and to provide foundation study for future development programs.

Exotic Species

Although the major focus of germplasm conservation is on native species, several exotic, introduced and adapted species have been widely used and cultivated in Brazil. Many of them, such as lemongrass [*Cymbopogon citratus* (D.C.) Stapf.] and aloe (*Aloe* spp.), are cultivated in backyard gardens. Others, such as picão-preto (*Bidens pilosum* L.), mastruço (*Chenopodium ambrosioides* L.), and mentrasto (*Ageratum conyzoides* L.), whose adaptation through the years, has allowed a spontaneous wide distribution throughout the country, have had their use well disseminated (Dias 1995). In southern Brazil, due to favorable cultural and environmental conditions, several exotic species are cultivated in large areas. These include chamomile (*Matricaria recutita*), calendula (*Calendula officinalis*), rosemary (*Rosmarinus officinalis*), *Duboisia* sp., and Japanese mint (*Mentha arvensis*), all of which are deserving of collection and preservation due to the use of their natural products and the agricultural-based industries that produce these crops. The germplasm collection of exotic species also needs to be expanded to provide genetic resource for species adapted in Brazil. Although Brazil is not their genetic center of origin, different chemotypes have been naturalized (Mattos, pers. commun. 1994) and need to be conserved. One example is *Coleus barbatus*, which was introduced from Africa, and is clonally propagated in Brazil. However, several volatile oils chemotypes are found in Brazil for this species, probably due to different introductions from Africa in the past.

Brazilian Guava

Psidium guineense Sw.

Psidium molle Bertol

Psidium schiedeanum Berg.

Psidium aracá Raddi

This guava relative has been the subject of much confusion, beginning with its scientific name, *Psidium guineense* Sw., based on the botanist Swartz' belief that it originated on the Guinea Coast of Africa. For a long time it was considered distinct from the guisaro, *P. molle* Bertol (syn. *P. schiedeanum* Berg.), but now these names as well as *P. aracá* Raddi, are treated as synonyms of *P. guineense*, and all the corresponding colloquial names should be applied to this one confirmed species.

In Brazil the popular names are *aracá, aracá do campo,* or *aracahy;* in the Guianas it is called wild guava or *wilde guave.* Among other regional names are: *guabillo, huayava, guayaba brava* and *sacha guayaba* (Peru); *allpa guayaba* (Ecuador); *guayaba de sabana, guayaba sabanera* and *guayaba agria* (Venezuela); *guayaba*, or *guayaba acida, guayaba hedionda, chamach, chamacch, pataj* and *pichippul* (Guatemala); *guisaro*, or *cas extranjero* (Costa Rica); *guayabita, guayaba arraijan,* and *guayabita de sabana* (Panama); *guayabillo* (El Salvador). The name, *guayaba agria*, seems to be the only one employed in Mexico. In California it is called either Brazilian or Castilian guava.

Description

The Brazilian guava is a relatively slow-growing shrub 3 to 10 ft (1-3 m) tall; sometimes a tree to 23 ft (7 m); with grayish bark, hairy young shoots and cylindrical or slightly flattened branchlets. The evergreen, grayish leaves, 1 1/3 to 5 1/2 in (3.5-14 cm) long and 1 to 3 1/8 (2.5-8 cm wide), are stiff, oblong, elliptic, ovate or obovate, sometimes finely toothed; scantily hairy on the upperside but coated beneath with pale or rusty hairs and distinctly dotted with glands. Flowers, borne singly or in clusters of 3 in the leaf axils, are white and have 150 to 200 prominent stamens. The fruit, round or pear-shaped, is from 1/8 to 1 in (1-2.5 cm) wide, with yellow skin, thick, pale-yellowish flesh surrounding the white central pulp, and of acid, resinous, slightly strawberry-like flavor. It contains numerous small, hard seeds and is quite firm even when fully ripe.

Distribution

The most wide-ranging guava relative, *P. guineense* occurs naturally from northern Argentina and Peru to southern Mexico, and in Trinidad, Martinique, Jamaica and Cuba, at medium elevations. It is cultivated to a limited extent in Martinique, Guadeloupe, the Dominican Republic and southern California. Trials in Florida have not been encouraging. At Agartala in Tripura, northeast India, this plant has become thoroughly naturalized and runs wild.

Cultivars

While no named cultivars have been reported, this species has been crossed with the common guava and the hybrids are dwarf, hardy and bear heavy crops.

Soil

The plant will not develop satisfactorily on light sandy soil.

Food Uses

This guava is suitable for baking and preserving. It makes a distinctive jelly which some consider superior to common guava jelly.

Other Uses

The **wood** is strong and used for tool handles, beams, planks and agricultural instruments. The **bark,** rich in tannin, is used for curing hides.

Medicinal Uses: In the interior of Brazil, a decoction of the bark or of the roots is employed to treat urinary diseases, diarrhea and dysentery. In Costa Rica, it is said to reduce varicose veins and ulcers on the legs. A leaf decoction is taken to relieve colds and bronchitis.

Related Species

The Pará guava has been known as *Britoa acida* Berg. Calvacante now shows this binomial as a synonym of *Psidium acutangulum* DC. and gives the Brazilian vernacular name as *aracá-pera*. Cruz (1965) calls it *araca piranga, aracandiva, aracanduba* and *goiabarana*. Le Cointe shows it as *araca comum do Pará* and he describes *P. aracá* Raddi as a separate species. In Bolivia, *P. acutangulum is* known as guabira; in Peru, as *ampi yacu, puca yacu, guayava del agua*.

The shrub or tree ranges in height from 26 to 40 ft (8-12 m). Its branchlets are quadrangular and winged near the leaf base. New growth is finely hairy. The leaves, with very short petioles, are elliptical, 4 to 5 1/2 in (10-14 cm) long, 1 1/2 to 2 3/8 in (4-6 cm) wide, rounded at the base, pointed at the apex. The long-stalked, white, 5-petalled flowers, with more than 300 stamens, are borne singly or in 2's or 3's in the leaf axils. The fruit is round, pear-shaped or ellipsoid, 1 1/4 to 3 3/16 in (3-8 cm) wide, pale-yellow, with yellowish-white, very acid but well-flavored pulp containing a few hard, triangular seeds. The crop ripens in the spring.

The tree occurs wild and cultivated at low and medium elevations throughout Amazonia and from Peru to Colombia, Bolivia, Venezuela and the Guianas. Some specimens have been grown in southern Florida in the past under the name *P. aracá.* The fruit is eaten mixed with honey or made into acid drinks or preserves.

Of recent interest as a possible new crop is *Eugenia stipitata* McVaugh, treated by Calvacante as a variable species, but separated by McVaugh *(Flora of Peru,* Vol. XIII, Pt. 4, No. 2, 1958) into 2 subspecies, as follows:

E. stipitata subsp. *stipitata* McVaugh, called *pichi* in Peru, *araca-boi* in Brazil, is a tree to 40 or 50 ft (12-15 m) tall, with short-petioled, opposite, broad-elliptic leaves, pointed at the apex, 3 to 7 in (7.5-18 cm) long and 1 1/3 to 3 1/4 in (3.4-8.25 cm) wide, with indented veins on the upper surface, densely hairy on the underside, faintly dotted with oil glands on both sides. The flowers, in compound, axillary racemes, are white, hairy, 3/4 in (2 cm) wide, with numerous prominent stamens.

According to horticulturists and Calvacante, the fruit is somewhat like a small guava; very aromatic, round to oblate, less than 2 oz (56 g) in the wild, up to 4 3/4 in (12 cm) wide under cultivation and weighing as much as 14 1/2 oz (420 g) or even 28 oz (800 g). The skin is thin and delicate; the pulp soft, juicy, very acid, containing 8 to 10 irregular-oblong or kidney-shaped seeds to 1 in (2.5 cm) long and 5/8 in (1.5 cm) wide. Ascorbic acid content has been reported as 38 to 40 mg per 100 g of edible portion. The fruiting season is February to May around Belem, Brazil. There may be 4 crops a year in Peru and Ecuador. The tree is native and abundant in the wild in Amazonian regions of Peru, Ecuador and Brazil. The fruit is eaten by the Indians and the tree is being cultivated experimentally in Peru and Ecuador and a collection of 360 seedlings has been established at Manaus. Seeds germinate in 4-12 months.

Seedlings grow slowly at first, are transplanted in about 6 months. They begin to fruit 18 months later. Yields of 12.7 tons per acre (28 T/ha) have been obtained in Peru. The tree is subject to leafspot and the fruit is prone to attack by fruit flies. The fruit loses flavor when cooked; is quick-boiled for jam. A Peruvian grower is exporting the frozen pulp to Europe.

Subspecies *sororia*, called *rupina caspi* in Peru, is a shrub or small tree to 10 ft (3 m) high with elliptic leaves 3 1/2 to 5 in (9-12.5 cm) long, 1 to 1 3/4 in (2.5-4.5 cm) wide with barely visible veins; minutely hairy beneath or hairless when fully mature; and having a few dark dots. The flowers are 1/2 in (1.25 cm) wide with 75 stamens. The fruit is oblate, 5/8 in (1.6 cm) wide, velvety, acid, with numerous kidney-shaped seeds, 1/8 to a little over 1/4 in (3-7 mm) long. McVaugh shows as native to Peru, Ecuador, Bolivia and Colombia.

Triticum aestivum L.

Poaceae
Common wheat, Bread wheat

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

Common wheat, best known and most widely cultivated of the wheats, is cultivated for the grain, used whole or ground. Fine ground, it is the source of flour for the world's breadmaking. Main use is for flour and bread-stuffs known by various names throughout the world. Grain also is the source of alcoholic beverages, beer, industrial alcohol made into synthetic rubber and explosives. Bran from flour milling also an important livestock feed; germ is valuable addition to feed concentrate. Grain fed to livestock whole or coarsely ground. Starch is used for pastes and sizing textiles. Straw made into mats, carpets, baskets, and used for packing material, cattle bedding, and paper manufacturing. Some wheat is cut for hay. Wheat grown for grain crop is also used for pasture before the stems elongate and as a temporary pasturage; it is nutritious and palatable.

Folk Medicine

According to Hartwell (1967–1971), the seeds are used in folk remedies for cancers, corns, tumors, warts, and whitlow. Reported to be antivinous, bilious, demulcent, discutient, diuretic, emollient, excipient, intoxicant, laxative, useful as a poultice, restorative, sedative, used as a shampoo and vulnerary, common wheat is a folk remedy for burns, cancer, diarrhea, dysentery, ecchymosis, epistaxis, fertility, fever, flux, gravel, hematuria, hemoptysis, hemorrhage, incontinence, leprosy, leucorrhea, menorrhagia, neurasthenia, nightsweat, perspiration, scald, tumor, warts, whitlow, and wounds (Duke and Wain, 1981).

Chemistry

Per 100 g, the grain is reported to contain 326–335 calories, 11.57–14.0 g H_2O, 9.4–14.0 g protein, 1.8–2.5 g fat, 69.1–75.4 g total carbohydrate, 1.8–2.3 g fiber, 1.7 g ash, 36–46 mg Ca, 354–400 mg P, 3.0–4.3 mg Fe, 370–435 mg K, 0.43–0.66 mg thiamine, 0.11–0.12 mg riboflavin, and 4.3–5.3 mg niacin. The grain contains allantoin plus uricase; sinapic acid has been isolated from wheat germ. The grain is said to cause poisoning in stock, though no toxic principle has been found. Wheat can absorb toxic concentrations of selenium but "selenium" wheat rarely causes poisoning (Watt and Breyer-Brandwijk, 1962). One kg of grain contains 0.03 mg As_2O_3; grain also contains Mg, Mn, Zn, Fe, and Cu. Amino acid composition is shown in the Table from the Wealth of India.

Essential amino acids in wheat proteins (after Wealth of India)

	Inner endosperm (%)	Outer endosperm (%)	Bran (%)	Germ (%)	Whole wheat (%)
Arginine	2.92	4.50	7.53	6.20	3.81
Histidine	1.65	1.74	1.68	3.03	1.65
Isoleucine	7.02	6.56	4.50	5.23	6.97
Leucine	9.14	7.98	6.52	7.33	8.27
Lysine	1.92	2.60	3.87	5.44	2.80
Methionine	1.12	1.40	1.09	1.28	1.32
Phenylalanine	3.95	3.43	2.45	2.47	3.68
Threonine	2.56	2.72	2.85	6.28	2.78
Tryptophan	0.93	1.12	1.83	0.90	1.03
Valine	3.65	4.02	4.10	4.20	4.00

Wheat germ oil is rich in tocopherols (vit. E) and essential fatty acids. Sitosterol, ergosterol, and campesterol, phospatidic and glyceroinositophosphatidic acids, phytoglycolipid, serine, etc., are also reported. Wheat contains ca 1% pectin. Wheat bran oil is also high in tocopherols, 68% of which is epsilon-tocopherol. Alpha-tocopherol, which has the highest vit. E activity of the tocopherols, constitutes only 11% of the tocopherols in the bran oil. Much more detail on wheat chemistry can be found in the Wealth of India (C.S.I.R., 1948–1976). Fresh forage contains 30–35% DM, of which (ZMB) 8.6–23.3% is CP, 15.1–21.5% CF, 6.1–11.6% ash, 1.8–3.7% EE, and 40.1–66.0 NFE. Straw, on the other hand, contains 92.0% DM, of which 3.1% is CP, 45.4% CF, 10.2% ash, 1.1% EE, and 40.2% NFE. Indian hay (ZMB) contained 5.1% CP, 35.1% CF, 7.2% ash, 1.3% EE, and 51.3% NFE; Indian silage 3.5% Cp, 39.4% CF, 14.6% ash, 0.5% EE, and 42.0% NFE (Gohl, 1981). Leaf protein isolate contains (g/16g N): methionine, 2.39; tryptophane, 1.41; histidine, 1.97; arginine, 9.16; and total lysine.

Description

Annual grass; culms simple, erect, hollow or pithy, glabrous, up to 1.2 m tall; leaves flat, narrow, 20–38 cm long, about 1.3 cm broad; spikes long, slender, dorsally compressed, somewhat flattened; rachis tough, not separating from spikelet at maturity; spikelets 2–5-flowered, relatively far apart on stem, slightly overlapping, nearly erect, pressed close to rachis; glumes keeled in upper half, firm, glabrous, shorter than the lemmas; lemmas awned or awnless, less than 1.3 cm long; palea as long as the lemma, remaining entire at maturity; caryopsis free-threshing, soft or hard, red or white. Hexaploid.

Germplasm

Reported from the China-Japan, Hindustani, and Central Asia Centers of Diversity, wheat, or cvs thereof, is reported to tolerate alkali, bunt, disease, drought, herbicide, hydrogen flouride, high pH, laterite, low pH, mildew, salt, nematodes, phage, rust, smog, smut, and virus (Duke, 1978). This species is the source of most US wheat cvs, there being >200 named cvs cultivated in the United States. Many other cvs exist elsewhere. Since so many cvs are available, one should consult the agricultural agent of a particular region to ascertain which ones are best for, that particular area. No attempt will be made here to describe these cvs, except to indicate they are classified in the following manner: Hard red spring wheats yielding high quality bread flour; Hard red winter wheats producing superior bread flours; Soft red winter wheats yielding flour for cakes and biscuits; Durum wheat hybrids yielding hard kernels made into semolina for macaroni products; red durum hybrids used in mixed wheat flours; white wheats yielding grain for breakfast foods, flour for cakes, pastries, and crackers, and various mixed wheats used mostly for feeds for livestock. The spring and winter types constitute about 95% of the wheat grown in the United States. ($2n$ = 42.)

Distribution

T. aestivum known only under cultivation; its nativity has been lost. Briggle (1981) states, "The precise origin of the wheat plant as we know it today is not known. Wheat evolved from wild grasses, probably somewhere in the Near East. A very likely place of origin is the area known in early historical times as the Fertile Crescent—a region with rich soils in the upper reaches of the Tigris-Euphrates drainage basin.

Ecology

Ranging from Boreal Moist to Rain through Tropical Very Dry to Dry Forest Life Zones, wheat is reported to tolerate annual precipitation of 1.9 to 25.0 dm (mean of 162 cases = 7.9), annual temperature of 4.9 to 27.8°C (mean of 162 cases = 13.4), and pH of 4.5 to 8.3 (mean of 141 cases = 6.5) (Duke, 1978). Adapted to a wide variety of climatic conditions. Principal wheat-growing areas of the world have similar growing conditions: the Russian prairies, the fertile pampas of Argentina, the Wheat belt of United States, all have fertile dark soils rich in nitrogen; rather hot, cloudless summers; rainfall which, although low, is well-distributed. A good wheat soil has physical structure which holds together, making good water retention and favorable conditions for nitrate formation. Hot, humid conditions are unfavorable for wheat-growing.

Cultivation

Propagation by seeds. Use minimum number of tillage operations to help prevent soil compaction and restriction of root and water penetration. The two principal purposes for preparing a seedbed are the development of nitrates and the conservation of moisture. In areas where rainfall is limited, as in western Kansas, summer fallowing is the most successful method for storing and conserving soil moisture. Good summer fallow is one in which the soil is kept free of plant growth and the soil surface is kept open to permit rapid penetration of moisture, and cloddy to prevent wind and water erosion. Avoid excessive turning up of new soil because such tillage dries out the soil. Start first tillage in spring as soon as weeds begin to grow, usually about May 1. After the first tillage, cultivate soil only enough to prevent weed growth and to maintain a rough surface. In some areas stubble mulch tillage method of fallowing is practiced, by which enough residue is anchored to soil surface to protect the crop and soil from wind and water erosion. Contour and stripe planting may be used. Cultivation of soil well in advance of seeding hastens the decay of organic matter, thus liberating nitrogen and making it available to plants as nitrates. Early seedbed preparation is necessary for highest yields. Crop rotation of fallow, wheat, and sorghum is an excellent practice in some areas. Date of planting wheat seed depends on the locality, type of wheat, and the hessian fly problem. Rates of seeding differ with the type of wheat, size of seed, and locality, varying from 22–100 kg/ha, generally 33 kg/ha is recommended. Local agents should be consulted about weed control. Irrigated wheat averages 86.25 bu/ha instead of 65.5 bu/ha. Wheat uses about 60 cm of water throughout the growing season. The type of fertilizer used should be determined by a soil test. The three main types being nitrogen, phosphorus, and potash. However, moisture, rather than plant food nutrients, is the limiting factor in production in most seasons under dryland farming. Yield response to nitrogen fertilizer is determined by moisture, soil, type of seedbed, and crop stand. Nitrogen may be supplied with anhydrous ammonia, nitrogen solution, or in dry forms as ammonium nitrate, urea or in mixed fertilizers. Phosphate is best supplied with superphosphate or in a mixed fertilizer. Potassium is best supplied with muriate of potash or in a mixed fertilizer. Nitrogen fertilizer and potash may be broadcast and worked into the seedbed before seeding or applied at time of seeding by using a combination fertilizer-grain drill, or applied as a top-dressing during the winter just prior to spring growth. Superphosphates are usually placed in the row with the seed (Reed, 1976).

Harvesting

Winter wheat is most widely used for temporary pasture crop. It can be grazed without apparent injury to the grain crop, provided it is not grazed severely over an extended period of time, or too late in the spring. Pasturing should not begin in fall until plants have become firmly rooted. Grazing should be discontinued just before plants begin to grow erect in preparation for jointing. Harvesting the grain should be delayed until the wheat is sufficiently mature to store well, with moisture content of 13.5% or less under ordinary conditions. Wheat is harvested with combine properly adjusted to minimize grain losses. Storage bins should be cleaned and treated before grain is placed in them. Seed storage to 3 years in dry storage bins.

Yields and Economics

In general, yields of wheat vary from 40.4 to 65.1 bu/ha, with higher yields up to 85 bu/ha obtained with irrigation. Yields depend on climatic conditions, variety or cultivar of wheat planted, size of kernel, and number of kernels per head. Production figures presented by Briggle (1981) showed Iran rather low with 1,100 kg/ha ranging to West Germany with 4,110 kg/ha, cf the US with 2,040 kg/ha. In the US, Ohio was high with 3,162 kg/ha compared with South Dakota at 1,608 kg/ha. In 1979 the world low production yield figure was 160 kg/ha in Jordan, the international production was 1,782 kg/ha, and the world high production yield was 7,000 in U.A.E. (FAO, 1980a). Dibb (1983) compares US yields of 2,100 kg/ha to 1,300 kg/ha in the developing countries and a world reported record of 14,500 kg/ha. Wheat is one of the most important food plants of man. It enters into international trade more than any other food. World production in 1971 was 303 million metric tons. Major producers are, in order, United States, USSR, China, Canada, France, Italy, Indian Union, Argentina, Australia, and Pakistan. The economic stability of many nations is affected by the exchange in wheat and other commodities (Reed, 1976).

Energy

According to the phytomass files (Duke, 1981b), annual productivity ranges from 4 to 18 MT/ha. Chaff is estimated to constitute 25% of the grain. Wheat straw is calculated at 1/2–2 times grain yield, more frequently, 1 1/2 times. However, in some countries, wheat biomass averages more than 6 MT/ha, double this if double cropped. The highest phytomass figure to date in our files is 18 MT/ha/yr. Australians figure that methanol produced from wheat stubble is about 7 times as expensive per GJ as Kuwaite oil, but half as expensive as ethanol from wheat grain ($A 1.25 per GJ for oil, 8.8 for methanol from stubble, 14.1–15.4 for ethanol from grain) (Boardman, 1980). Research reiterated by Palz and Chartier (1980) indicated that straw from winter wheat, summer wheat, winter barley, summer barley, winter rye, and oats all gave calorific values based on moisture-free dry matter of 17.04 (± 5%) MJ/kg, or based on air dry matter 15.06 (± 3.5%) MJ/kg. High N fertilization raised calorific values by ca 425 KJ/kg. Increasing moisture content from 14 to 20% reduced calorific value by 9%. Since straw available as feedstock is normally air-dry, a calorific value of 15 MJ/kg is assumed by Palz and Chartier (1980) for all cereal varieties and species. The assumed grain straw ratio for:
wheat is 1.23

barley is 1.45
oats is 1.16
rye is 0.70
other cereals are 1.10
Elsewhere Palz and Chartier assume 17.5 MJ/kg as the typical energy value for the dry matter of herbaceous materials. Reducing Kvech's (1979) numbers by 10% to convert approximately to DM yields for residues, we have the following figures for Kourim, Czechoslovakia, rounded to the nearest MT: *Medicago sativa*, 7; *Trifolium pratense*, 4; *Vicia faba*, 4; *Avena sativa*, 3; *Lolium perenne*, 3; *Secale cereale*, 3; *Trifolium repens*, 3; *Triticum aestivum*, 3; *Brassica Tapa*, 2; *Hordeum vulgare*, 2; *Phacelia tanacelifolia*, 2; *Beta vulgaris*, 1; *Sinapis alba*, 1; *Solanum tuberosum*, 1. The harvest index of cereals in general is ca 0.36, meaning that 64% of total above ground crop production is residue, at least 1/3 of which should be left in the field. 'Prior' barley has the HI ranging from 0.48 to 0.41 with increasing N fertilizer levels. Wheat usually runs about 0.30 to 0.35 HI. Rice often has a high HI, while grain sorghum generally has a low HI. The 'Green Revolution' cereals with short straw and high grain yields have relatively high HI. Biomass engineers might prefer a low HI. The estimated cost of ethanol and methanol from cereal grains is $0.35 per liter, and $0.16 per liter; the overall energy efficiency, i.e. the ratio of the energy value of the gross liquid fuel output to the total energy inputs including feedstocks is 0.34 for ethanol and 0.40 for methanol. For each ton of ethanol produced from cereal grains, there is another ton of dry distiller's residue, valued in the U.S. as animal feed (Stewart et al. 1979). Briggle's figures show that fertilizer constitutes the biggest energy input for spring wheat, 2,102,000 Btu/ha out of a total energy input of 5,646,000 Btu/ha, compared with 3,401,000 out of 7,478 for winterwheat. Preplanting required 1,025,000 Btu/ha for spring wheat, 994,000 for winterwheat; planting takes 268,000–235,000, fertilizer application 10,000–57,000, pesticide application 18,000–44,000, pesticides 14,000–60,000, irrigation 146,000–953,000, harvesting 257,000–398,000, truck 271,000–368,000, grain handling 7,000–15,000, farm pickup 763,000–800,000, farm auto 220,000–233,000, electricity and overhead, 42,000, miscellaneous 54,000 to 326,000 Btu/ha (Briggle, 1981). Briggle's earlier work (1980) showed wide variation in output/input ratios, the highest ratio (4.64) representing hard red spring wheat yields of ca 4.7 MT/ha (equiv. 15,500,000 kcal/ha) from energy inputs of only 3,350,000 kcal/ha in Idaho, the lowest ratio being 0.43, representing Texan winter wheat yields of ca 2.4 MT/ha. Energy inputs ranged from 2–18 million kcal/ha and yields from ca 1,000 to 5,000 kg. Briggle (1980) adds that wheat is an energy frugal crop, produced with the energy equivalent of less than 5 barrels oil/ha compared to corn at closer to 10 barrels and potatoes at nearly 25.

Biotic Factors

Wheats are attacked by many fungi and other organisms. Some cvs are resistant to the various rusts, smuts, and virus diseases. The most important fungal diseases of wheats are the following. Extension agents should be consulted concerning diseases in an area before growing wheat. Also cvs should be selected for growing which are resistant to such diseases. Fungal diseases of wheat: Rusts (Stem or Black rust, *Puccinia graiminis* f. sp. *tritici*; Leaf or Brown rust, *P. recondita*; Stripe or Yellow rust, *P. glumarum*); Smuts (Bunt or Covered smut, *Tilletia caries* and *T. foetida*; Dwarf Loose smut, *Ustilago tritici*); Mildews (Downy mildew, *Sclerospora macrospora*; Powdery mildew, *Erysiphe graminis* f. sp. *tritici*); Root rots (Common root rot, *Helminthosporium* spp. and

Fusarium spp.; Take-all root rot, *Ophiobolus graminis;* Browning root rot, *Pythium* spp.); Foot rots (Eye spot, *Cercosporella herpotrichoides;* Snow mold, *Fusarium* spp.); Blights and Scabs (Head blight or scab, *Fusarium* spp.; Rhizoctonia blight, *Rhizoctonia* spp.; Typhula blight, *Typhula* spp.; Anthracose, *Colletotrichum graminicola*; Kernel smudge, *Helminthosporium* spp., *Alternaria* spp.); Blotches (Glume blotch, *Septoria nodorum*; Leaf blotch, *S. tritici*; Speckled leaf disease, *Leptosphaeria avenaria* f. sp. *triticea;* Ergot, *Claviceps purpurea*. Diseases caused by bacteria include the following: *Pseudomonas atrofaciens* (Basal glume rot or bacterial black-tip) and *Xanthomonas transluscens* f. sp. *undulosa* (Black shaff). Diseases caused by viruses include the following: Wheat mosaic, Wheat streak mosaic, Wheat striate mosaic, and Yellow dwarf. Insect pests encountered in various areas include: English grain aphid is the most common aphid affecting wheat, attacking the heads and being very damaging when populations become high prior to the late-dough stage. Other insects and cutworms, darkling beetles, hessian fly, and salt marsh caterpillars, may cause damage during the seedling stage. A great number of species of nematodes have been isolated from wheats in various parts of the world. Where nematodes are a problem, the agricultural agent should be consulted.

Chemical Analysis of Biomass Fuels

Analysing 62 kinds of biomass for heating value, Jenkins and Ebeling (1985) reported a spread of 17.51 to 16.49 MJ/kg, compared to 13.76 for weathered rice straw to 23.28 MJ/kg for prune pits. On a % DM basis, the **straw** contained 71.30% volatiles, 8.90% ash, 19.80% fixed carbon, 43.20% C, 5.00% H, 39.40% O, 0.61% N, 0.11% S, 0.28% Cl, and undetermined residue.

Analysing 62 kinds of biomass for heating value, Jenkins and Ebeling (1985) reported a spread of 16.20 to 15.16 MJ/kg, compared to 13.76 for weathered rice straw to 23.28 MJ/kg for prune pits. On a % DM basis, the **dust** contained 69.85% volatiles, 13.68% ash, 16.47% fixed carbon, 41.38% C, 5.10% H, 35.19% O, 3.04% N, 0.19% S, and undetermined residue.

Broccoli Raab

Rapa, Rapini, Taitcat, Italian turnip, Broccoli turnip

Cruciferae *Brassica campestris* L. (Ruvo group)

Source: Magness et al. 1971

This plant is grown for its tender leaves and flowers shoots which are used as greens or pot herbs. Plants develop rather rapidly and are harvested before the flower buds open. General growth habit and exposure of edible parts are similar to spinach.

Season, seeding to harvest: About 60 days.

Production in U.S.: No data, very limited.

Use: As pot herb.

Part of plant consumed: Entire top, leaves, stems and flower buds.

Last update February 18, 1999 by ch

Brome grasses

Gramineae *Bromus* sp.

Source: Magness et al. 1971

Some 43 species of *Bromus* are native in the United States. Some of these are important forage sources, others are troublesome weeds. Most bromes are highly palatable during succulent growth, even the ones classed as weeds. The leaf blades are flat, and the seed heads are open, spreading panicles. Species of major value in agriculture are field bromegrass, California brome, rescuegrass, smooth brome, mountain brome, cheatgrass, downy brome, Japanese chess, and hairy chess.

California brome

Gramineae *Bromus carinatus* Hock. and Arn.

Source: Magness et al. 1971

This is a bunchgrass native in the Rocky Mountain and Pacific Coast regions.
The plant grows up to 4 feet. Leaf blades are up to 8 inches long, about 0.5 inch wide. It produces large quantities of leafy forage, relished by all kinds of livestock while immature. The mature foliage is less palatable, but the seed heads are palatable and nutritious. The plant is relatively short lived.

Mountain brome

Gramineae *Bromus marginatus* Nees

Source: Magness et al. 1971

Mountain brome is a bunchgrass native to the Rocky Mountain and Pacific Coast regions. Plants grow to 4 feet, with leaves up to 12 inches long and about 0.25 inch wide. Leaf blades are flat, and haily underneath. Growth starts early in the spring, producing much leafy forage relished by livestock. Because of rapid seedling growth and a well-branched, deep root system, mountain brome is excellent where a rapid cover development is needed. This grass is frequently seeded with alfalfa or sweet clover in the Pacific Northwest. The mixture is ideal both for prevention of erosion and as a well balanced animal diet. Stands of mountain brome grass are readily established by seeding.

Bromus inermis Leyss.

Syn.: *Zerna inermis* (Leyss.) Lindm.
Bromus glabrescens Honda
Bromus tatewakii Honda

Poaceae

Smooth bromegrass

We have information from several sources:

Handbook of Energy Crops—James A. Duke. 1983. unpublished.

Cool-Season Grass Seed Production: Alternative Field Crops Manual, University of Wisconson Cooperative Extension Service, University of Minnesota Extension Service, Center for Alternative Plant & Animal Products

Magness, J.R., G.M. Markle, C.C. Compton. 1971. Food and feed crops of the United States.

Field bromegrass

Gramineae *Bromus arvensis* L.

Source: Magness et al. 1971

This is a winter annual grass introduced from Europe in the late 1920's and now grown in the Cornbelt and eastward. When seeded in late summer it develops an extensive fibrous root system, making it excellent for erosion control. It is winter hardy and grows rapidly the following spring. The seeds ripen in midsummer and the plants die. Although most used for erosion control and soil improvement, it furnishes palatable pastilrage during the spring.

Last update February 18, 1999 by ch

Minor annual brome grasses

Gramineae *Bromus* sp.

Cheatgrass (Chess) *B. secalinus* L.
Downy brome (Bronco grass) *B. tectorum* L.
Japanese chess *B. japonicus* Thunb.
Hairy chess *B. commutatus* Schrad.

Source: Magness et al. 1971

These are all winter annual grasses that are widely distributed in pasture and range lands and may be troublesome weeds in grain fields. They are prolific seed producers and may become dominant in overgrazed perennial pastures. For a short period in spring they furnish good pasturage. None of these is seeded commercially.

Last update February 18, 1999 by ch

Rescuegrass

Gramineae, Poaceae *Bromus willdenowii* Kunth.

Source: Magness et al. 1971

This bunch grass is native in Argentina, but was introduced into the Southern States around 1850. It is now naturalized there in many areas. It is a short-lived perennial, adapted to humid areas with mild winters. Plants reach up to 3 feet, with leaves up to a foot long and about 0.25 inch wide. Young plants are pubescent, but mature plants are sparingly so. Growth occurs throughout the winter, the plants becoming mature in early summer. On strong soils, a good amount of forage palatable to livestock is produced. Seed is produced in quantity, and stands are readily obtained by seeding.

Bruguiera gymnorrhiza (L.) Savigny

Syn.: *Bruguiera conjugata* Auct.
Rhizophoraceae
Burma mangrove

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

The heavy wood (sp. grav. 0.87–1.08) is durable but hard to saw and work. It is used for construction, furniture, houseposts, and pilings (Little, 1983). Thousands of tons of Bruguiera wood chips are exported annually from Indonesia, Sabah, and Sarawak for pulp and for rayon manufacture (NAS, 1980a). Fruits are eaten, but not when anything better is available. More often, they are chewed as astringent with the betel quid. Chinese in Java make a sweetmeat therefrom. Dutch Indians use the bark to flavor raw fish. The leaves and peeled hypocotyls are eaten in the Moluccas after soaking and boiling (Hou, 1958). The phlobaphene coloring matter is used in China and Malaya for black dye (Burkill, 1966). In South Africa, the tree has been planted to stabilize dunes and in freshwater swamps.

Folk Medicine

Reported to be astringent (Duke and Wain, 1981), the bark is used for diarrhea and fever in Indonesia (Perry, 1980). Cambodians use the astringent bark for malaria (Burkill, 1966).

Chemistry

In Burma, leaves may contain 18.3% H_2O, 13.5% tannin; outer cortex (small trees) 14.6 and 7.9, outer cortex (large trees) 14.2 and 10.8; twig bark 13.1 and 14.8, bole bark (small trees) 16.3 and 31.7, while the bole bark of large trees contains 12.5% H_2O, 42.3% tannin. Bark contains from ca 4–32% tannin, 12.77–53.12% according to Watt and Breyer-Brandwijk (1962) and the Wealth of India (C.S.I.R., 1948–1976).

Toxicity

Eating too much (bark) is dangerous (Burkill, 1966).

Description

Evergreen tree 8–25(-35) m high, with straight trunk 40–90 cm in diameter, buttressed at base, and with many upright pneumatophores rising to 45 cm from long horizontal roots. Bark gray to blackish, smooth to roughly fissured, thick; inner bark reddish. Leaves opposite, elliptical, 9–20 cm long, 5–7 cm wide, acute at both ends, entire, without visible veins, thick, leathery, glabrous. Petiole 2–4.5 cm long. Flowers single in leaf axile 3–4 cm long, usually drooping on stalk of 1–2.5 cm, red to yellowish or cream-colored, with red to pink-red bell-shaped hypanthium. Calyx with 10–14 very narrow, leathery lobes. Petals 10–14, 13–15 mm long, white turning brown, each with 2 narrow lobes ending in 3–4 bristles. Stamens 2, nearly hidden, at base of each petal. Pistil with inferior 3–4-celled ovary, each cell with 2 ovules, style slender; stigma with 3–4 short forks. Berry drooping, ovoid or turbinate, 2–2.5 cm long. Seed 1, viviparous, finally 1.5–2 cm in diameter (Little, 1983).

Germplasm

Reported from the Hindustani, Africa, Australian, and Indonesian-Indochina Centers of Diversity, Burma mangrove, or cvs thereof, is reported to tolerate alkali, disease, high pH, insects, pest, salt, shade, waterlogging (NAS, 1980a; Little, 1983). ($2n = 18$)

Distribution

Tropical South and East Africa, Madagascar, Seychelles, Sri Lanka, southeastern Asia, Ryukyu; throughout Malaysia to Philippines, Australia, Micronesia, and Polynesia. Introduced into Hawaii (Little, 1983).

Ecology

Estimated to range from Tropical Moist to Rain through Subtropical Moist to Rain Forest Life Zones, Burma mangrove is reported to tolerate annual precipitation of 10 to 80 dm, annual temperature of 20 to 26°C, and pH of 6.0 to 8.5. One of the largest trees in the Malayan mangroves, usually on drier well-aerated soils toward the landward side, often dominating, with occasional stems >35 m tall. It is probably the longest lived of the mangroves. It can stand "any amount of shade" (Hou, 1958). Mostly on brackish or saline silts of depositing shores and marshes.

Cultivation

According to the NAS (1980a), planting is usually not needed because natural regeneration is so successful. In Avicennia and Rhizophora, direct seeding results in ca 90% survival.

Harvesting

Mostly harvested from natural stands. Species of Rhizophoraceae, growing only from the tips of the branches, are often killed by indiscriminate lopping of branches (NAS, 1980a). After felling, its regeneration is often very scant and there is danger of overgrowth by Acrostichum (but once seedlings have established themselves, the "fern acts rather as a nurse, forcing the seedling up.") (Hou, 1958).

Yields and Economics

Good mangrove stand can show annual productivity of (-25) MT/ha/yr, but for firewood purposes, I would reduce that to 10–20(-25) m^3 /ha/yr, figuring that at optimal rather than average. Litterfall may account for 1/3–1/2 of aboveground productivity. Because of the heaviness of the wood, mangrove is generally more valuable than other species.

Energy

Wood widely used for charcoal and fuel (Little, 1983). For charcoal, the tree seems to rank with Rhizophora, with an even higher calorific value. According to WOI, the calorific value of moisture-free sapwood is 5,169 cals, heartwood 5,079.

Biotic Factors

No data uncovered.

Buffalograss

Gramineae *Buchloe dactyloides* (Nutt.) Engelm

Source: Magness et al. 1971

Buffalograss, a native species, is the dominant grass in parts of the Great Plains. It is a fine-leaved, sod-forming perennial, generally only 6 to 8 inches high, with leaves 3 to 6 inches long and less than 0.125 inch wide. It spreads by surface runners to form a dense sod, Growth starts in late spring and continues through the summer. It is very palatable and stands grazing well. It is readily established either by seeding or by sod pieces, and is valuable both as pasture and for erosion control. The species is unisexual, about half the plants being female and producing seed; and half male, the flowers of which produce only pollen.

Bugleweed

Lycopus virginicus L.

Figure 27.—Bugleweed (*Lycopus virginicus*)

Other common names.—Buglewort, sweet bugleweed, American water hoarhound, carpenter's herb, green archangel, gypsyweed, Paul's betony, woodbetony, wolf foot, purple archangel, water bugle, gypsywort, gypsy herb, Virginia hoarhound.

Habitat and range.—Bugleweed is a native herb frequenting wet, shady places from Canada to Florida, Missouri, and Nebraska.

Description.—This herb has long, threadlike runners and a bluntly 4-angled, smooth, slender, erect stem from 6 inches to 2 feet in height. The leaves are about 2 inches in length, pointed, rather narrow, and dark green or of a purplish tinge. The whitish flowers, which appear from about July to September, are small, tubular, and bell-shaped, and are produced in dense clusters in the axils of the leaves. They are followed by four nutlets. The plant has a rather pleasant, mintlike odor, but a disagreeable bitter taste.

Part used.—The entire herb, gathered during the flowering period.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Love grasses

Teff

Gramineae, (Poaceae) *Eragrostis* sp.

Source: Magness et al. 1971

Some 250 species of *Eragrostis*, the love grasses, are known - with about 40 native in the United States. Only a few have agricultural value. Some species produce abundant growth on soils of low fertility and are valuable for protection of eroding sites. The species of most value in the United States are Boer lovegrass, Weeping lovegrass, Lehmann lovegrass, and Sand lovegrass.

Last update September 22, 1997

Burnet

Rosaceae *Sanguisorba minor* Scop,

Source: Magness et al. 1971

The plant is a hardy perennial 1 to 2.5 feet in height, with long compound leaves, each with 6 to 10 pairs of small leaflets. It is sometimes grown in gardens for the fresh young Ieaves which are used in salads. While it has long been listed in gardening manuals, it is not grown commercially in U.S., and so far as known not in other countries.

Juglans cinerea L.

Juglandaceae

Butternut

We have information from several sources:

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Magness, J.R., G.M. Markle, C.C. Compton. 1971. Food and feed crops of the United States.

Outside links:

Butternut accessions from the National Germplasm Repository, Corvallis, Oregon

Walnuts, *Juglans* spp.

Conocarpus erectus L.

Combretaceae
Button mangrove

Source: James A. Duke. 1983. Handbook of Energy Crops. unpublished.

Uses

The heavy wood (sp. grav. 1-0) is durable and takes a fine polish. Durable in water, it is used for barges, boats, and maritime construction. Though suceptible to dry-wood termites, it is also used for crossties, fences, and turnery. Describing it as keeping well underground and in salt water, Irvine (1961) notes it is used for piling and firewood. Bark has been used for tanning leather. Sometimes introduced as an ornamental evergreen.

Folk Medicine

Reported to be astringent, styptic, and tonic, button mangrove is a folk remedy for anemia, catarrh, conjunctivitis, diabetes, diarrhea, fever, gonorrhea, headache, hemorrhage, orchitis, pricklyheat, swellings, and syphilis (Duke and Wain, 1981; Irvine, 1961; Morton, 1981). The leaves are eaten, or their decoction drunk, for fever (Irvine, 1961).

Chemistry

Bark contains 16-18% tannin.

Description

Evergreen tree to 6 m tall, 20 cm in diameter, with spreading crown. Bark gray or brown, becoming rough, furrowed, thick; inner bark light brown. Leaves alternate, lanceolate, or ellipticaL, 3-8 cm long, 1.5-3 cm broad, leathery and slightly fleshy, long-pointed at both ends, not entire, yellow-green on both surfaces, usually with several gland-dots near vein angles on lower surface. Petiole 3-10 mm long, slightly broad and winged with 2 gland-dots. Flower clusters mostly 3-8 cm long at end of twigs and in leaf axils, of several small heads, about 5 mm in diameter on slender stalks. Flowers many in each ball, 2 mm long, mostly bisexual. Bisexual flowers have hairy, grayish, 2-winged tubular base, cuplike green calyx with 5 lobes, 5-10 protruding stamens, and inferior ovary with slender style. Male flowers lack tubular base and pistil but have longer stamens. Multiple fruits rounded, 10-12 mm in diameter, purplish-brown. Drupes many, scalelike, dry, 3 mm long, 2-winged (Little, 1983).

Germplasm

Reported from the African and Middle and South American Centers of Diversity, button mangrove, or cvs thereof, is reported to tolerate diseases, insects light frosts, pests, salt, and waterlogging (NAS, 1980a; Little, 1983).($2n$ = 24)

Distribution

Bermuda and Bahamas through West Indies to central Florida. From northern Mexico southward on Atlantic Coast to Brazil and on Pacific Coast to Ecuador including Galapagos and northwestern Peru. Western tropical Africa from Senegal to Zaire. Not widely introduced (Little, 1983).

Ecology

Estimated to range from Tropical Dry to Rain through Subtropical Dry to Rain Forest Life Zones, button mangrove is reported to tolerate annual precipitation of 8.7 to 21.5 dm (mean of 2 cases = 15.1), annual temperature of 25.8 to 26.0°C (mean of 2 cases = 25.9), and estimated pH of 6 to 8.5. It can surely tolerate much higher annual precipitation and annual temperature down to 17deg.C (without heavy frost). Usually in brackish or saline silts of depositing shores, marshes, and stream banks.

Cultivation

According to the NAS (1980a), planting is usually not needed because natural regeneration is so successful. In Avicennia and Rhizophora direct seeding results in ca 90% survival. The plants can be grown on dry land away from seashores. They can be propagated from cuttings as living fenceposts (Little, 1983).

Harvesting

No data available.

Yields and Economics

Good mangrove stand can show annual productivity of 10-20(-25) MT/ha/yr, but for firewood purposes, I would reduce that to 10-20 (-25) m^3 /ha/yr, figuring that at optimal, rather than average. Because of the heaviness of the wood, a cubic meter of mangrove is generally more valuable than other species. Litterfall may account for 1/3-1/2 of aboveground productivity.

Energy

The wood "has high calorific value as fuel but is most widely used for high-grade charcoal (Morton, 1981). Little (1983) says it makes a good slow-burning fuel and charcoal.

Biotic Factors

Suceptible to attack by dry-wood termites (Little, 1983).

Button-Snakeroot

Eryngium aquaticum L.

Synonym.—*Eryngium yuccifolium* Michx.

Figure 31.—Button-snakeroot (*Eryngium aquaticum*)

Other common names.—Eryngium, eryngo, water eryngo, corn snakeroot, rattlesnake master, rattlesnake-weed, rattlesnake flag.

Habitat and range.—Although sometimes occurring on dry land, button-snakeroot usually inhabits swamps and low, wet ground from Connecticut and the pine barrens of New Jersey to Illinois and South Dakota and south to Texas and Florida.

Description.—This plant has grasslike, rigid, parallel-veined leaves 1 to 2 feet in length and about one-half inch in width. The stout furrowed stem reaches a height of from 2 to 6 feet and is generally unbranched except near the top. . The insignificant whitish flowers are borne in dense, stout-stemmed heads from June to September. The stout rootstock is very knotty, with numerous short branches, and produces many thick, rather straight roots.

Part used.—The rootstock, collected in autumn.

Sievers, A.F. 1930. The Herb Hunters Guide. Misc. Publ. No. 77. USDA, Washington DC.

Shea butter

Bambuk butter

Sapotaceae *Butyrospermum parkii* (Don) Kotschy

Source: Magness et al. 1971

This fat is obtained from nuts of the above species, which is a large tree native to West Africa. The dried fruit consists of a thin shell, enclosing an egg shaped seed. The seeds are about 3 grams in weight. The kernels contain about 50 percent of a non-drying fat. Both nuts and the fat are exported to Europe as well as used locally. In Europe, the fat is used as a cooking fat, in the manufacture of margarine, and as a substitute for cacao butter. The press cake or extracted meal is fed to cattle.

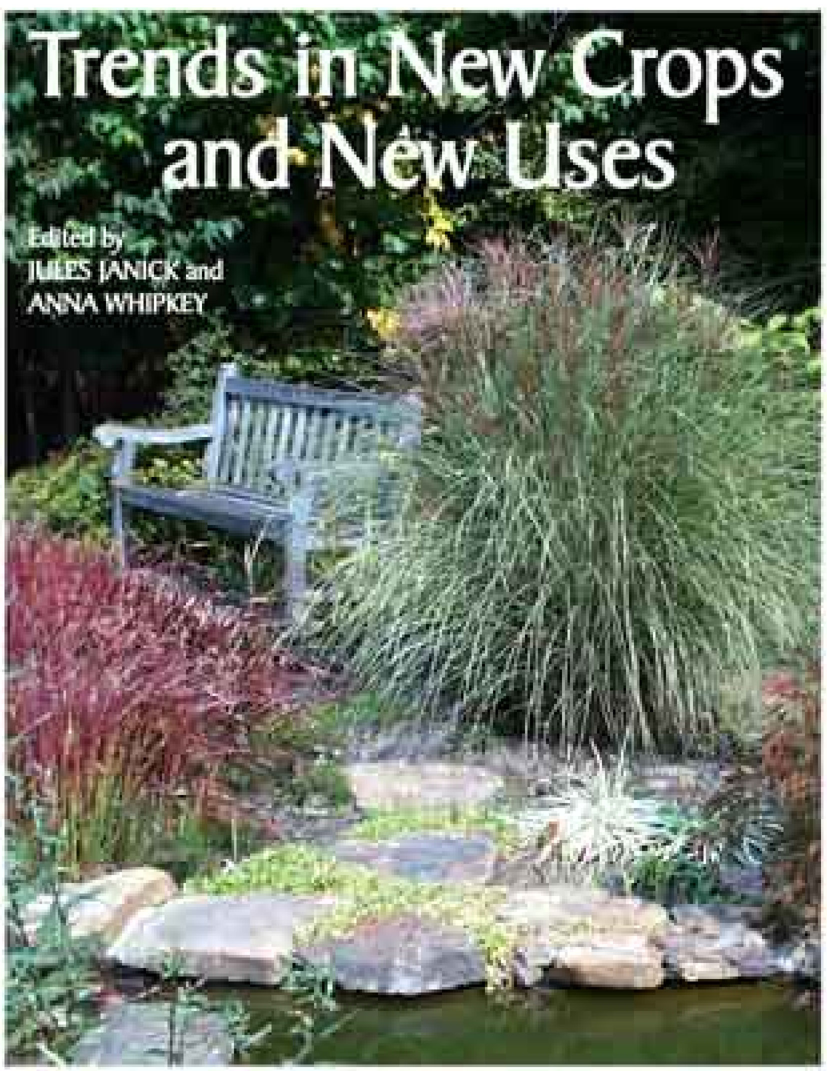
Trends in New Crops and New Uses

Proceedings of the fifth National Symposium New Crops and New Uses: Strength in Diversity

Jules Janick and Anna Whipkey (eds.). 2002. ASHS Press, Alexandria, VA



The issue of crop diversity has never been more urgent. Present day agriculture is faced with an erosion of crop variability as the trend toward monoculture persists throughout the world. As a result farmers face increased risks, both biologic and economic, due to a combination of market forces and subsidies that leads inexorably away from rather than toward diversity. An expected doubling of world population continues to be a looming specter upon the horizon, while at the same time, ironically, over-production in the developed world leads to a collapse of small farmers and rural communities. The issue of agricultural sustainability is ever present, especially on fragile soils. In addition, there are new geopolitical pressures brought about by the increasing demands of an oil-based economy. There have been many solutions proposed but the balance still eludes us. Genetic and management solutions to increase production is necessary for the developing world but aggravate overproduction in the developed world. New industrial uses for crops could increase demand and farmer income. Many suggest that a move to a bio-based economy could solve two problems: reduce our dependence on imported petroleum while providing new opportunities to farmers. New crop alternatives could lead to new options for both consumers and farmers. The strategies above are not mutually exclusive.

This book, the fifth of a series, is based on the symposium entitled New Crops and New Uses: Strength in Diversity held Nov. 8 to 11, 2001 in Atlanta, Georgia and organized by the Association for the Advancement of Industrial crops (AAIC), the Purdue University Center for New Crops and Plant Products, the Thomas Jefferson Agricultural Institute, and the New Uses Council, Inc. It supplements four other proceedings: Progress in New Crops (1990, Timber Press, Portland, Oregon); New Crops (1993, Wiley Press, New York), Advances in New Crops, (1996, ASHS Press, Alexandria, Virginia), and Perspectives on New Crops and New Uses (1999, ASHS Press, Alexandria, Virginia). These volumes represent an encyclopedic compendium of new crop information useful to growers, marketers, and researchers.

Hardback, 599 pages
ISBN 0-970756-5-5

Available from:

ASHS Press
113 South West Street, Suite 200
Alexandria, VA 22314-2851 USA
tel: 703-836-4606
Fax: 703-836-2024
email: ashspress@ashs.org

There are four other volumes in the New Crops series:

Advances in New Crops—1990
New Crops—1993
Progress in New Crops—1996
Perspectives on New Crops and New Uses—1999

The New Crop Compendium CD-ROM was produced by the Purdue University Center for New Crops and Plant Products in cooperation with the Crop and Grassland Service of the Crop Production and Protection Division of the United Nations Food and Agriculture Organization (FAO).

The New Crop Compendium CD-ROM, a searchable resource of new crop information, was edited by Jules Janick and Anna Whipkey and contains the entire text and figures from the proceedings of the three National New Crop Symposia:

- J. Janick and J.E. Simon (eds.). 1990. Advances in New Crops. Timber Press, Portland, Oregon.
- J. Janick and J.E. Simon (eds.). 1993. New Crops. Wiley, New York.
- J. Janick (ed.). 1996. Progress in New Crops. ASHS Press, Alexandria, Virginia.

The New Crop Compendium provides a valuable source of information on new, specialty, neglected, and underutilized crops for scientists, growers, marketers, processors, and extension personnel. It employs an intuitive, easy to use interface. There are several ways you can access the information contained on this CD-ROM.

- **Table of Contents** has links to each article grouped by subject.
  - Policy
  - International Development
  - Regional & State Development
  - Research & Development
  - Germplasm & Breeding
  - New Crop Centers
  - Information Systems
  - Economics, Marketing, & Commercialization
  - Cereals & Pseudocereals
  - Grain Legumes
  - Forages, Fodder, & Cover Crops
  - Oilseeds
  - Industrial Crops
  - Fiber Crops
  - Fruits & Nuts
  - Vegetable Crops
  - Floral & Landscape Crops
  - Aromatic Crops
  - Herb & Spice Crops
  - Medicinal Crops
  - Bioactive Crops & Others
  - Crops in Space
- **Crop and Plant Products Index** is a comprehensive list of the indexed words from the original

three volumes of the proceedings. Although the index is not linked, it can be used to copy and paste words into the key word field of the search engine.

- **Author Index** is sorted alphabetically by last name with links to each article by that author.
- **Key Word Search** enables you to search all files for key words using natural language or boolean logic. Features include a dictionary, related word search, use of concept operators, and on-line help.
- **Technical Support** is available by phone or e-mail.

ISBN 0-931682-70-3

System Requirements

The html files are accessible on any platform with a web browser. In order to use the search engine the following system requirements must be met:

Windows

- Windows 3.1 or Win95
- Minimum 486 processor, 33 MHz
- RAM 16 Mb, if using Win95 then 32 Mb is preferred
- CD-ROM drive, double speed, 150 Kb transfer rate
- Web browser such as Netscape Navigator or Internet Explorer
- Must have "winsock.dll" installed in the Windows directory
- Mouse or other pointing device
- Minimum 10 Mb free on hard drive

Macintosh

- Mac OS 7.1 or higher with Quicktime extensions
- 68020 processor
- 16 Mb RAM, 32 Mb preferred with OS 8
- CD-ROM drive, double speed, 150 Kb transfer rate
- Web browser such as Netscape Navigator or Internet Explorer that supports the "open a URL" AppleEvent
- Mouse or other pointing device
- Minimum 10 Mb free on hard drive

The New Crop Compendium is now available from the office of Distance Education Services at Purdue University.

Payment may be made by check or purchase order (payable to Purdue University in US funds), or by charge (Visa, Mastercard, Discover)

Telephone orders to: (800) 830-0269 or (765) 494-2748

Print the Order Form and **Fax** (using a credit card or purchase order) to: (765) 496-2484

Print the Order Form and **Mail** to:

HELP
How to use the NewCROP site

To access crop information:

1. Use **CropINDEX** if you already know the name of the crop or species, or just want to browse.

   CropINDEX, is an extensive alphabetical list of all common and scientific crop names held on this site, but does not include **Famine Foods** entries which are indexed separately.

2. Or use **CropSEARCH**, for keyword subject searching.

   The CropSEARCH locates crops by name, topic, uses, geography, commodity, author citations, etc; and locates any terms entered.

To access special topics:

There are a number of specialized subject areas that are embedded in new crops:

1. Famine Foods - These are unconventional food sources used in times of desperation.
2. Aromatic, Herbal and Medical Plants
3. The following publications can be found on the NewCROP website:
   - Trends in New Crops and New Uses. 2002. Proceedings of the Fourth National Symposium New Crops and New Uses: Strength in Diversity. Jules Janick and Anna Whipkey (eds.). ASHS Press, Alexandria, VA. 599 pages.
   - Perspectives on New Crops and New Uses. 1999. Proceedings of the Fourth National Symposium New Crops and New Uses: Biodiversity and Agricultural Sustainability. Jules Janick (ed.). ASHS Press, Alexandria, VA. 528 pages.
   - Progress in New Crops. 1996. Proceedings of the Third National Symposium NEW CROPS: New Opportunities, New Technologies. Jules Janick (ed.). ASHS Press, Alexandria, VA. 660 pages.
   - New Crops. 1993. Proceedings of the Second National Symposium NEW CROPS: Exploration, Research, Commercialization Jules Janick and J.E. Simon (eds.). Wiley

and Sons, Inc., New York. 710 pages.

- Advances in New Crops. 1990. Proceedings of the First National Symposium NEW CROPS: Research, Development, Economics. Jules Janick and J.E. Simon (eds.). Timber Press, Portland, Oregon. 560 pages.
- Fruits of Warm Climates. 1987. Julia F. Morton. J.F. Morton, Pub. 20534 SW 92 Ct., Miami Fl 33189. 505 pages.
- Handbook of Energy Crops. 1983. James A. Duke.
- The Alternative Field Crops Manual. 1992. University of Minnesota.
- Neglected Crops: 1492 from a Different Perspective. 1994. FAO. Rome.
- Famine Foods. 1995. Robert (Bob) L. Freedman Orinda, CA 94563. Unpublished. 500+ pages.
- Food and Feed Crops of the United States 1971. J.R. Magness, G.M. Markle, C.C. Compton. Interregional Research Project IR-4, IR Bul. 1 (Bul. 828 New Jersey Agr. Expt. Sta.).
- Savory Herbs: Culture and Use. 1946. M.S. Lowman, and M. Birdseye. Farmer's Bulletin No. 1977. USDA, Washington, DC.
- The Herb Hunters Guide. 1930. A.F. Sievers, Misc. Publ. No. 77. USDA, Washington DC.

To email queries to the New Crop discussion group:

Enroll in the NewCROP discussion group - you can post specific crop questions to the approximately 400 members of this group.

NewCROP DISCUSSION GROUP

Jules Janick *Coordinator*

To Subscribe

Follow this link to the Majorcool E-mail List Manager site.

Fill in Your email address and Find newcrops. Click Go.

Overview

WELCOME to our NewCROP DISCUSSION GROUP. To facilitate communication between newcrops researchers, Purdue launched this NewCROP email list in April of 1995. We hope that this system will continue to act as a stimulus for real interaction–which is the purpose of all electronic communication groups.

For those new to such an electronic mail system, the main purpose of an e-mail list is to create a vehicle for rapid and easy communication over the Internet. An e-mail list permits all subscribers to communicate regularly with each other–and for free. This electronically based mail system functions very simply: subscribers can write in and ask questions, make announcements, and raise other issues for discussion to the group. Every subscriber receives this information. Any or all subscribers receiving this new mail item can file it for their own information, or opt to respond and reply. The reply is automatically sent to the entire group, unless noted otherwise, and this often leads to more responses and a lively electronic debate. The art of writing remains alive and well via electronic mail! Such a system is highly effective if it is used by the subscribers. Basic information such as sourcing new germplasm, identifying those researching a particular area all can be quickly handled via this system. This type of electronic mail is known as "mailing list", and is not an electronic bulletin board, but a mail system.

Policies

From the past years experience, we must ask that subscribers refrain from using the mailing list as a vehicle for political action and polemics of any kind, and refrain from profanity.

Do not send attachments.

Please do not post announcements about papers unless it is in response to an inquiry.

This list is not a place to post classified ads. Although inquiries about marketing and markets may be appropriate for this list please do not treat it as a commercial marketing site.

Using the New CROP DISCUSSION GROUP

To send a message to the group send E-mail to: newcrops@purdue.edu

Please administrative questions to: owner-newcrops@purdue.edu, not the list.

This discussion group is managed by an automated mailing list management program called Majordomo. You can get detailed explanations of "documented" commands which Majordomo understands by asking for "help" from Majordomo (send a message containing just the word "help" as the message text to majordomo@purdue.edu).

NewCrop mailing list Archives

A searchable archive of the NewCrop DISCUSSION GROUP is now available. The archive contains messages from 4/25/95 to 12/2/1999.

*At the discretion of the archive maintainer, off-topic posts, "spam", etc. will be removed from the archive.

We welcome news, inquiries, announcements and all other discussion.

Jules Janick

NewCROP Home Page

A Guide to Medicinal and Aromatic Plants

Welcome to the Medicinal and Aromatic Plant home page, sponsored by the Center for New Crops and Plant Products. The **Guide to Medicinal and Aromatic Plants** has several main components:

Plant/Crop Descriptors	The plant/crop descriptors are general monographs providing background information about each herb plant. Plants are listed in alphabetical order by common and Latin names.
Guide to Herb Varieties	The Guide to Herb Varieties provides a listing of herb varieties available from commercial sources.
Sources of Herb Seeds and Plants	The herb seed and plants directory provides a guide to public and commercial sources of these plants.
Botanical Companies Database	Searchable database of companies in the botanical products industry. This project was funded in part by ASNAPP
Flavor, Fragrance and Essential Oils Companies Database	Searchable database of companies in the flavor, fragrance and essential oils industries. This project was funded in part by ASNAPP
Links to Other Web Sites	Links provides a direct bridge and listing to other related web sites.

You can also find:

Aromatic, Spice, and Medicinal Plants	General information about this site, instruction for use, acknowledgments, a comment/suggestion form, and information on contacting our personnel.
NewCROP	This will bring you into our main new crop server (NewCROP) of which this site can be considered a subset built to highlight information on these commodities of plants. NewCROP offers the most comprehensive library and compilation of new and alternative crop information available on the world-wide web.

We hope that this web site will provide technical assistance to you in your search for sound scientific information about medicinal, spice and aromatic plants, and in particular be of benefit in the introduction and production of these unique and fascinating specialty crops and natural plant products.

Famine Foods:

by Robert (Bob) L. Freedman
Orinda CA 94563
email: namdeerf@ispwest.com

The Famine Foods Database:

> Plants that are not normally considered as crops are consumed in times of famine. This botanical-humanistic subject has had little academic exposure, and provides insight to potential new food sources that ordinarily would not be considered.

Search the Famine Foods Database

About The Author

Photo by Frank D. Venning

JULIA F. MORTON is Research Professor of Biology and Director of the Morton Collectanea, University of Miami, a research and information center devoted to economic botany. She received her D.Sc. from Florida State University in 1973 and was elected a Fellow of the Linnean Society of London in 1974. She has conducted extensive field studies for the U.S. National Institutes of Health and the Department of Defense, has served as horticultural development consultant in Florida and tropical America, and, since 1954, has been consultant for the Poison Control Centers in Florida. In 1978, she was selected as the First Distinguished Economic Botanist by the international Society for Economic Botany. She served as President of the Florida State Horticultural Society in 1979. She is a member of the Board of Trustees of Fairchild Tropical Garden, Miami, and of the Board of Directors of the Florida National Parks and Monuments Association. She is the author of 10 books and co-author of or contributor to 12 others; has written 94 scientific papers and co-authored 27 others; has produced 2 full-color wall charts of poisonous plants; a set of Survival Cards for Southeast Asia and a 157-page report on the Survival-related Flora and Fauna of the Mekong for the U.S. Department of Defense. She is well known as a lecturer on toxic, edible and otherwise useful plants.

Morton, J. 1987. Date. p. 5–11. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Date

Phoenix dactylifera

Most of the dozen or more species of the genus *Phoenix* (family Palmae) are grown as ornamental palms indoors or out. Only the common date, P. *dactylifera* L., is cultivated for its fruit. Often called the edible date, it has few alternate names except in regional dialects. To the French, it is *dattier;* in German, it is *dattel;* in Italian, *datteri;* or *dattero;* in Spanish, *datil;* and, in Dutch, *dadel.* The Portuguese word is *tamara.*

Description

The date is an erect palm to 100 or 120 ft (30.5-36.5 m), the trunk clothed from the ground up with upward-pointing, overlapping, persistent, woody leaf bases. After the first 6 to 16 years, numerous suckers will arise around its base. The feather-like leaves, up to 20 ft (6 m) long, are composed of a spiny petiole, a stout midrib, and slender, gray-green or bluish-green pinnae 8 to 16 in (20-40 cm) long, and folded in half lengthwise. Each leaf emerges from a sheath that splits into a network of fibers remaining at the leaf base. Small fragrant flowers (the female whitish, the male waxy and cream colored), are borne on a branched spadix divided into 25 to 150 strands 12 to 30 in (30-75 cm) long on female plants, only 6 to 9 in (15-22.5 cm) long on male plants. One large inflorescence may embrace 6,000 to 10,000 flowers. Some date palms have strands bearing both male and female flowers; others may have perfect flowers. As the fruits develop, the stalk holding the cluster may elongate 6 ft (1.8 m) while it bends over because of the weight. The fruit is oblong, 1 to 3 in (2.5-7.5 cm) long, dark-brown, reddish, or yellowish-brown when ripe with thin or thickish skin, thick, sweet flesh (astringent until fully ripe) and a single, cylindrical, slender, very hard stone grooved down one side.

Origin and Distribution

The date palm is believed to have originated in the lands around the Persian Gulf and in ancient times was especially abundant between the Nile and Euphrates rivers. Alphonse de Candolle claimed that it ranged in prehistoric times from Senegal to the basin of the Indus River in northern India, especially between latitudes 15 and 30. There is archeological evidence of cultivation in eastern Arabia in 4,000 B.C. It was much revered and regarded as a symbol of fertility, and depicted in bas relief and on coins. Literature devoted to its history and romance is voluminous. Nomads planted the date at oases in the deserts and Arabs introduced it into Spain. It has long been grown on the French Riviera, in southern Italy, Sicily and Greece, though the fruit does not reach perfection in these areas. Possibly it fares better in the Cape Verde Islands, for a program of date improvement was launched there in the late 1950's. Iraq has always led the world in date production. Presently, there are 22 million date palms in that country producing nearly 600,000 tons of dates annually. The Basra area is renowned for its cultivars of outstanding quality. The date has been traditionally a staple food in Algeria, Morocco, Tunisia, Egypt, the Sudan, Arabia and Iran. Blatter quotes the writer, Vogel, as stating: "When Abdel-Gelil besieged Suckna in 1824, he cut down no fewer than 43,000 trees, to compel the town to surrender; nevertheless, there are still at least 70,000 left."

In 1980, production in Saudi Arabia was brought to nearly a half-million tons from 11 million palms because of government subsidies, improved technology, and a royal decree that dates be included in meals in govern ment and civic institutions and that hygienically-packed dates be regularly available in the markets. Farmers receive financial rewards for each offshoot of a high-quality date planted at a prescribed spacing. The Ministry of Agriculture has established training courses throughout the country to teach modern agricultural methods, including mechanization of all possible operations in date culture, and recognition and special roles of the many local cultivars. In West Africa, near the Sahara, only dry, sugary types can be grown.

Bonavia introduced seeds of 26 kinds of dates from the Near East into northern India and Pakistan in 1869; and, in 1909, D. Milne, the Economic Botanist for the Punjab, introduced offshoots and established the date as a cultivated crop in Pakistan. The fruits ripen well in northwestern India and at the Fruit Research Center in Saharanpur. In southern India, the climate is unfavorable for date production. A few trees around Bohol in the Philippines are said to bear an abundance of fruits of good quality. The date palm has been introduced into Australia, and into northeastern Argentina and Brazil where it may prosper in dry zones. Some dates are supplying fruits for the market on the small island of Margarita off the coast from northern Venezuela. Seed-propagated dates are found in many tropical and sub-tropical regions where they are valued as ornamentals but where the climate is unsuitable for fruit production.

In November 1899, 75 plants were sent from Algiers to Jamaica. They were kept in a nursery until February 1901 and then 69 were planted at Hope Gardens. The female palms ultimately bore large bunches of fruits but they were ready to mature in October during the rainy season and, accordingly, the fruits rotted and fell. Only occasionally have date palms borne normal fruits in the Bahamas and South Florida.

Spanish explorers introduced the date into Mexico, around Sonora and Sinaloa, and Baja California. The palms were only seedlings. Still, the fruits had great appeal and were being exported from Baja California in 1837. The first date palms in California were seedlings planted by Franciscan and Jesuit missionaries in 1769. Potted offshoots from Egypt reached California in 1890 and numerous other introductions have been made into that state and into the drier parts of southern Arizona around Tempe and Phoenix. In 1912, Paul and Wilson Popenoe purchased a total of 16,000 offshoots of selected cultivars in Algeria, eastern Arabia and Iraq and transported them to California for distribution by their father, F.O. Popenoe who was a leader in encouraging date culture in California. It became a profitable crop, especially in the Coachella Valley. There are now about a quarter of a million bearing trees in California and Arizona.

Varieties

It would be impractical to deal in depth with date cultivars here. Paul Popenoe listed 1,500 and provided descriptions of the fruit and palm, as well as the history and significance, of the most important, country by country, in 90 pages of his book, *The Date Palm*, written in 1924 but published in 1973 and readily available. In Iraq, there are presently 450 female cultivars, the most important of which are: 'Zahdi' (43% of the crop; low in price); 'Sayer' 23% of the crop and high-priced); 'Halawi' (13% of the crop and high-priced); 'Khadrawi (6% of the crop and high-priced); also 'Khastawi, 'Brem', and 'Chipchap'. Sawaya and colleagues (1983) have reported on the sugars, tannins and vitamins in 55 major date cultivars of Saudi Arabia.

The following, with brief comments, are the dates most commonly grown:

'Barhi'— introduced into California in 1913 from Basra, Iraq; nearly cylindrical, light amber to dark brown when ripe; soft, with thick flesh and rich flavor; of superb quality. For shipment needs refrigeration as soon as picked, then curing and special packing.

'Dayri' (the "Monastery Date")—introduced into California from convent grounds in Dayri, Iraq, in 1913; long, slender, nearly black, soft. Palm requires special care. Not grown extensively in California.

'Deglet Noor'—a leading date in Algeria and Tunisia; and in the latter country it is grown in inland oases and is the chief export cultivar. It was introduced into California in 1900 and now constitutes 75% of the California crop. It is semi-dry, not very sweet; keeps well; is hydrated before shipping. Much used for cooking. The palm is high yielding but not very tolerant of rain and atmospheric humidity.

'Halawy' ('Halawi')—introduced into California from Iraq; soft, extremely sweet, small to medium; may shrivel during ripening unless the palm is well-watered. It is especially tolerant of humidity.

'Hayany' ('Hayani')—the cultivar most extensively planted in Egypt; but not exported. Introduced into California in 1901, and is sold fresh; is not easy to cure. The fruit is dark-red to nearly black; soft. The palm is one of the most cold-tolerant.

'Khadrawy' ('Khadrawi')—important in Iraq and Saudi Arabia, and is grown to some extent in California and Arizona. It is the cultivar most favored by Arabs but too dark in color to be popular on the American market, though it is a soft date of the highest quality. It is early-ripening; does not keep too well. This cultivar is the smallest edible date palm grown in the United States and it is fairly tolerant of rain and humidity.

'Khastawi' ('Khustawi'; 'Kustawy')—the leading soft date in Iraq; sirupy, small in size; prized for dessert; keeps well. The palm is large and vigorous and produces its offshoots high on the trunk in California. The fruit is resistant to humidity.

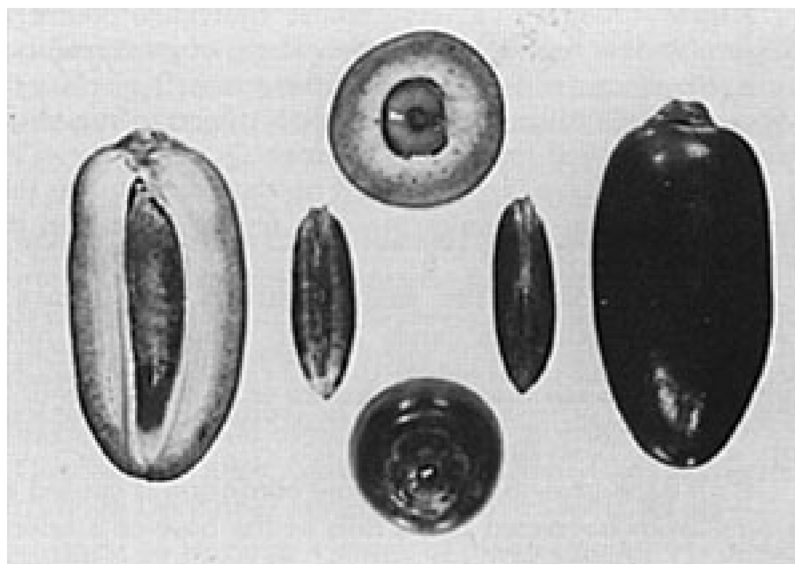
'Maktoom'—introduced into California from Iraq in 1902; large, red-brown; thick-skinned, soft, mealy, medium sweet; resistant to humidity.

'Medjool'—formerly exported from Morocco; 11 off-shoots imported into California from Bou Denib oases in French Morocco in 1927; is now marketed as a deluxe date in California; is large, soft, and luscious but ships well.

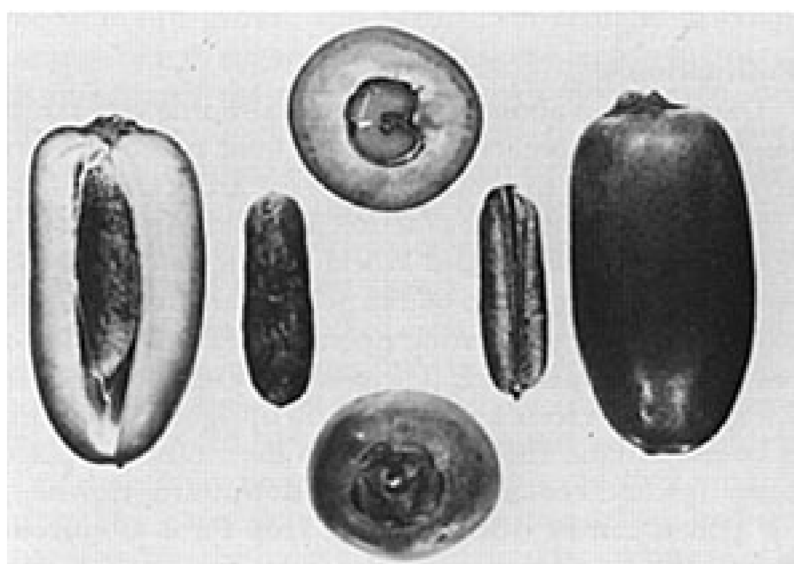
'Saidy' ('Saidi')—highly prized in Libya; soft, very sweet; palm is a heavy bearer; needs a very hot climate.

'Sayer' ('Sayir')—the most widely grown cultivar in the Old World and much exported to Europe and the Orient; dark orange-brown, of medium size, soft, sirupy, and sometimes some of the sirup is drained out and sold separately; not of high quality but the palm is one of the most tolerant of

Fig. 1: An 8-year old-'Deglet Noor' date palm in a private garden near Indio, California Photo'd by Avery Edwin Field, Oct. 1924. In: W.T. Swingle, *Date Growing*: *a new industry for Southwest States* U.S. Dept. of Agriculture Yearbook 1926.

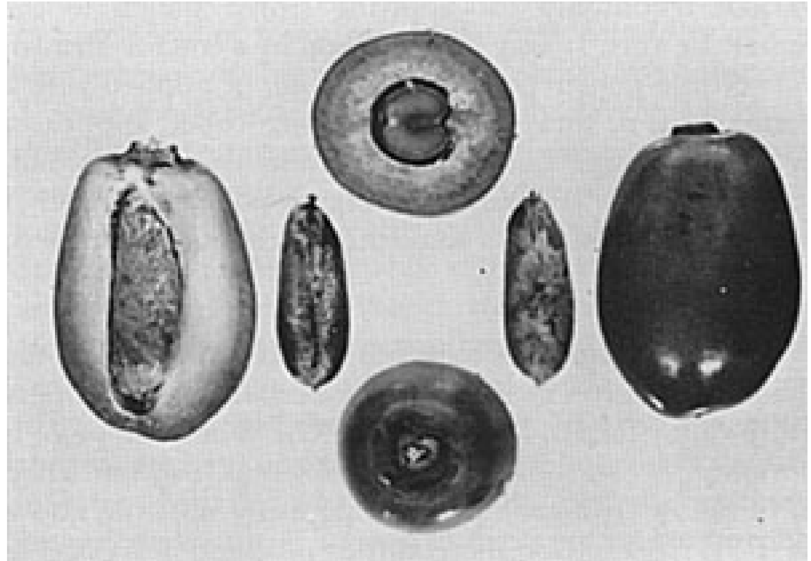


'Deglet Noor'



salt and other adverse factors.

'Halawi'



'Zahdi'

Fig. 2: 'Deglet Noor', (top) a semi soft date. 'Halawi', (center) a leading export date of Iraq. 'Zahdi', (bottom) a small date from northern Iraq. In: D.W. Albert and R H. Hilgeman, Date growing in Arizona. Bull. 149, U. Arizona, Agr. Exper. Sta., Tucson, Ariz. May 1935.

'Thoory'('Thuri')—popular in Algeria; does well in California. Fruit is dry; when cured is brown-red with bluish bloom with very wrinkled skin and the flesh is sometimes hard and brittle but the flavor is good, sweet and nutty. Keeps well; often carried on journeys. The palm is stout with short, stiff leaves; bears heavily, and clusters are very large; somewhat tolerant of humidity.

'Zahdi'('Zahidi')—the oldest-known cultivar, consumed in great quantity in the Middle East; introduced into California about 1900. Of medium size, cylindrical, light golden-brown; semi-dry but harvested and sold in 3 stages: soft, medium-hard, and hard: very sugary; keeps well for months; much used for culinary purposes. The palm is stout, fast growing, heavy bearing; drought resistant; has little tolerance of high humidity.

Among the less well-known cultivars in California are:

'Amir Hajj'—introduced from Mandali Oasis in Iraq in 1929. The fruit is soft, with thin skin and thick flesh; of superior quality but little grown in the United States.

'Iteema'—offshoots from Algeria were introduced into California in 1900. The fruit is large, oblong, light amber, soft, very sweet. Much grown in Algeria but not rain resistant and little grown in California.

'Migraf' ('Mejraf)—a very popular cultivar in Southern Yemen. Fruit is light golden-amber, large; of good quality.

In inland oases of Tunisia, in addition to the 'Deglet Noor', there is **'Ftimi'** ('Alligue') which is equally subject to humidity, less productive and less disease-resistant.

'Manakbir' has a large fruit and ripens earlier but has the disadvantage that the palm produces few offshoots and its multiplication is limited.

In coastal oases, the main cultivars are 'Kenta', Agnioua', 'Bouhatam' and 'Lemsi' which come into season early and ripen before the fall rains. They require less heat than other cultivars. The fruits are more or less dry and the flesh firm.

In all date-growing areas, some confusion is caused if a seed from harvested fruits falls at the base of a select cultivar and the seedling springs up unnoticed among the offshoots. Such seedlings should be watched for and discarded lest they be mistakenly transplanted with the offshoots and later bear fruits of inferior quality.

Pollination

Date pollen is abundant but is not airborne very far. It has become customary to plant one male palm for every 48 or 50 females to provide pollen for artificial pollination which is an ancient practice. In Saudi Arabia and a few other areas of the Old World and in California and Arizona, the long spines on the petioles are first removed to facilitate the pollinating operation. Traditionally, a few strands of open male flowers are put upside-down in a female inflorescence while it is still upright, and a cord is bound around the latter to keep the strands in place when the cluster enlarges and bends downward. However, the pollen can be dried and will keep for 6 months at room temperature. Pollen stored for one year at 8°F (-13.33°C) has given 58%fruit set. Some has been found viable after 7 years of storage, and it is reported that pollen has been kept 14 years in Iran. There are various techniques for applying stored pollen to the female flowers. It may be dusted on by a tractor-drawn, convertible pollen/pesticide machine, or applied with a cotton pad, or sprayed on with a long tubed applicator or other device. Lack of pollination results in small, seedless fruits. In acute shortages, pollen of another species of *Phoenix* or of some other genera may be used.

Climate

The date palm must have full sun. It cannot live in the shade. It will grow in all warm climates where the temper ature rarely falls to 20°F (-6.67°C). When the palm is dormant, it can stand temperatures that low, but when in flower or fruit the mean temperature must be above 64°F (17.78°C). Commercial fruit production is possible only where there is a long, hot growing season with daily maximum temperatures of 90°F (32.22°C) and virtually no rain—less than 1/2 in (1.25 cm) in the ripening season. The date can tolerate long periods of drought though, for heavy bearing, it has a high water requirement. This is best supplied by periodic flooding from the rivers in North Africa and by subsurface water rather than by rain. (See remarks on irrigation under "Culture").

Soil

The date thrives in sand, sandy loam, clay and other heavy soils. It needs good drainage and aeration. It is remarkably tolerant of alkali. A moderate degree of salinity is not harmful but excessive salt will stunt growth and lower the quality of the fruit.

Propagation

Date palms grow readily from seeds if the seeds and seedlings are kept constantly wet. But seedlings are variable and take 6 to 10 years to fruit. Furthermore, 50% of the seedlings may turn out to be males. The best and common means of propagation is by transplanting the suckers, or offshoots when they are 3 to 5 years old and weigh 40 to 75 lbs (18-34 kg). They are usually separated from the parent palm as needed, but in southern Algeria suckers are often put on sale standing in tubs of water. Some offshoots are maintained in nurseries until roots are formed, though most are set directly in the field after a seasoning period of 10 to 15 days just lying on the ground, in order to lose 12 to 15% of their moisture. In parts of Egypt subject to annual flooding, very large offshoots—up to 500lbs (226 kg) are planted to avoid water damage. In general, it is said that at least 2 offshoots can be taken from each palm annually for a period of 10 to 15 years. The potential of tissue culture for multiplication of date palms is being explored in Iraq, Saudi

Arabia and in California.

Culture

In Tunisia, in former times, it was customary to plant 200 date palms per acre (500/ha). Today, optimum density is considered to be 50 per acre (120/ha) and this is about the standard in the Coachella Valley of California, but small-growing palms may be set much closer. The off shoots, trimmed back 1/3 or 1/4, leaving some of the stiff outer leaves to protect the inner ones, are usually planted 30 to 33 ft (9-10 m) apart each way. The holes should be 3 ft (0.9 m) wide and deep, prepared and enriched several months in advance, and may be encircled by a watering ditch. If the soil dries out prior to planting, the holes are filled with water at that time. In Algeria and Oman, the palms may be set much deeper in order to be closer to ground water, but this may result in drowning the palms when irrigating or they may be smothered by sandstorms.

Planting may be done at any time of year, but most often takes place in spring or fall. In Tunisia planting is done in April and May. The base is set vertically in the ground and the curving fronds will gradually assume an upright position, especially if the concave side is set to face south. Most plants will root in 2 months if the soil is kept constantly moist, while some may be delayed for a year or even several years before they show vigorous growth. Some growers expect a loss of 25% of the off shoots. Formerly, the young plants in nursery rows were wrapped nearly to the top with old leaves, paper or burlap sacks for the first year to prevent dehydration by cold, heat or wind. But it is now held that such wrapping interferes with the proper development of the leaves.

The offshoots that survive may begin to bloom in 3 years and fruit a year later but a substantial crop is not possible before the 5th or 6th year. In 8 or 10 years, the date will attain full production and it will keep on for a century though productivity declines after 60 to 80 years and also the flowers will be too high to pollinate and the fruits too high to pick. The palm grows at the rate of 1 to 11/2 ft (30-45 cm) a year and can reach 20 ft in 15 to 20 years depending on the cultivar and soil and water conditions.

In Iraq, date palms are fertilized once a year with manure at the rate of 44 lbs (20 kg) per tree. Commercial fertilizers are utilized in Saudi Arabia and the United States. Of more importance is the supply of water, a large amount being necessary and it is usually supplied by irrigation ditches. In some Old World plantations rising tides cause rivers to flood the ditches twice a day. Where this natural irrigation does not occur, the palms are watered 15 to 40 times a year. Overhead moisture (including rain) during fruit development will cause minute cracks (checking), beginning at the apex of the fruit which ultimately darkens. In California, the fruit clusters are covered with paper bags to shelter them from rain, dust, and predators.

The female inflorescences may be shortened, thinned out, or some removed entirely at pollinating time, or several weeks later when the stalk has drooped lower, in order to conserve the palm's energy for the following season. Some growers advise leaving no more than 12 bunches per palm. Many leave only 30 strands per cluster, each with about 30 fruits. Without thinning, fruits would be borne only every other year. During the pollinating operation, a grower may tie the elongating flower stalk to a palm frond to prevent breaking when later laden with fruit.

The palms are pruned twice a year, dry fronds being removed in the fall and the leaf bases may be taken off in the spring in order that their fiber may be used as a substitute for coir

In Iraq, growth regulators have been experimentally applied to developing dates. In 'Zahdi' and 'Sayer', naphthaleneacetic acid, at 60 ppm, applied 15 to 16 weeks after pollination, improved quality and increased fruit weight by 39%. Moisture content was elevated. Ripening was delayed for 30 days or more.

In the Old World, most date plantations are intercropped with vegetables, cereals or fodder crops in the first few years and subsequently with low growing fruit trees or grapevines. Some authorities hold that this practice distracts the grower from proper care of the dates. In mechanized plantations, intercropping is not possible inasmuch as space must be left for the mobile equipment.

Yield

Ordinarily, in palms 5 to 8 years old, the first crop will be 17.5 to 22 lbs (8-10 kg) per palm; at 13 years, 132 to 176 lbs (60-80 kg). Some improved cultivars, at high densities, have yielded over 220 lbs (100 kg) per year. 'Deglet Noor' in California may yield 4.5 to 7 tons per acre (11-17 tons/ha).

Harvesting and Ripening

Some high-quality dates are picked individually by hand, but most are harvested by cutting off the entire cluster. In North Africa, the harvesters climb the palms, use forked sticks or ropes to lower the fruit clusters, or they may pass the clusters carefully down from hand to hand. Growers in California and Saudi Arabia use various mechanized means to expedite harvesting—saddles, extension ladders, or mobile steel towers with catwalks for pickers. All fruits in a cluster and all clusters on a palm do not ripen at the same time. A number of pickings may have to be made over a period of several weeks. In the Coachella Valley, dates ripen from late September through December and there are 6 to 8 pickings per palm.

Dates go through 4 stages of development: 1) Chimri, or Kimri, stage, the first 17 weeks after pollination: green, hard, bitter, 80% moisture, 50% sugars (glucose and fructose) by dry weight; 2) Khalal stage, the next 6 weeks: become full grown, still hard; color changes to yellow, orange or red, sugars increase, become largely sucrose; 3) Rutab stage, the next 4 weeks: half-ripe; soften, turn light brown; some sucrose reverts to reducing sugar which gains prominence; 4) Tamar stage: ripe; the last 2 weeks; in soft dates, the sugar becomes mostly reducing sugar; semi-dry and dry dates will have nearly 50% each of sucrose and reducing sugars.

Soft dates may be picked early while they are still light colored. Semi dry dates may be picked as soon as they are soft and then ripened artificially at temperatures of 80° to 95°F (26.67°-35°C), depending on the cultivar. Dry dates may be left on the palm until they are fully ripe. Dry dates that have become too dehydrated and hardened on the palm are rehydrated by soaking in cold, tepid or hot water, or by exposure to steam or a humid atmosphere. Extremely dry weather will cause dates to shrivel on the palm. In the Sudan, the fruits are picked when just mature and then are ripened in jars to prevent so much loss of moisture. Rain, high humidity or cool temperatures during the maturing period may cause fruit drop or checking, splitting of the skin, darkening, blacknose, imperfect maturation, and excessive moisture content, or even rotting. Under such adverse weather conditions, as may occur in the Salt River Valley, Arizona, dates must be harvested while still immature and ripened artificially. In the Old World, there are many different methods of doing this: storing in earthen jars, placing the jars in sun hot enough to prevent spoilage, boiling the fruits in water and then sun drying. In Australia, entire clusters are kept under cover with the cut end of the stalk in water until the fruits are fully ripe. In modern packing houses, prematurely harvested dates are ripened in controlled atmospheres, the degrees of temperature and humidity varying with the nature of the cultivar.

Where there is low atmospheric humidity outdoors and adequate sunshine, harvested dates are sun dried whole or cut in half. For fresh shipment in California, the normally ripe, harvested fruits are carried to packing plants, weighed, inspected by agents of the United States Department of Agriculture, fumigated, cleaned, graded, packed, stored under refrigeration, and released to markets according to demand. Saudi Arabia has constructed a number of extra-modern processing plants for fumigation, washing, drying, and packing of dates prior to cold storage.

Keeping Quality

Slightly underripe 'Deglet Noor' dates will keep at 32°F (0°C) up to 10 months; fully mature, for 5 to 6 months. Freezing will extend the storage life for a much longer period. In India, sun-dried dates, buried in sand, have kept well for 1 1/2 years and then have been devoured by worms.

Pests and Diseases

Unripe fruits are attacked by *Coccotrypes daclyliperda* which makes them fall prematurely. Ripe fruits are often infested by nitidulids—*Carpophilus hemipterus*, *C. multilatus* (*C. dimidiatus*), *Urophorus humeralis*, and *Heptoncus luteolus*, which cause decay. Control by insecticides is necessary to avoid serious losses. In Israel, the fruit clusters are covered with netting to protect them from such pests as *Vespa orientalis, Cadra figulilella* and *Arenipes sabella* as well as from depredations by lizards and birds.

In Pakistan, the red weevil, or Indian palm weevil, *Rhynchophorus ferrugineus*, bores into the leaf bases at the top of the trunk, causing the entire crown to wither and die. The rhinocereus beetle, or black palm beetle, *Oryctes rhinocerus*, occasionally attacks the date. Its feeding damage may provide entrance-ways for the weevil. Scale insects may infest the leaves and the trunk. They have been controlled by trimming off the heavily infested leaves, spraying the remaining ones, and treating the fire resistant trunk with a blowtorch. Two of the most destructive scales are the Marlatt scale, *Phoenicoccus marlatti*; which attacks the thick leaf bases, and the Parlatoria scale, *Parlatoria blanchardii*, which is active in summer. The latter was the object of an eradication campaign in California and Arizona in the late 1930's. The date mite scars the fruits while they are still green.

A tineid moth and a beetle, *Lasioderma testacea*, have damaged stored dates in the Punjab. Dates held in storage are subject to invasion by the fig-moth, *Ephestia cautella*, and the Indian meal-moth, *Plodia interpunctella*.

Fusarium albedinis causes the disastrous Bayoud, or Baioudh, disease in Morocco and Algeria. It is evidenced by a progressive fading and wilting of the leaves. Over a 9-year study period of 26 resistant varieties in Morocco, Bayoud disease reduced the planting density from 364 palms per acre (900/ha) to 121 to 142 per acre (300-350/ha). It is because of this disease that 'Medjool' can no longer be grown commercially in Morocco and Algeria.

Decay of the inflorescence is caused by *Manginiella scaeltae* in humid seasons. Several brown stains will be seen on the unopened spathe and the pedicels of the opened cluster will be coated with white "down". Palm leaf pustule, small, dark-brown or black cylindrical eruptions exoding yellow spores, resulting from infestation by the fungus *Graphiola phoenicis*, is widespread but often a serious problem in Egypt. Date palm decline may be physiological or the result of a species of the fungus genus *Omphalia*. Diplodia disease is a fungus manifestation on leafstalks and offshoots and it may kill the latter if not controlled. The fungus caused condition called "black scorch" stunts, distorts and blackens leaves and adjacent inflorescences. Other fungus diseases include pinhead spot (*Diderma effusum*), gray blight *(Pestalotia palmarum*) and spongy white rot (*Polyporus adustus*). The date, as well as its relative, *Phoenix canariensis* Hort. ex Chaub., has shown susceptibility to lethal yellowing in Florida and Texas. No commercial plantings have been affected.

Food Uses

Dry or soft dates are eaten out-of-hand, or may be seeded and stuffed, or chopped and used in a great variety of ways: on cereal, in pudding, bread, cakes, cookies, ice cream, or candy bars. The pitting may be done in factories either by crushing and sieving the fruits or, with more sophistication, by piercing the seed out, leaving the fruit whole. The calyces may be mechanically removed also. Surplus dates are made into cubes, paste, spread, powder (date sugar), jam, jelly, juice, sirup, vinegar or alcohol. Decolored and filtered date juice yields a clear invert sugar solution. Libya is the leading producer of date sirup and alcohol.

Cull fruits are dehydrated, ground and mixed with grain to form a very nutritious stockfeed. Dried dates are fed to camels, horses and dogs in the Sahara desert. In northern Nigeria, dates and peppers added to the native beer are believed to make it less intoxicating. The First International Date Conference was held in Tripoli, Libya in 1959, and led to the development of a special program under the Food and Agriculture Organization of the United Nations to promote the commercial utilizetion of substandard or physically defective dates.

Young leaves are cooked and eaten as a vegetable, as is the terminal bud or heart, though its removal kills the palm. In India, date seeds are roasted, ground, and used to adulterate coffee. The finely ground seeds are mixed with flour to make bread in times of scarcity.

In North Africa, Ghana and the Ivory Coast, date palms are tapped for the sweet sap which is converted into palm sugar, molasses or alcoholic beverages, but each palm should not be tapped more than 2 or 3 times. Tapping the edible date palm interferes with fruit production and it is wiser to tap *P. sylvestris*, which is not valued for its fruit, or some other of the 20 well-known palm species exploited for sugar. When the terminal bud is cut out for eating, the cavity fills with a thick, sweet fluid (called *lagbi* in India) that is drunk for refreshment but is slightly purgative. It ferments in a few hours and is highly intoxicating. Fresh spathes, by distillation, yield an aromatic fluid enjoyed by the Arabian people.

Other Uses

Seeds: Date seeds have been soaked in water until soft and then fed to horses, cattle, camels, sheep and goats. Dried and ground up, they are now included in chicken feed. They contain 7.17-9% moisture, 1.82-5.2% protein. 6.8-9.32% fat, 65.5% carbohydrates, 6.4-13 6% fiber, 0.89-1.57% ash, also sterols and estrone, and an alkali-soluble polysaccharide. The seeds contain 6 to 8% of a yellow-green, non-drying oil suitable for use in soap and cosmetic products. The fatty acids of the oil are: lauric, 8%; myristic, 4%; palmitic, 25%; stearic, 10%, oleic, 45%, linoleic, 10%; plus some caprylic and capric acid. Date seeds may also be processed chemically as a source of oxalic acid, the yield amounting to 65%. In addition, the seeds are burned to make charcoal for silversmiths, and they are often strung in necklaces.

Leaves: In Italy, there are some groves of date palms maintained solely to supply the young leaves for religious use on Palm Sunday. In Spain, only the leaves of male palms are utilized for this purpose. In North Africa, the leaves have been commonly used for making huts. Mature leaves are made into mats, screens, baskets, crates and fans. The processed leaflets, combined with ground up peanut shells and corn cobs, are used for making insulating board. The leaf petioles have been found to be a good source of cellulose pulp. Dried, they are used as walking sticks, brooms, fishing floats, and fuel. The midribs are made into baskets. The leaf sheaths have been prized for their scent. Fiber from the old leaf sheaths is used for various purposes including packsaddles, rope, coarse cloth and large hats. It has been tested as material for filtering drainage pipes in Iraq, as a substitute for imported filters. Analyses of the leaves show: 0.4-0.66% nitrogen; 0.025 0.062% phosphorus; 0.33-0.66% potassium; 10-16.4% ash. There is some coumarin in the leaves and leaf sheaths.

Fruit clusters: The stripped fruit clusters are used as brooms. The fruit stalks contain 0.28-0.42% nitrogen, 0.017-0.04% phosphorus; 3.46-4.94% potassium; 7.7-9.88% ash.

Fruits: In Pakistan, a viscous, thick sirup made from the ripe fruits, is employed as a coating for leather bags and pipes to prevent leaking.

Wood: Posts and rafters for huts are fashioned of the wood from the trunk of the date palm, though this wood is lighter than that of the coconut. It is soft in the center and not very durable. That of male trees and old, un productive females is readily available and used for aqueducts, bridges and various kinds of construction, also parts of dhows. All left over parts of the trunk are burned for fuel.

Medicinal Uses: The fruit, because of its tannin content, is used medicinally as a detersive and astringent in intestinal troubles. In the form of an infusion, decoction, sirup or paste, is administered as a treatment for sore throat, colds, bronchial catarrh. It is taken to relieve fever, cystisis, gonorrhea, edema, liver and abdominal troubles. And it is said to counteract alcohol intoxication.

The seed powder is an ingredient in a paste given to relieve ague.

A gum that exudes from the wounded trunk is employed in India for treating diarrhea and genito-urinary ailments. It is diuretic and demulcent. The roots are used against toothache. The pollen yields an estrogenic principle, estrone, and has a gonadotropic effect on young rats.

Food Value Per 100 g of Edible Portion*

	Fresh, uncooked	*Dried*
Calories	142	274 293

*Based on standard analyses.

Sawaya et al., in their studies of fresh dates in Saudi Arabia, reported ascorbic acid content as 1.8-14.3 mg/100 g in the Khalal stage; 1.1-6.1 in the Tamar state. They found that vitamin A ranged from 20 to 1.416 I.U. in the Khalal stage; from 0-259 l.U. in the Tamar stage. Tannin varied from 1.2 to 6.7% in the Khalal stage. 0.6 to 3.2 % in the Tamar stage.

The sap contains 10% sucrose. Jaggery made from it contains 9.6% moisture, 86.1 % carbohydrates, 1.5% protein, 0.3% fat, 2.6% minerals, 0.36% calcium, 0.06% phosphorus.

Morton, J. 1987. Pejibaye. p. 12–14. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Pejibaye

Bactris gasipaes

Highly regarded today as a source of nutritious food, the pejibaye, *Bactris gasipaes* HBK. (syns. *B. speciosa* Karst.; *Guilielma gasipaes* L.H. Bailey; *G. speciosa* Mart.; *G. utilis* Orst.), family Palmae, is also called peach palm. It is known as *pejivalle* in Costa Rica; peach-nut, *pewa* or *pupunha* in Trinidad; *piva* in Panama; *cachipay, chichagai, chichaguai, contaruro, chonta, choritadura, chenga, jijirre, pijiguay, pipire, pirijao, pupunha*, or *tenga* in Colombia; *bobi, cachipaes, rnacanilla, melocoton, pichiguao, pihiguao, pijiguao, piriguao*, or *pixabay* in Venezuela; *comer, chonta*, and *tempe* in Bolivia; *chonta dura, chonta ruru, pijuanyo, pifuayo, sara-pifuayo, pisho-guayo* in Peru; *amana*, in Surinam; *parepon* in French Guiana; *popunha* in Brazil.

Description

The palm is erect, with a single slender stem or, more often, several stems to 8 in (20 cm) thick, in a cluster; generally armed with stiff, black spines in circular rows from the base to the summit. There are occasional specimens with only a few spines. The pejibaye attains a height of 65 to 100 ft (20 30 m) and usually produces suckers freely. The leaves, with short, spiny petioles, are pinnate, about 8 to 12 ft (2.4-3.6 m) long, with many linear, pointed leaflets to 2 ft (60 cm) long and 1 1/4 in (3.2 cm) wide; dark green above, pale beneath, spiny on the veins. The inflorescence, at first enclosed in a spiny spathe, is composed of slender racemes 8 to 12 in (20-30 cm) long on which the yellowish male and female flowers are mingled except for the terminal few inches where there are only male flowers.

The fruit, hanging in clusters of 50 to 100 or sometimes as many as 300, weighing 25 lbs (11 kg) or more, is yellow to orange or scarlet, yellow-and-red, or brownish at first, turning purple when fully ripe. It is ovoid, oblate, cylindrical or conical, 1 to 2 in (2.5-5 cm) long, cupped at the base by a green, leathery, 3-pointed calyx. A single stem may bear 5 or 6 clusters at a time. The skin is thin, the flesh yellow to light-orange, sweet, occasionally with a trace of bitterness, dry and mealy. Some fruits are seedless. Normally there is a single conical seed 3/4 in (2 cm) long, with a hard, thin shell and a white, oily, coconut-flavored kernel. Rarely one finds 2 fused seeds.

Origin and Distribution

This useful palm is apparently indigenous to Amazonian areas of Colombia, Ecuador, Peru and Brazil, but it has been cultivated and distributed by Indians from ancient times and is so commonly naturalized as an escape that its natural boundaries are obscure. Of prehistoric introduction into Costa Rica, it is plentiful in a seemingly wild state of the Atlantic side of that country and also much cultivated. Every Indian dwelling has a patch of pejibaye palms. The palm has also been planted as partial shade for coffee. It is not as common anywhere else in Central America, though it is fairly abundant in Nicaragua, Honduras and Guatemala, and has long been grown in commercial plots in Panama to furnish fruits for local markets. In Colombia and Peru, great quantities of the fruits appear in the markets and vendors sell them along the streets. There are large stands of this palm in the Orinoco region of Venezuela and equatorial Brazil. The Indians of Colombia and Ecuador hold festivals when the pejibayes are in season, though in the latter country the fruits are valued more as feed for livestock than as food for humans.

The United States Department of Agriculture received seeds from Costa Rica in 1920 (S.P.I. #50679), but those in the first lot had lost viability. The United Fruit Company shipped whole fruits but they fermented en route and were mistakenly thrown overboard at New York, the stevedores not being aware that they were imported only for their seeds. Another shipment was made with adequate instructions and 1,000 seedlings were grown in greenhouses in Maryland and distributed. Today there are scattered specimens in southern Florida, Cuba, Puerto Rico and Trinidad. The palm was introduced into the Philippines in 1924. In the 1970's, the possibility of growing pejibayes in India was inspired by settlers of East Indian lineage in Trinidad and South America who produce and sell the fruits. In 1978, Brazilian horticulturists undertook a study to determine the feasibility of establishing pejibaye plantations in the State of Sao Paulo with a view to exploiting the fruit and the tenninal bud (heart, or *palmito).* There has been much interest generated in recent years in the cultivation of the palm solely for its hearts which are of high quality. Costa Rica is a leader in this enterprise and there the hearts are being canned commercially.

Fig. 3: A single-stemmed pejibave palm *(Bactris gasipaes)*, photo'd by the author at Buenaventura, Colombia, in 1969.

Varieties

There is much variation in form, size, color and quality of the fruits. Some with longitudinal scars *(pejibaye rayodo)* are considered of superior quality. These scars indicate low water content, firmness and a minimum of fiber in the flesh. In Costa Rica there are palms that bear clusters having a majority of seedless fruits. These are called *pejibaye macho* (male pejibaye) and are much prized. It has been found in surveys that only 30 to 60 palms in a seedling planting of 400 will yield highgrade fruit. As many as 100 may yield fruit of such low quality that it is not marketable for human consumption.

In recent years, germplasm collections have been initiated in Costa Rica, Panama, Colombia and Brazil, and there is a great potential for crop improvement and standardization. Spineless forms *(tapire)*, especially, are being sought for breeding purposes.

Plate I: PEJIBAYE, *Bactris gasipaes* (green and ripe)

Climate

The pejibaye requires a tropical climate. It is generally restricted to elevations below 6,000 ft (1,800 m). Fruiting is reduced above 5,000 ft (1,500 m). The ideal average annual temperature ranges between 64.4° and 75.2°F (18°-24°C). At low elevations with excessive rainfall, the palm cannot succeed. Optimum rainfall is 78 to 156 in (200-400 cm), rather evenly distributed the year around.

Plate II: PEJIBAYE, *Bactris gasipaes* (in foreground)

Soil

The palm does well even on poor soils but thrives best on fertile, well drained land. In a favorable producing region of Costa Rica, the soil varies from clay loam to nearly pure clay. However, riparian, alluvial soils are deemed most desirable.

Propagation

The pejibave is grown from seed or from suckers. Seeds can be shade-dried for a few hours, packed in moist sphagnum moss or charcoal and shipped to any part of the world. When planted, they will germinate in 3 months. Young plants must be protected from ants which will destroy the tender shoots.

Culture

The palm grows rapidly and reaches 43 ft (13 m) in 10 to 15 years. At low altitudes, seedlings begin to bear in 6 to 8 years. In cool regions, bearing may not begin until the plant is 10 to 12 years old. Productive life is said to be 50 to 75 years.

In fruit plantations, the palms are set 20 ft (6 m) apart. After a few years the suckers emerge and only 2 to 4 are allowed to remain to maturity. When they are 4 to 6 ft (1.2-1.8 m) high and about 3 in (7.5 cm) thick at the base, excess suckers are taken up, cut back severely, kept in the shade and watered until new roots are formed, and then transplanted to new locations. Weeding is done 2 or 3 times a year.

For the production of palm hearts, the spacing is closer, from 5 to 10 ft (1.5-3 m), as the terminal buds can be harvested in 2 1/2 to 3 years. Researchers have found that an application of flurenol (10 ppm) will induce formation of lateral shoots. At 200 ppm, shoot growth is inhibited.

Season

In Colombia, the fruits of cultivated palms mature in January and February. Wild palms may bear twice a year. There are 2 crops a year in Trinidad, one without seeds, the other with seeds. In Costa Rica, the flowers appear in April, May and June in the lowlands, later in the highlands, and fruits mature from September to April.

Harvesting

Because of the spines on the stems, the fruits are knocked down with long poles or harvested with long poles equipped with cutters, unless ladders are available and the bunches can be cut intact and lowered by rope. If the bunch is dropped down, it is caught in a leaf-lined sack held by 2 men, or may land on a deep pile of banana leaves. When the palm gets too tall, the farmer usually cuts it down to obtain the fruits and the heart. If he is fortunate enough to have a number of nearly spineless palms, the spines can be trimmed off and the palm can be climbed. If all the spines are cut off the spiny trunks, the palm will die, but 5 to 8 ft (1.5 2.5 m) of trunk can be despined safely. Special gear of rope and stirrups has been devised to facilitate climbing. Then, too, if the palms have single trunks and are close enough together, the worker need climb only every other tree, using a specially equipped pole to cut bunches from the neighboring tree. Johannessen (1966) provides details of the modes of handling the crop and the economic role of the pejibaye in the lives of Costa Rican farmers.

In the period 1948 to 1963 in Costa Rica, the harvesting cost was calculated as representing 11.4% of the total cash value of the crop. Hunter (1969) has developed data showing that, efficiently managed, the pejibaye crop, in terms of financial return to the grower, compares favorably with maize (corn).

Yield

A palm with 4 or 5 stems may produce 150 lbs (68 kg) of fruit in a season.

Keeping Quality

Undamaged, raw fruits keep in good condition in a dry atmosphere with good air circulation for a long time, gradually dehydrating. Roughly handled and bruised fruits ferment in only 3 to 4 days. The cooked fruits, as commonly marketed, can be held for 5 or 6 days. In refrigerated storage at 35.6° to 41°F (2°-5°C), uncooked fruits can be kept for 6 weeks with a minimum of dehydration or spoilage.

Pests and Diseases

In Costa Rica, a stem borer, *Metamasius hemipterus*, sometimes penetrates the stalk of the fruit cluster, causing the fruits to rot. There have been no reports of diseases attacking the palm. Fruits injured during harvesting or transport are soon invaded by rot-inducing fungi.

Food Uses

The fruit is caustic in its natural state. It is commonly boiled; in fact, it is customary to boil the fruits for 3 hours in salted water, sometimes with fat pork added, before marketing. Boiling causes the flesh to separate easily from the seed and usually the skin as well, though in some varieties the skin adheres to the flesh even after cooking. It is only necessary to remove the skin from the cooked flesh which can then be eaten out-of-hand. The pre-boiled fruit is sometimes deep-fried or roasted and served as a snack garnished with mayonnaise or a cheese-dip. It is also mixed with cornmeal, eggs and milk and fried, and is often employed as stuffing for roasted fowl. Occasionally it is made into jam. Oven dried fruits have been kept for 6 months and then boiled for half an hour which causes them to regain their characteristic texture and flavor. Peeled, seeded, halved fruits, canned in brine, have been exported to the United States. Dried fruits can be ground into flour for use in various dishes. A strong alcoholic drink is made by allowing the raw, sugared flesh to stand for a few days until it ferments. This is prohibited in some parts of tropical America.

Young flowers may be chopped and added to omelettes. The cooked seeds are eaten like chestnuts but are hard and considered difficult to digest.

The palm heart is excellent raw or cooked. It is served in salads or prepared with eggs and vegetables in a casserole. It is a traditional food of the Indians and its harvesting has greatly reduced the stands of wild palms.

Food Value

One average pejibaye fruit contains 1,096 calories. Analyses made in Honduras and Costa Rica show the following values for 100 g of ripe flesh and skin combined:

Food Value Per 100 g of Edible Portion

Moisture	36.4-60.9 g
Protein	0.340-0.633 g
Fat	3.10-8.17 g
Crude Fiber	0.8-1.4 g

Ash	0.72-1.64 g
Calcium	8.9-40.4 mg
Phosphorus	33.5-55.2 mg
Iron	0.85-2.25 mg
Carotene	0.290-2.760 mg
Thiamine	0.037-0.070 mg
Riboflavin	0.099-0.154 mg
Niacin	0.667-1.945 mg
Ascorbic Acid	14.8-41.4 mg

The protein contains 7 of the 8 essential amino acids: threonine 2.5%/g/N; valine, 2.7%; methionine, 1.3%; isoleucine, 1.7% leucine, 2.6%; phenylalanine, 1.3%; lysine, 4.6%; and 10 others. Tests for tryptophan have given negative results.

The following approximate values are shown for the seed kernels per 100 g: moisture (loss at 212°F [100°C]), 6.9%; protein (N x 6.25), 8.8%; fat, 31.3%; crude fiber, 18.2%; starch (by acid hydrolysis), 20.8%; ash, 1.9%; undetermined material, 12.1%.

Other Uses

Fruit: Excess fruits and peelings are used as feed for poultry and pigs.

Leaves: Leaflets stripped off for better visibility in harvesting are fed to livestock. The leaves have been importent for thatching huts.

Sap: The trunk may be tapped for sap which is fermented into wine.

Bark: The bark is peeled off in one piece, despined and used like canvas to make a substitute for a flat spring in a crude bed or bunk.

Wood: The dark brown wood is very hard but elastic and takes a good polish. It has been used for spears, Indian satires, bows, arrowheads, staffs and walking sticks. More modern uses are siding for houses, veneer and tool handles. Small pieces are fashioned into spindles and other parts used in weaving. Split trunks are used as water troughs.

Morton, J. 1987. Ceriman. p. 15–17. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Ceriman

Monstera deliciosa

Of the many aroids (members of the family of Araceae) that are cultivated as ornamental plants, only this one has been grown as well for its fruit. The ceriman, *Monstera deliciosa* Liebm. (syn. *Philodendron pertusum* Kunth & Bouche), is often called merely monstera and, inappropriately, false breadfruit. Because of the apertures in its leaves, some have called it Swiss-cheese plant, or hurricane plant, suggesting that the holes and slits permit the wind to pass through without damaging the foliage. Generally, in Mexico and other Latin American countries it is known as *pinanona,* or *pina anona,* but in Venezuela it is called *ojul* or *huracan;* in Colombia, *hojadillo;* in Guatemala, *harpon* or *arpon comun.* In Guadeloupe it is *caroal, liane percee,* or *liane franche;* in Martinique, *siguine couleurre;* in French Guiana, *arum du pays* or *arum troud.* In Brazil it is catalogued by a leading nursery as *ananas japonez* (Japanese pineapple).

Description

The plant is a fast-growing, stout, herbaceous vine spreading over the ground and forming extensive mats if unsupported, but climbing trees to a height of 30 ft (9 m) or more. The stems are cylindrical, heavy, 2 1/2 to 3 in (6.25-7.5 cm) thick, rough with leaf scars, and producing numerous, long, tough aerial roots. The leathery leaves, on stiff, erect, flattened petioles to 3 1/2 ft (105 cm) long, are oval, cordate at the base, to 3 ft (90 cm) or more in length and to 2 3/4 ft (82.8 cm) wide; deeply cut into 9-in (22.8 cm) strips around the margins and perforated on each side of the midrib with elliptic or oblong holes of various sizes.

Fig. 4: The ceriman (*Monstera deliciosa*) in flower and fruit at Palm Lodge Tropical Grove, Homestead, Fla. In: J.F. Morton, *Some Useful and Ornamental Plants of the Caribbean Gardens*, 1955.

Several inflorescences arise in a group from the leaf axils on tough, cylindrical stalks. The cream colored spadix, sheltered at first by a waxy, white, calla-lily-like spathe, develops into a green compound fruit 8 to 12 in (20-30 cm) or more in length and 2 to 3 1/2 in (5-8.75 cm) thick, suggesting an ear of corn. The thick, hard rind, made up of hexagonal plates or "scales", covers individual segments of ivory-colored, juicy, fragrant pulp much like diced pineapple. Between the segments there are thin, black particles (floral remnants). Generally there are no seeds, but sometimes, pale-green, hard seeds the size of large peas, may occur in a dozen or so of the segments.

Origin and Distribution

The ceriman is native to wet forests of southern Mexico, Guatemala and parts of Costa Rica and Panama. It was introduced into cultivation in England in 1752; reached Singapore in 1877 and India in 1878. Specimens of the fruit were exhibited by the Massachusetts Horticultural Society in 1874 and 1881. It has become familiar as an ornamental in most of the warm countries of the world and is widely used in warm and temperate regions as a potted plant indoors,—especially in conservatories and greenhouses—though it does not bloom nor fruit in confinement. In Guatemala, it is raised in pots in patios to prevent too rampant growth, as it is apt to become an aggressive nuisance.

The fruits are marketed to some extent in Queensland and, in the past, were sometimes shipped from Florida to gourmet grocers in New York and Philadelphia.

Climate

The ceriman is strictly tropical and cannot tolerate frost. It does best in semi-shade and has a high moisture requirement.

Soil

The plant grows vigorously in almost any soil, including limestone but flourishes best in well drained, rich loam. It is not adapted to saline conditions.

Propagation

In some European nurseries, the ceriman is raised from imported seed. Rapid multiplication has been achieved through tissue culture in Denmark. Generally, propagation is by means of stem cuttings, which may be simply set in beds or pots in the ground where the vine is intended to grow. Suckers or offshoots, with or without roots, can be separated from parent plants and transplanted successfully. Mulching is desirable as well as watering until new roots have become well-established.

Culture

Suckers will fruit in 2 to 4 years; cuttings in 4 to 6 years, depending on the location, soil and attention given. Out-of-doors, the ceriman requires little care. If it is desired to expedite growth and fruiting, a complete fertilizer may be applied 3 or 4 times a year. Indoor plants need frequent repotting to accommodate the root system, and they should be set outside at least once a year in direct light.

Season

Flowering and fruiting overlap because it requires 12 to 14 months from the opening of the inflorescence to the maturity of the fruit. Therefore, there are often unopened inflorescences, immature fruits and ripening fruits together on the same plant. The current year's crop is ripening through summer and fall while the following year's crop is forming beside it.

Harvesting

The rind is always green though it assumes a lighter shade as the fruit matures. The fruit, with at least an inch (2.5 cm) of stem, should be cut from the plant when the tile-like sections of rind separate slightly at the base, making it appear somewhat bulged. At this state, the fruits have been shipped to local or distant markets. If kept at room temperature, the ceriman will ripen progressively toward the apex over a period of 5 or 6 days. The flesh should be eaten only from that portion of the fruit from which the rind segments have so loosened as to be easily flicked off. To ripen the whole fruit at one time, it should be wrapped in paper or plastic, or possibly aluminum foil, as soon as cut from the plant and kept at room temperature until the rind has loosened the entire length of the fruit. At this stage, it will be found that the flesh also falls easily away from the inedible core. Once ripened, the fruit can be kept in the refrigerator in good condition for a week or a little more. Rinsing off the floral remnants improves the appearance of the flesh, but it does cause some loss of juice.

Pests and Diseases

When grown indoors, the plants are subject to infestation by scale insects, mites and mealybugs. Outdoors, they are usually pest-free. However, in dry seasons in Florida, the lubber grasshopper *(Romalea microptera)* has rapidly consumed entire leaves, leaving only the base of the midrib and the petiole. In India, wire cages are placed around developing fruits to protect them from rats, squirrels, monkeys and other creatures.

The following diseases have been recorded in Florida: leaf spot caused by *Leptosphaeria* sp., *Macrophoma philodendri, Phytophthora* sp., and *Pseudomonas cichorri;* anthracnose from *Glomerella cingulata;* bacterial soft rot from infection by *Erwinia carotovora;* and root rot caused by *Pythium splendens* and *Rhizoctonia solani.*

Food Uses

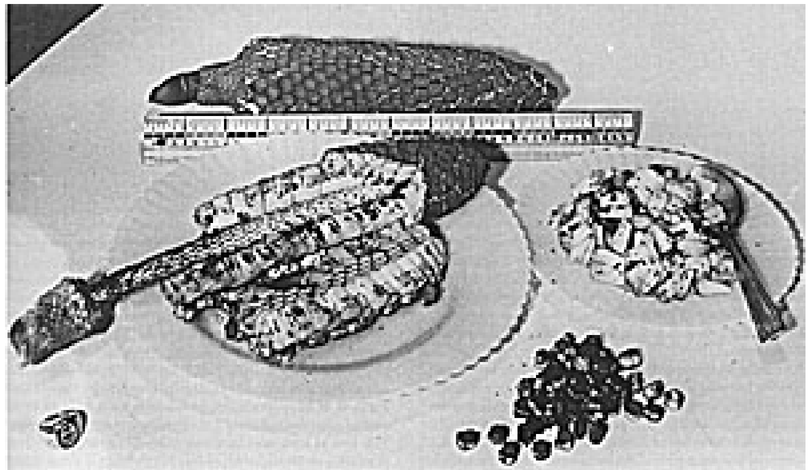

Fig. 5: Compound fruit of the ceriman fully ripe, with loose segments of rind removed and flesh separated for eating. Black specks are floral remnants.

Fully ripe pulp is like a blend of pineapple and banana. It may be served as dessert with a little light cream, or may be added to fruit cups, salads or ice cream. Some people cut cross-sections right through the core, creating wheel like disks that can be held with the thumb and fore finger pinching the "hub" while the edible part is nibbled from the rim. To make a preserve, rinsed segments can be stewed for 10 minutes in a little water, a cup of sugar and a tablespoon of lime juice is then added for each 2 cups of fruit, the mixture is simmered again for 20 minutes and preserved in sterilized jars. Some cooks substitute honey for sugar.

Food Value

Philippine analyses show the following values for the edible portion: calories, 335/lb (737/kg); moisture, 77.88%; protein, 1.81%; fat, 0.2%; sugar, 16.19%; fiber 0.57%; ash, 0.85%.

Toxicity

The oxalic acid, and possibly other unidentified principles, in the unripe fruit, the floral remnants of the ripe fruit, and all parts of the plant, cause oral and skin irritation. Some sensitive individuals claim that even the ripe fruit irritates the throat. It would be well to avoid eating the ceriman in quantity until it is determined that there are no undesirable reactions. Some individuals have experienced urticaria and anaphylaxis after eating ceriman. Some children and adults have reported diarrhea and intestinal gas after consuming the flesh or products made from it.

Other Uses

The aerial roots have been used as ropes in Peru. In Mexico, they are fashioned into coarse, strong baskets.

Medicinal Uses: In Mexico, a leaf or root infusion is taken daily to relieve arthritis. A preparation of the root is employed in Martinique as a remedy for snakebite.

Morton, J. 1987. Pineapple. p. 18–28. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Pineapple

Ananas comosus

The pineapple is the leading edible member of the family Bromeliaceae which embraces about 2,000 species, mostly epiphytic and many strikingly ornamental. Now known botanically as *Ananas comosus* Merr. (syns. *A. sativus* Schult. f., *Ananassa sativa* Lindl., *Bromelia ananas* L., *B. comosa* L.), the fruit has acquired few vernacular names. It is widely called *pina* by Spanish-speaking people, *abacaxi* in the Portuguese tongue, *ananas* by the Dutch and French and the people of former French and Dutch colonies; *nanas* in southern Asia and the East Indes. In China, it is *po-lo-mah;* sometimes in Jamaica, sweet pine; in Guatemala often merely "pine" .

Description

The pineapple plant is a terrestrial herb 2 1/2 to 5 ft (.75-1.5 m) high with a spread of 3 to 4 ft

(.9-1.2 m); a very short, stout stem and a rosette of waxy, straplike leaves, long-pointed, 20 to 72 in (50-180cm) 1ong; usually needle tipped and generally bearing sharp, upcurved spines on the margins. The leaves may be all green or variously striped with red, yellow or ivory down the middle or near the margins. At blooming time, the stem elongates and enlarges near the apex and puts forth a head of small purple or red flowers, each accompanied by a single red, yellowish or green bract. The stem continues to grow and acquires at its apex a compact tuft of stiff, short leaves called the "crown" or "top". Occasionally a plant may bear 2 or 3 heads, or as many as 12 fused together, instead of the normal one.

Fig. 6: A spiny-leaved pineapple in the Supply garden, Homestead, Fla., 1946.

As individual fruits develop from the flowers they join together forming a cone shaped, compound, juicy, fleshy fruit to 12 in (30 cm) or more in height, with the stem serving as the fibrous but fairly succulent core. The tough, waxy rind, made up of hexagonal units, may be dark-green, yellow, orange-yellow or reddish when the fruit is ripe. The flesh ranges from nearly white to yellow. If the flowers are pollinated, small, hard seeds may be present, but generally one finds only traces of undeveloped seeds. Since hummingbirds are the principal pollinators, these birds are prohibited in Hawaii to avoid the development of undesired seeds. Offshoots, called "slips", emerge from the stem around the base of the fruit and shoots grow in the axils of the leaves. Suckers (aerial suckers) are shoots arising from the base of the plant at ground level; those proceeding later from the stolons beneath the soil are called basal suckers or "ratoons".

Origin and Distribution

Native to southern Brazil and Paraguay (perhaps especially the Parana-Paraguay River) area where wild relatives occur, the pineapple was apparently domesticated by the Indians and carried by them up through South and Central America to Mexico and the West Indies long before the arrival of Europeans. Christopher Columbus and his shipmates saw the pineapple for the first time on the island of Guadeloupe in 1493 and then again in Panama in 1502. Caribbean Indians placed pineapples or pineapple crowns outside the entrances to their dwellings as symbols of friendship and hospitality. Europeans adopted the motif and the fruit was represented in carvings over doorways in Spain, England, and later in New England for many years. The plant has become naturalized in Costa Rica, Guatemala, Honduras and Trinidad but the fruits of wild plants are hardly edible.

Spaniards introduced the pineapple into the Philippines and may have taken it to Hawaii and Guam early in the 16th Century. The first sizeable plantation 5 acres (2 ha)—was established in Oahu in 1885. Portuguese traders are said to have taken seeds to India from the Moluccas in 1548, and they also introduced the pineapple to the east and west coasts of Africa. The plant was growing in China in 1594 and in South Africa about 1655. It reached Europe in 1650 and fruits were being produced in Holland in 1686 but trials in England were not success ful until 1712. Greenhouse culture flourished in England and France in the late 1700's. Captain Cook planted pineapples on the Society Islands, Friendly Islands and elsewhere in the South Pacific in 1777. Lutheran missionaries in Brisbane, Australia, imported plants from India in 1838. A commercial industry took form in 1924 and a modern canning plant was erected about 1946. The first plantings in Israel were made in 1938 when 200 plants were brought from South Africa. In 1939, 1350 plants were imported from the East Indies and Australia. but the climate is not a favorable one for this crop.

Over the past 100 years, the pineapple has become one of the leading commercial fruit crops of the tropics. In 1952-53, world production was close to 1,500,000 tons and reportedly nearly doubled during the next decade. Major producing areas are Hawaii, Brazil, Malaysia, Taiwan, Mexico, the Philippines, South Africa and Puerto Rico. By 1968, the total crop had risen to 3,600,000 tons, of which only 100,000 tons were shipped fresh (mainly from Mexico, Brazil and Puerto Rico) and925.000 tons were processed. In the period 1961-66, imports of fresh pineapples into Europe rose by 70%. Soon many new markets were opening. In 1973, the total crop was estimated at 4,000,000 tons with 2.2 million tons processed. The increased worldwide demand for canned fruit has greatly stimulated plantings in Africa and Latin America. For years, Hawaii supplied 70% of the world's canned pineapple and 85% of canned pineapple juice, but labor costs have shifted a large segment of the industry from Hawaii to the Philippines. Because production costs in Hawaii (which are 50% labor) have increased 25% or more, Dole has transferred 75% of its operation to the Philippines, where, in 1983, it employed 10,000 laborers on about 25,000, mostly rented, acres (10,117 ha).

Pineapples were first canned in Malaya by a retired sailor in 1888 and exporting from Singapore soon followed. By 1900, shipments reached a half million cases. The industry alternately grew and declined, and then ceased entirely for 3 1/2 years during World War II. The Malaysian Pineapple Industry Board was established in 1959. Thereafter there has been steady progress. The pineapple, was a very minor crop in Thailand until 1966 when the first large cannery was built. Others followed. Since then processing and exporting have risen rapidly. In 1977-78 many farmers switched from sugarcane to pineapple. Of the annual production of 1 1/2 million tons, 1/8 is canned as fruit or Julce.

South Africa produces 2.7 million cartons of canned pineapple yearly and exports 2.4 million. In addition, 31,000 tons of fresh pineapple are sold on the domestic market and 500,000 cartons exported yearly. As in many areas, pineapple culture existed on a small scale on the Ivory Coast until post WW II when cultural efforts were stepped up. By 1950, annual production amounted to 1800 tons. By 1972, it had risen to 200,000 tons for shipment, fresh or canned, to western Europe. Cameroun's annual production is about 6,000 tons.

In the Azores, pineapples have been grown in green-houses for many years for export mainly to Portugal and Madeira. They are of luxury quality, carefully tended and blemish free, graded for uniform size and well padded in each box for shipment.

As of 1971, the ten leading exporters of fresh pineapples were (in descending order): Taiwan (39,621 tons), Puerto Rico, Hawaii, Ivory Coast, Brazil, Guinea, Mexico, South Africa, Philippines and Martinique (5,000 tons). The ten leading exporters of processed pineapples were (in descending order): Hawaii, Philippines, Taiwan, South Africa, Malaysia (Singapore), Ivory Coast, Australia, Ryukyu, Mexico, Thailand (10,500,000 tons).

In Puerto Rico, the pineapple is the leading fruit crop, 95% produced, processed and marketed by the Puerto Rico Land Authority. The 1980 crop was 42,493 tons having a farm value of 6.8 million dollars.

For 250 years, pineapples have been grown in the Bahama Islands. At one time plantings on Eleuthera, Cat Island and Long Island totaled about 12,000 acres. The pineapple was a pioneer crop along the east coast of Florida and or, the Keys. In 1860 fields were established on Plantation Key and Merritt's Island. And in 1876 planting material from the Keys was set out all along the central Florida east coast. Shipping to the North began in 1879. In 1910 there were 5000 to 10,000 acres stretching as far north as Ft. Pierce. There were more than a dozen families raising pineapples on Elliott's Key where an average crop was 50,000 to 75,000 dozen fruits, mostly sent by schooner to New York. When the industry was flourishing, Florida shipped to New York, Philadelphia and Baltimore one million crates of pineapples a year from the sandy ridge along the Indian River. It was believed in those days that the pineapple benefitted by closeness to salt water.

Wood-lath sheds roofed with palmetto fronds, Spanish moss or tobacco cloth were constructed to provide shade which promoted vigorous plant growth and high fruit quality. Wood-burning ovens were scattered through the sheds for frost protection in winter. Small, open boxcars operating on steam or horsepower ran on wooden rails the length of the shed to transport loads of fruit to the packing station. In open fields, plants were sheltered by palmetto fronds from mid-December to mid-March. 'Smooth Cayenne' had to be grown in sheds. It was not successful in the open. One early planter on Eden Island moved his farm to the mainland because bears ate the ripe fruits. With the coming of the railroad in 1894, pineapple growing expanded. The 1908-09 crop was 1,110,547 crates. Then Cuban competition for U.S. markets caused prices to fall and many Florida growers gave up. The ridge pineapple fields begain to fail as the humus was exhausted by cultivation. Fertilization was steadily raising the pH too high for the pineapple. World War I brought on a shortage of fertilizer, then several freezes in 1917 and 1918 devastated the industry.

In the early 1930's, the United Fruit Company supplied slips for a new field at White City but the pressure of coastal development soon reduced this to a small patch. Shortly after World War II, a plantation of 'Natal Queen' and 'Eleuthera' was established in North Miami but, after a few years, the operation was shifted inland to Sebring, in Highlands County, Central Florida, where it still produces on a small scale.

Varieties

In international trade, the numerous pineapple cultivars are grouped in four main classes: 'Smooth Cayenne', 'Red Spanish', 'Queen', and 'Abacaxi', despite much variation in the types within each class.

'Smooth Cayenne' or 'Cayenne', 'Cayena Lisa' in Spanish (often known in India, Sri Lanka, Malaysia and Thailand as 'Sarawak' or 'Kew') was selected and cultivated by Indians in Venezuela long ago and introduced from Cayenne (French Guyana) in 1820. From there it reached the Royal Botanical Gardens, Kew, England, where it was improved and distributed to Jamaica and Queensland, Australia. Because of the plants near freedom from spines except for the needle at the leaftip and the size-4 to 10 lbs (1.8 4.5 kg)-cylindrical form, shallow eyes, orange rind, yellow flesh, low fiber, juiciness and rich mildly acid flavor, it has become of greatest importance worldwide even though it is subject to disease and does not ship well. Mainly, it is prized for canning, having sufficient fiber for firm slices and cubes as well as excellent flavor.

It was the introduction of this cultivar into the Philippines from Hawaii in 1912 that upgraded the Philippine industry from the casual growing of the semi-wild type which was often seedy. There are several clones of 'Smooth Cayenne' in Hawaii which have been selected for resistance to mealybug wilt. It is the leading cultivar in Taiwan. In 1975, the Queensland Department of Primary Industries, after 20 years of breeding and testing, released a dual purpose cultivar named the 'Queensland Cayenne'. South Africas Pineapple Research Station, East London, after 20 years of selecting and testing of 'Smooth Cayenne' clones, has chosen 4 as superior especially for the canning industry.

'Hilo'is a variant of 'Smooth Cayenne' selected in Hawaii in 1960. The plant is more compact, the fruit is smaller, more cylindrical; produces no slips but numerous suckers It may be the same as the 'Cayenne Lisse' strain grown in Martinique and on the Ivory Coast, the fruit of which weighs from 2 to 2 3/4 lbs (1-1 1/2 kg) and has a very small crown.

'St. Michael', another strain of 'Smooth Cayenne' is the famous product of the Azores. The fruit weighs 5 to 6 lbs (2.25-2.75 kg), has a very small crown, a small core, is sweet with low acidity, and some regard it as insipid when fully ripe.

'Giant Kew', well-known in India, bears a large fruit averaging 6 lbs (2.75 kg), often up to 10 lbs (4.5 kg) and occasionall up to 22 lbs (10 kg). The core is large and its extraction results in too large a hole in canned slices.

'Charlotte Rothschild', second to 'Giant Kew' in size in India, tapers toward the crown, is orange-yellow when ripe, aromatic, very juicy. The crop comes in early. 'Baron Rothschild', a Cayenne strain, grown in Guinea, has a smaller fruit 1 3/4 to 5 lbs (0.8-2 kg) in weight, marketed fresh.

'Perolera' (also celled 'Tachirense', 'Capachera', 'Motilona', and 'Lebrija') is a 'Smooth Cayenne' type ranking second to 'Red Spanish' in importance in Venezuela. It has long been grown in Colombia. The plant is entirely smooth with no spine at the leaftip. The fruit is yellow, large-7 to 9 1bs (3-4 kg) and cylindrical.

'Bumanguesa', of Venezuela and Colombia, is probably a mutation of 'Perolera'. The fruit is red or purple externally, cylindrical with square ends, shallow eyes, deep-yellow flesh, very slender core but has slips around the crown and too many basal slips to suit modern commercial requirements.

'Monte Lirio', of Mexico and Central America, also has smooth leaves with no terminal spine. The fruit is rounded, white-fleshed, with good aroma and flavor. Costa Rica exports fresh to Europe.

Other variants of 'Smooth Cayenne' include the 'Esmeralda' grown in Mexico and formerly in Florida for fresh, local markets; 'Typhone', of Taiwan; 'Cayenne Guadeloupe', of Guadeloupe, which is more disease resistant than 'Smooth Cayenne'; and 'Smooth Guatemalan' end 'Palin' grown in Guatemala; also 'Piamba da Marquita' of Colombia. Some who have made efforts to classify pineapple strains have proposed grouping all smooth-leaved types under the collective name 'Maipure'. In Amazonas, Venezuela, this name is given to a large plant with smooth leaves stained with red. The fruit has 170 to 190 eyes.

Philipps Platts, a leading pineapple authority, experimented with 60 to 70 cultivars in Florida but **'Red Spanish'** proved most dependable. Despite the spininess of the plant, it still is the most popular among growers in the West Indies, Venezuela and Mexico. 'Red Spanish' constitutes 85% of all commercial planting in Puerto Rico and 75% of the production for the fresh fruit market. It is only fair for canning. The fruit is more or less round, orange-red externally, with deep eyes, and ranges from 3 to 6 lbs (1.36-2.7 kg). The flesh is pale-yellow, fibrous, with a large core, aromatic and flavorful. The fruit is hard when mature, breaks off easily and cleanly at the base in harvesting, and stands handling and transport well. It is highly resistant to fruit rot though subject to gummosis.

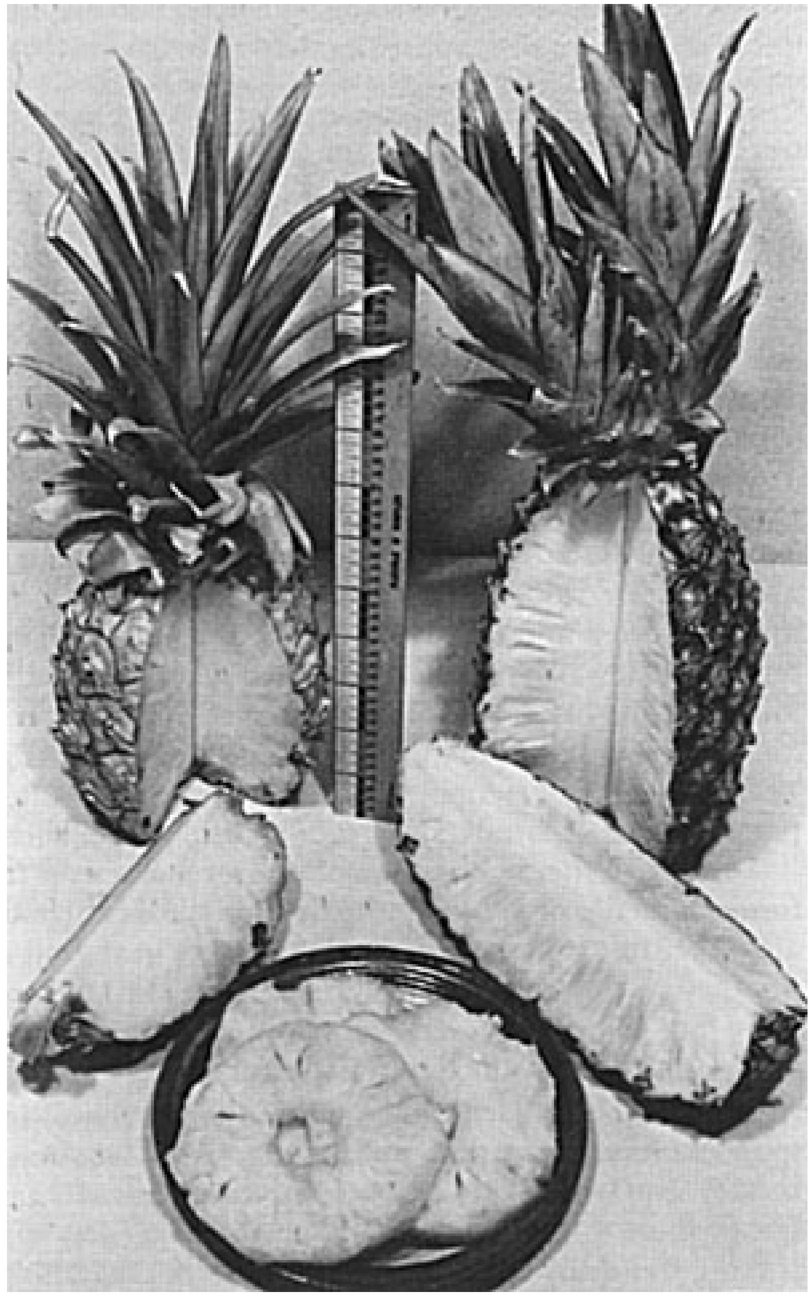

Fig. 7: 'Red Spanish' (left) and 'Abacaxi' (called 'English' in the Bahamas) (right). In: K. and J. Morton, *Fifty Tropical Fruits of Nassau*, 1946.

Two vigorous hybrids of 'Smooth Cayenne' and 'Red Spanish' were developed at the Agricultural Experiment Station of the University of Puerto Rico and released in 1970—'P.R. 1-56' and the slightly larger 'P.R. 1 67', both with good resistance to gummosis and mealybug wilt and of excellent fruit quality. 'P.R. 1 67' averages 5 3/4 lbs (2.5 kg), gives a high yield—32 tons per acre (79 tons/ha). The fruit is sweeter yet with more acidity than 'Red Spanish', less fibrous and good for marketing fresh and for canned juice. It was introduced into Venezuela about 1979 and is grown in the State of Lara.

'Cabezona' ('Bull Head', or 'Pina de ague') is a prominent variant (a natural tetraploid) of 'Red Spanish' long grown in Puerto Rico in the semiarid region of Lajas, to which it is well suited; also in El Salvador. The plant is large, over 3 ft (1 m) high; the leaves are gray-green. The fruit is conical but not as tall as that of 'Valera'; averages 4 to 6 lbs (1.8-2.75 kg) and may reach 18 lbs (8 kg) or more. It is orange-yellow at maturity, has few fibers and sweet-acid flesh. The stem is large and extends up into the base of the fruit and if the fruit is broken off when harvested it leaves a cavity. Consequently, it must be cut with a machete and later trimmed flush with the base in the packing house. It is marketed fresh only. It is resistant to gummosis. Platts reported that it gave a low yield and was disease prone in Florida. There are small plantings in the States of Trujillo and Monagas, Venezuela. It has been cultivated frequently in the Philippines.

'Valera' ('Negrita', or 'Andina'), is an old cultivar originating in Puerto Rico; it is grown in the States of Lara, Merida and Trujillo in Venezuela. It is a small to medium plant with long, narrow, spiny, purple green leaves. The fruit is conical cylindrical, weighing 3 1/2 to 5 1/2 lbs (1.5-2.5 kg); is purple outside with white flesh.

'Valera Amarilla' is a 'Red Spanish' strain grown in the States of Lara and Trujillo in Venezuela. The fruit is broad cylindrical and tall with a large crown; weighs 4 1/2 to 9 lbs (2-4 kg); is yellow externally with very deep eyes, about 72 to 88 in number. The flesh is pale-yellow and very sweet in flavor.

'Valera Roja', grown in Lara, Trujillo and Merida, Venezuela, is a small-to-medium plant with cylindrical fruit 1 1/2 to 2.2 lbs (0.6-1 kg) in weight, reddish externally, with 100 eyes. It has pale-yellow flesh.

'Castilla' is a 'Red Spanish' strain grown in Colombia and El Salvador.

'Cumanesa', supposedly a selection of 'Red Spanish', grown mainly in the State of Sucre, Venezuela, is a medium-sized plant, very spiny, producing an oblong fruit with a large crown. It is orange-yellow externally; weighs 2 to 3 3/4 lbs (0.9-1.70 kg). and has yellowish-white flesh.

'Morada', believed to be a variant of 'Red Spanish', is one of the less important cultivars of Colombia and the State of Monagas, Venezuela. The plant is large, with long, narrow, purple-red leaves. The fruit is broad-cylindrical, purple-red externally, with white flesh.

'Monte Oscuro' ('Pilon'), is a large plant with broad, sawtoothed, spiny-edged leaves. The fruit is barrel-shaped, large, weighing 6.6 lbs (3 kg); has 160-180 medium-deep eyes; is yellow outside with deep-yellow, fibrous flesh. It is ,grown among *Mauritia* palms in the State of Monagas, Venezuela.

'Abacaxi' (also called 'White Abacaxi of Pernambuco', 'Pernambuco', 'Eleuthera', and 'English') is well known in Brazil, the Bahamas and Florida. The plant is spiny and disease-resistant. Leaves are bluish-green with red-purple tinge in the bud. The numerous suckers need thinning out. The fruit weighs 2.2 to ll lbs (1-5 kg), is tall and straight-sided; sunburns even when erect. It is very fragrant. The flesh is white or very pale yellowish, of rich, sweet flavor, succulent and juicy with only a narrow vestige of a core. This is rated by many as the most delicious pineapple. It is too tender for commercial handling, and the yield is low. The fruit can be harvested without a knife; breaks off easily for marketing fresh.

'Sugarloaf' (also called 'Pan de Azucar') is closely related to 'Abacaxi', and much appreciated in Central and South America, Puerto Rico, Cuba and the Philippines. The leaves of the plants and crowns pull out easily and this fact gave rise to the unreliable theory that pineapple ripeness is indicated by the looseness of the leaves. The fruit is more or less conical, sometimes round; not colorful; weighs 1 1/2 to 3 lbs (0.68-1.36 kg). Flesh is white to yellow, very sweet, juicy. This cultivar is too tender for shipping.

Among several strains of 'Sugarloaf' are 'Papelon', and 'Black Jamaica', and probably also 'Montufar' ('Sugar Slice' of Guatemala). The latter fruit is green, conical, weighs 2 to 5 1/2 lbs (0.8 2.5 kg); has yellow, very juicy, flesh, sweet yet a little acid. This pineapple also is too tender to ship.There are a number of tropical American cultivars not categorized as to groups, and among them are:

'Brecheche', grown to a limited extent in southern Venezuela, is a small fruit with small, spineless crown. Average weight is 1 1/2 to 2.2 lbs (0.7-1 kg). The fruit is yellow externally. Flesh is yellow, with little fiber, small core, very fragrant, very juicy.

'Caicara', grown to a small extent in the State of Bolivar, Venezuela, is a large fruit weighing 4 to 5 1/2 lbs (1.8-2.5 kg). with a large, spiny crown. It is cylindrical conical with deep eyes; yellow externally with white flesh, a little fiber, very juicy, with large core.

'Chocona' and 'Sante Clara' are cultivars that have been introduced into Trinidad.

'Congo Red' is a plant with bright-red, long-lasting flowers. The fruit bends over and cracks in hot, dry weather. It weighs up to 5 lbs (2.25 kg), is waxy, with yellow flesh of good flavor.

'Panare', named after the tribe of Indians that has grown it for a long time, is commercially grown to a small extent in the State of Bolivar, Venezuela. The plant is of medium size with long, spiny leaves. The fruit is bottle-shaped, small, 1 to 1 l/2 lbs (0.45-0.70 kg), with small crown; ovate, with deep eyes; orange externally with deep-yellow flesh; slightly fragrant, with little fiber and small core.

'Santa Marta' of Colombia, is subject to cracking of the core in hot, dry weather.

In Peru, farmers still grow the old common 'Criolla' because it can be sold fresh and is not easily damaged in shipment. But modern pineapple production in that country depends on the 'Smooth Cayenne' for canning.

Minor cultivars in Colombia include: 'Amarilla de Cambao', 'Amarilla de Tocaima', 'Blanca Chocoana', 'Blanca del Atrato', 'Blanca de Valle del Cauca', 'Cimarrona', 'Espanola de Santander', 'Hartona', 'Jamaiquena' and 'Manzana'.

'Cacho de Venado' is grown to a small extent in Monagas and Sucre, and 'Injerta' in Trujillo, Venezuela.

'Pearl', 'Itaparica', 'Paulista', and 'Maranhao' (or 'Amarella') are spoken of in Brazil; 'Azucaron' in El Salvador; 'Roja' in Mexico. It remains to be determined if some of these names are merely synonyms for cultivars already referred to.

'Mauritius' (also known as 'European Pine', 'Malacca Queen', 'Red Ceylon' and 'Red Malacca') is one of the 2 leading pineapple cultivars in Malaya; also important in India and Ceylon. The leaves are dark green with broad red central stripe and red spines on the margins. The fruit is small, 3 to 5 lbs (1.36-2.25 kg), yellow externally; has a thin core and very sweet flesh. It is sold fresh and utilized for juice.

'Singapore Red' (Also called 'Red Jamaica', 'Singapore Spanish', 'Singapore Queen', 'Singapore Common') is second to 'Mauritius' in popularity. The leaves are usually all-green but sometimes have a reddish stripe near the margins; they are rarely spiny except at the tips. The fruits, cylindrical, reddish, with deep eyes, are small—3 1/2 to 5 lbs (1.6-2.25 kg)—with slender core, fibrous, golden-yellow flesh; insipid raw but valued for canning. The plant is disease and pest-resistant.

The related 'Green Selangor' (also called 'Selangor Green', 'Green Spanish', and 'Selassie') of Malaysia has all-green leaves prickly only at the tips. The flesh is golden-yellow, often with white dots. This cultivar is grown for canning.

'Queen' (also called 'Common Rough' in Australia) is the leading cultivar in South Africa, Queensland and the Philippines. The plant is dwarf, compact, more cold-resistant and more disease-resistant then 'Smooth Cayenne'. It matures its fruit early but suckers freely and needs thinning, and the yield is low. The fruit is conical, deep-yellow, with deep eyes; weighs 1 to 2 1/2 lbs (0.45-1.13 kg); is less fibrous than 'Smooth Cayenne', but more fragrant; it is juicy, of fine flavor with a small, tender core. It is sold fresh and keeps well. It is only fair for canning because of its shape which makes for much waste.

'Natal Queen' of South Africa, also grown in El Salvador, produces many suckers. The fruit weighs 1 1/2 to 2 lbs (0.75-0.9 kg).

'MacGregor', a variant of 'Nasal Queen' selected in South Africa and grown also in Queensland, is a spreading, more vigorous plant with broad leaves and large suckers produced less freely. The fruit is cylindrical, medium to large, with firm flesh and flavor resembling 'Queen'.

'James Queen' (formerly 'Z') is a mutation of 'Nasal Queen' that originated in South Africa. It has larger fruit with square shoulders.

'Ripley' or 'Ripley Queen', ,grown in Queensland, is a dwarf, compact plant with crimson tinge on leaves; takes 22 weeks from flowering to fruit maturity; is an irregular bearer. The fruit weighs 3 to 6 lbs (1.36-2.7 kg); is pale-copper externally; flesh is pale-yellow, non-fibrous, very sweet and rich. In Florida this cultivar tends to produce suckers without fruiting.

'Alexandria', a selection of 'Ripley Queen' in Queensland, is more vigorous with large suckers and fruit. The fruit is conical, tender, with 'Ripley Queen' flavor.

'Egyptian Queen' was introduced into Florida in 1870. It was popular at first, later abandoned. The fruit weighs 2 to 4 lbs (0 9-1.8 kg).

'Kallara Local' is a little-known cultivar in India. Minor strains in Thailand are 'Pattavia', 'Calcutta', 'Sri Racha', 'Intorachit' and 'Chantabun'.

In the evaluation of pineapples, the crown can be an asset or a liability. Small crowns detract from the decorative appearance of the fruit; large crowns are more attractive but hamper packing and constitute too great a proportion of inedible material from the standpoint of the purchaser.

Climate

The pineapple is a tropical or near tropical plant limited (except in greenhouses) to low elevations between 30°N and 25°S. A temperature range of 65°-95°F (18.33-45°C) is most favorable, though the plant can tolerate cool nights for short periods. Prolonged cold retards growth, delays maturity and causes the fruit to be more acid. Altitude has an important effect on the flavor of the fruit. In Hawaii, the 'Smooth Cayenne' is cultivated from sea level up to 2,000 ft (600 m). At higher elevations the fruit is too acid. In Kenya, pineapples grown at 4500 ft (1371 m) are too sweet for canning; between 4500 and 5700 ft (1371-1738 m) the flavor is most suitable for canning; above 5700 ft (1738 m) the flavor is undesirably acid. Pineapples are grown from sea level to 7545 ft (2300 m) in Ecuador but those in the highlands are not as sweet as those of Guayaquil.

Ideally, rainfall would be about 45 in (1,143 mm), half in the spring and half in the fall; though the pineapple is drought tolerant and will produce fruit under yearly precipitation rates ranging from 25 to 150 in (650-3,800 mm), depending on cultivar and location and degree of atmospheric humidity. The latter should range between 70 and 80 degrees.

Soil

The best soil for pineapple culture is a well-drained, sandy loam with a high content of organic matter and it should be friable for a depth of at least 2 ft (60 cm), and pH should be within a range of 4.5 to 6.5. Soils that are not sufficiently acid are treated with sulfur to achieve the desired level. If excess manganese prevents response to sulfur or iron, as in Hawaii, the plants require regular spraying with very weak sulfate or iron. The plant cannot stand waterlogging and if there is an impervious subsoil, drainage must be improved. Pure sand, red loam, clay loam and gravelly soils usually need organic enrichment. Filter presscake from sugar mills, worked into clay soils in Puerto Rico, greatly enhances plant vigor, fruit yield, number of slips and suckers.

Propagation

Crowns (or "tops"), slips (called nlbs or robbers in New South Wales), suckers and ratoons have all been commonly utilized for vegetative multiplication of the pineapple. To a lesser degree, some growers have used "stumps", that is, mother plant suckers that have already fruited. Seeds are desired only in breeding programs and are usually the result of hand pollination. The seeds are hard and slow to germinate. Treatment with sulfuric acid achieves germination in 10 days, but higher rates of germination (75-90 %) and more vigorous growth of seedlings results from planting untreated seeds under intermittent mist.

The seedlings are planted when 15-18 months old and will bear fruit 16-30 months later. Vegetatively propagated plants fruit in 15-22 months.

In Queensland, tops and slips from the summer crop of 'Smooth Cayenne' are stored upside down, close together, in semi-shade, for planting in the fall. Some producers salvage the crowns from the largest grades of fruits going through the processing factory to be assured of high quality planting material.

South African experiments with 'Smooth Cayenne' have shown medium-size slips to be the best planting material. Next in order of yield were large crowns, medium-size suckers, medium-size crowns and large suckers. Medium and large suckers, however, fruited earlier. Trimming of basal leaves increased yields. Workers in Johore, Malaya, report, without specifying cultivar, that large crowns give highest yield and more slips, followed by small crowns, big slips, small slips, large and small suckers in descending order.

With the 'Red Spanish' in Puerto Rico, the utilization of large slips for planting in the first quarter of the year, medium slips during the next six months, and small slips in the final quarter, provides fruits of the maximum size over an extended period of harvest. Storage of slips until optimum planting time prevents premature bloom and diminished fruit size.

The 'Red Spanish' reaches shipping-green stage (one week before coloring begins) in Puerto Rico 150 days after natural blooming.

In South Africa the 'Queen' is grown mainly from stumps, secondly from suckers. The stumps which have fruited are detached from the mother plant as soon as possible to avoid their developing suckers of their own. In comparison with suckers, the stumps are consistently heavier in yield after the 4th crop. When suckers are used, those of medium size, approximately 18 in (45 cm) long, planted shallow and upright, yield best.

In the past, growers preferred plants that supplied abundant basal slips for planting, not recognizing the fact that such plants gave smaller fruits than those without slips or suckers. Also, breeders aim toward elimination of slips to facilitate harvesting. Because of the increased demand for planting material, a new method of mass propagation received wide attention in 1960. During the harvest, plants that have borne single-crowned, superior fruits without basal slips are selected and marked. Following harvest, these plants are cut close to the ground, the leaves are stripped off and the stems—usually 1 to 2 ft (30-60 cm) long and 3 to 4 in (7.5-10 cm) thick—are sliced lengthwise into 4 triangular strips. The strips are disinfected and placed 4 in (10 cm) apart, with exterior side upward, in beds of sterilized soil, semi-shaded and sprinkler-irrigated. Shoots emerge in 3 to 5 weeks and are large enough to transplant to the nursery in 6 to 8 weeks. 'Smooth Cayenne' yields an average of 3 shoots per slice. 'Red Spanish' and 'Natal Queen', 4 per slice.

This use of the stem is a major improvement over the former practice of allowing it to develop suckers high up after the fruit is harvested. If such suckers bear fruit *in situ* they are not strong enough to support it and collapse. They are better removed for planting, but repeated removal of suckers weakens the mother plant.

In Sri Lanka, the shortage of planting material inspired experiments at first utilizing stem cross-sections 1 in (2.5 cm) thick—15 to 24 from each stem. These sprouted in 4 weeks but plant growth was slow and fruiting was delayed for 30 months. Most of the cuttings developed a single sprout, some as many as 5, others, none at all. Accordingly, this technique was abandoned in favor of a system developed for purposes of reproducing a selected strain in Hawaii. Stems are cut into segments bearing 3 to 5 whorls of leaves. The leaves are trimmed to 4 to 5 in (10-12.5 cm) and the disinfected cuttings set upright in beds until each gives rise to one strong plantlet which is then transferred to the nursery.

The butts, or bases, of mother plants, with leaves intact, are laid end to end in furrows in nurseries and covered with 2 to 3 in (5-7.5 cm) of soil. Sprouting occurs in 6 to 8 weeks. The butts give an average of 6 suckers each, though some have put forth up to 25. A one-acre (0.4 ha) nursery of 25,000 butts, therefore, yields between 100,000 and 200,000 suckers.

The Pineapple Research Institute in Hawaii has also employed axillary buds at the base of crowns. Each crown segment may develop 20 plantlets. This method has been adopted in Sri Lanka for perpetuating superior strains but not for commercial cultivation because the resulting plants require 24 months or more to fruit.

In India, because of low production of slips and suckers in 'Smooth Cayenne', crown cuttings (15-16 per crown) have been adopted for propagation with 95% success, and this method is considered more economical than the utilization of butts.

Vegetative propagation does not assure facsimile reproduction of pineapple cultivars, as many mutations and distinct clones have occurred in spite of it.

Culture

The land should be well prepared at the outset because the pineapple is shallow-rooted and easily damaged by post-planting cultivation. Fumigation of the soil contributes to high quality and high yields.

Planting: In small plots or on very steep slopes, planting is done manually using the traditional short-handled narrow-bladed hoe, the handle of which, 12 in (30 cm) long, is used to measure the distance between plants. Crowns are set firmly at a depth of 2 in (5 cm); slips and suckers at 3 1/2 to 4 in (9 10 cm). Butts, after trimming and drying for several days, are laid end-to-end in furrows and covered with 4 in (10 cm) of soil.

Double-rowing has been standard practice for many years, the plantlets set 10 to 12 in (25 30 cm) apart and staggered, not opposite, in the common rows, and with 2 ft (60 cm) between the two rows. An alley 3, 5 1/2 or 6 ft (.9, 1.6 or 1.8 m) wide is maintained between the pairs, allowing for plant populations of 17,400, 15,800 or 14,500 per acre (42,700, 37,920 or 33,800 per ha) respectively. Close spacing gives highest total crop weight—e.g.. 18,000 plants/acre = 28.8 tons (43,200 plants/ha = 69.12 tons). However, various trials have shown that overcrowding has a negative effect, reducing fruit size and elongating the form undesirably, and it reduces the number of slips and suckers per plant. Density trials with 'P.R. 1-67' in Puerto Rico demonstrated that 21,360 plants per acre (51,265/ha) yielded 35.8 tons/:acre (86 tons/ha) in the main crop and 18.9 tons/acre (45.43 tons/ha) in the ratoon crop, but only one slip per plant for replanting. Excessively wide spacing tends to induce multiple crowns in 'Smooth Cayenne' in Hawaii and in 'Red Spanish' in Puerto Rico.

Some plantings are mulched with bagasse. In large operations, asphalt-treated paper, or black plastic mulch is regarded as essential. It retards weeds, retains warmth in cool seasons, reduces loss of soil moisture, and can be laid by machines during the sterilization and pre-fertilization procedures. Mulch necessitates removal of basal leaves of crowns, slips and suckers and the use of a tool to punch a hole at the pre-marked planting site for the insertion of each plantlet. The mulch is usually rolled onto rounded beds 3 1/4 ft (1 m) wide.

Mechanical planting: Research on the potential of machines to replace the hard labor of planting pineapples was begun in Hawaii in 1945. A homemade device was first employed in Queensland in 1953. Early semi-mechanical planters were self propelled platforms with driver and two men who made the holes in the mulch and set the plants in place. With a 2-row planter, 3 men can set 7,000 plants per hour of operation. Frequent stops are necessary to reload with planting material. With improved equipment, mechanical planting has become standard practice in large plantations everywhere. The most sophisticated machines have attachments which concurrently apply premixed fertilizer and lay a broad center strip of mulch, set the plantlets along each edge, and place a narrow strip along the outer sides. The only manual operation, apart from driving, is feeding of the plantlets to the planting unit. With this system, up to 50,000 plants have been set out per day.

Fertilization: Nitrogen is essential to the increase of fruit size and total yield. Fertilizer trials in Kenya show that a total of 420 lbs N/acre (471.7 kg/ha) in 4 equal applications during the first year is beneficial, whereas no advantage is apparent from added potassium and, phosphorus. Puerto Rican studies have indicated that maximum yields are achieved by urea sprays supplying 147 lbs N/acre (151 kg/ha). In Queensland, total yield of mother plants and ratoons was increased 8% by urea spraying. Normal rate of application is 3 1/2 gals (13.3 liters) per 1,000 plants. On acid Bayamon sandy clay in Puerto Rico, addition of magnesium to the fertilizer mix or applying it as a spray (300 lbs magnesium sulfate per acre—327 kg/ha) increased yield by 3 tons/acre (7 tons/ ha). On sloping, stony clay loam high in potassium, Queensland growers obtained high yields of 'Smooth Cayenne' from side dressings of NPK mixture 5 times a year. On poor soils, nitrogen and potassium levels of the plants may become low toward the end of the crop season. This must be anticipated early and suitable adjustments made in the application of nutrients. Potassium uptake is minimal after soil temperatures drop below 68°F (20°C). On fine sandy loam in Puerto Rico, the cultivar 'P.R. 1-67' performed best with 13-3-12 fertilizer applied at the rate of 1.5 tons/acre (3.74 tons/ha). In this expertmeet, 13,403 plants/acre (32,167/ha) produced 9,882 fruits/acre (23,717/ha), weighing 31.28 tons/acre (75 tons/ha). In Venezuela, 6,250 medium-size fruits per acre (15,000 fruits/ha) is considered a very good crop.

Fruit weight has been considerably increased by the addition of magnesium. In Puerto Rican trials, magnesium treatment resulted in 54% more total weight providing an average of 2.7 more tons/acre (64.8 tons/ha) than in control plots. Fruit size and total yield have been enhanced by applying chelated iron with nitrogen; also, where chlorosis is conspicuous, by accompanying nitrogen with foliar sprays of 0.10% iron and manganese.

Some growers thin out suckers and slips to promote stronger growth of those that remain.

Irrigation: Irrigation is desirable only in dry seasons and should not exceed 1 in (2.5 cm) semi-monthly.

Weed Control: Manual weeding in pineapple fields is difficult and expensive. It requires protective clothing and tends to induce soil erosion. Coir dust has been used as mulch in Sri Lanka to discourage weeds but it has a deleterious effect on the crop, delaying or preventing flowering. The use of paper or plastic mulch and timely application of approved herbicides are the best means of preventing weed competition with the pineapple crop.

Flower Induction: Pineapple flowering may be delayed or uneven, and it is highly desirable to attain uniform maturity and also to control the time of harvest in order to avoid overproduction in the peak periods. In 1874 in the Azores it was accidentally discovered that smoke would bring pineapple plants into bloom in 6 weeks. The realization that ethylene was the active ingredient in the smoke led to the development of other methods.

As far back as 1936, compressed acetylene gas, or a spray of calcium carbide solution (which generates acetylene) were employed to expedite uniform blooming. Some growers have merely deposited calcium carbide in the crown of each plant to be dissolved by rain. A more advanced method is the use of the hormone, *a*-naphthaleneacetic acid (ANA) or *B* naphylacetic acid (BNA) which induce formation of ethylene. In recent years, *B*-hydroxyethyl hydrazine (BOH) came into use. Treatment is given when the plants are 6 months old, 3 months before natural flowering time. The plants should have reached the 30 leaf stage at this age.

Spraying of a water solution of ANA on the developing fruit has increased fruit size in 'Smooth Cayenne' in Hawaii and Queensland. In West Malaysia, spraying 'Singapore Spanish' 6 weeks after flowering with Planofix, an ANA-based trade product, delayed fruit maturity, increased fruit size, weight and acidity. Similar results have been seen after hormone treatment of 'Cayenne Lisse' on the Ivory Coast.

Trials with 'Sugarloaf' in Ghana showed calcium carbide and BOH equally effective on 42-to 46-week-old plants, and Ethrel performed best on 35-to 38-week-old plants. 'Sugarloaf' seems to respond 10 days earlier than 'Red Spanish'.

Ethrel, or the more recently developed Ethephon, applied at the first sign of fruit ripening in a field will cause all the fruit to ripen simultaneously. It brings the ratoons into fruit quickly. There is a great saving in harvesting costs because it reduces the need for successive pickings.

Plants treated with naphthaleneacetic acid produce long, cylindrical, pointed fruits, maturing over an extended period of time, ripening first at the base while the apex is still unripe. Ethylene treatment results in a square shouldered, shorter fruit maturing over a shorter period and ripening more uniformly.

In Puerto Rico, treatment in 'Cabezona' can be done to induce flowering at any time of the year.

Pests

Nematodes *(Rotylenchulus, Meloidogyne, Pratylenchus, Ditylenchus, Helicotylenchus,* and other genera) cause stunting and degeneration in pineapple plants unless soil is fumigated. In Queensland, nematicides have increased yields by 22-40%. Crop rotation has been found effective in Puerto Rico. Turning the field over to Pangola grass *(Digitaria decumbens* Stent.) or green foxtail grass *(Setaria viridis* Beauv.) for 3 years suppresses nematode populations and benefits the soil but may not be practicable unless spare land is available for pineapple culture in the interim.

Mealybugs *(Pseudococcus brevipes* and P. *neobrevipes)* attack leaf bases and cause wilt. The leaves turn orange-brown and wither due to root rot. Prevention requires spraying and dusting to control the fire ants *(Solenopsis* spp.) which carry the mealybugs from diseased to healthy plants. Control is difficult because there are many weeds and other local plants acting.as mealybug hosts. Some success was achieved in Florida in combatting mealybugs with the parasitic wasp, *Hambletonia pseudococciaa* Comp., though the general use of insecticides limits the activity of the wasp.

The pineapple mite, or so-called red spider *(Dolichote-tranychus* (or *Stigmacus) floridanus* (Banks) also attacks leaf bases and is troublesome during prolonged droughts, heavily infesting the slips. The pineapple red scale *(Diaspis bromeliae)* has been a minor pest in Florida. Since 1942 this scale has spread to many pineapple districts in southeastern Queensland, with occasional serious infestations. Natural predators afford about 40% control. The palmetto beetle *(Rhynchophorus cruentatus)*, which feeds on palm logs, enters the bud and lays eggs in young fruits and the fruit stalk.

The sap beetle *(Carpophilus humeralis) is* one of the main enemies of pineapple fruits in Puerto Rico, Hawaii and Malaysia and is especially attracted to fruits affected by gummosis. Populations have been diminished by sanitary procedures and growing of cultivars resistant to gummosis, and chemical control is being evaluated.

In Brazil, larvae of the large moth, *Castnia licus,* and of the butterfly, *Thecla basilides,* damage the fruit. The latter is a problem in other parts of tropical America also and in Trinidad.

Cutworms eat holes in the base of the immature fruit. Fruit fly larvae do not pupate in 'Smooth Cayenne' but new hybrids lack resistance and may require treatment.

In New South Wales, poison baits are employed to combat fruit damage by crows, rats and mice. Rats may eat the base of the stem and destroy ratoons and suckers. Rabbits in winter eat the leaves as high as they can reach.

Diseases

In Queensland, top rot and root rot are caused by the soil fungi *Phytophthora cinnamomi* and P. *nicotianae* var. *parasitica* which are most prevalent in prolonged wet weather in autumn and winter. Improved drainage helps reduce the risk and monthly spraying with fungicide gives good control. P. *cinnamomi* may also cause rot in green fruit on ratoons. These diseases are largely prevented by the use of paper or plastic mulch on raised beds.

Base rot is caused by the fungus *Ceratocystis paradoxa,* especially where drainage is poor. The imperfect form (conidial state) of this fungus, known as *Thielaviopsis paradoxa,* causes butt rot in planting material, also soft rot or breakdown of fruits during shipment and storage. If 1/4-ripe 'Red Spanish' fruits are kept at temperatures between 44.6° and 46.4°F (7°-8°C) while in transit, soft rot will not develop.

Fusarium spp. in the soil are the source of wilt. Black heart is a physiological disorder not visible externally, usually occuring in winter particularly in locations where air flow is inadequate. Highest incidence in West Africa has been reported in midsummer. It begins as "endogenous brown spot" at the base of the fruitless close to the core. Later, affected areas merge. It has been attributed to chilling or low light intensity from dense planting or cloudiness. It can be controlled by one-day heat treatment at 90° to 100°F (32°-38°C) before or after refrigerated storage. In 1974, the microorganism *Erwinia chrysanthemi* was identified in Malaya as the cause of bacterial heart rot and fruit collapse.

Yellow spot virus on leaves is transmitted by *Thrips tabaci* Lind. Black speck and water blister are mentioned among other problems of the pineapple.

A condition called Crookneck is caused by zinc deficiency. It occurs mainly in plants 12-15 months old but is also frequent in suckers. The heart leaves become curled and twisted, waxy, brittle, and light yellowish-green. Sometimes the plant bends over and grows in a nearly horizontal position. Small yellow spots appear near the edges of the leaves and eventually merge and form blisters. Later, these areas become grayish or brownish and sunken. Treatment is usually a 1% solution of zinc sulfate. Many growers use a combined spray of 10% urea. 2% iron sulfate and 1% zinc sulfate. If burning occurs. the proportion of urea should be changed to 5%. Excessive use of urea for this or any other purpose can lead to leaf tip dieback and yellowing of older leaves due to the biuret content in urea.

Copper deficiency is evident in concave leaves with dead tips and waxiness without bloom on the underside.

Sunburn or sunscald develops when fruits fall over and expose one side to the sun, though 'Abacaxi' may sunburn even when erect. Affected fruits soon rot and become infested with pests. They must be cut as soon as noticed and safely disposed of where they will not contaminate other fruits. Dry grass, straw, excelsior or brown paper sleeves may be placed over fruits maturing in the summer to prevent sunburn.

Harvesting

It is difficult to judge when the pineapple is ready to be harvested. The grower must depend a great deal on experience. Size and color change alone are not fully reliable indicators. Conversion of starch into sugars takes place rapidly in just a few days before full maturity. In general, for the fresh fruit market, the summer crop is harvested when the eye shows a light pale green color. At this season, sugar content and volatile flavors develop early and steadily over several weeks. The winter crop is about 30 days slower to mature, and the fruits are picked when there is a slight yellowing around the base. Even then, winter fruit tends to be more acid and have a lower sugar level than summer fruit, and the harvest period is short. Fruits for canning are allowed to attain a more advanced stage. But overripe fruits are deficient in flavor and highly perishable.

Maturity studies conducted with 'Giant Kew' in India showed that highest quality is attained when the fruit is harvested at a specific gravity of 0.98-1.02, total soluble solids of 13.8-17%, or total soluble solids/acid ratio of 20.83-27.24 with development of external yellow color. Some people judge ripeness and quality by snapping a finger against the side of the fruit. A good, ripe fruit has a dull, solid sound; immaturity and poor quality are indicated by a hollow thud.

In manual harvesting, one man cuts off or breaks off the fruits (depending on the cultivar) and tosses them to a truck or passes them to 2 other workers with baskets who convey them to boxes in which they are arranged with the stems upward for the removal of bracts and application of a 3% solution of benzoic acid on the cut stem of all fruits not intended for immediate processing. The harvested fruits must be protected from rain and dew. If moist, they must be dried before packing. All defective fruits are sorted out for use in processing.

If the work is semi-mechanized, the harvesters decrown and trim the fruits and place them on a 30-ft conveyor boom which extends across the rows and carries the fruits to a bin on a forklift which loads it onto a truck or trailer. Some conveyors take the fruits directly into the canning factory from the field. In most regions of the world, pineapples are commonly marketed with crowns intact, but there is a growing practice of removing the crowns for planting. For the fresh fruit market, a short section of stem is customarily left on to protect the base of the fruit from bruising during shipment.

Total mechanical harvesting is achieved by 2 hydraulically operated conveyors with fingers on the top conveyor to snap off the fruit, the lower conveyor carrying it away to the decrowners. After the fruit has been conveyed away, the workers go through the field to collect the crowns (where they have been left on the tops of the plants) and place them on the conveyors for a trip to the bins which are then fork lifted and the crowns dumped into a planting machine.

Life of plantation

In Florida, 'Abakka' fields were maintained for 2, 3, or 4 crops. Some plantings of 'Red Spanish' were prolonged for 25-26 years. In current practice, after the harvesting of the first crop, workers trim off all but 2 ratoons which will bear fruit in 15-18 months. Perhaps there may be a second or third ratoon crop. Then the field is cleared to minimize carryover of pests and diseases. The method will vary with the interest in or practicality of making use of by products. In Malaya, fields have been cleared by cutting the plants, leaving them to dry for 12-16 weeks, then piling and burning. Spraying with kerosene or diesel fuel makes burning possible in 9 weeks. Spraying with Paraquat allows burning in 3 weeks but does not destroy the stumps which take 3-5 months to completely decay while new plants are set out between them.

Field practices will differ if pineapples are interplanted with other crops. In Malaya, pineapples have been extensively grown in young rubber plantations. In India and Sri Lanka the pineapple is often a catchcrop among coconuts. Venezuelan farmers may interplant with citrus trees or avocados.

Storage

Cold storage at a temperature of 40°F (4.44°C) and lower causes chilling injury and breakdown in pineapples. At 44.6-46.4°F (7-8°C) and above, 80-90% relative humidity and adequate air circulation, normal ripening progresses during and after storage. At best, pineapples may be stored for no more than 4-6 weeks. There is a possibility that storage life might be prolonged by dipping the fruits in a wax emulsion containing a suitable fungicide. Irradiation extends the shelf life of half- ripe pineapples by about one week.

Food Uses

In Puerto Rico and elsewhere in the Caribbean, Spaniards found the people soaking pineapple slices in salted water before eating, a practice seldom heard of today.

Field ripe fruits are best for eating fresh, and it is only necessary to remove the crown, rind, eyes and core. In Panama, very small pineapples are cut from the plant with a few inches of stem to serve as a handle, the rind is removed except at the base, and the flesh is eaten out-of-hand like corn on the cob. The flesh of larger fruits is cut up in various ways and eaten fresh, as dessert, in salads, compotes and otherwise, or cooked in pies, cakes, puddings, or as a garnish on ham, or made into sauces or preserves. Malayans utilize the pineapple in curries and various meat dishes. In the Philippines, the fermented pulp is made into a popular sweetmeat called *nata de pina*. The pineapple does not lend itself well to freezing, as it tends to develop off flavors.

Canned pineapple is consumed throughout the world. The highest grade is the skinned, cored fruit sliced crosswise and packed in sirup. Undersize or overripe fruits are cut into "spears", chunks or cubes. Surplus pineapple juice used to be discarded after extraction of bromelain (q.v.). Today there is a growing demand for it as a beverage. Crushed pineapple, juice, nectar, concentrate, marmalade and other preserves are commercially prepared from the flesh remaining attached to the skin after the cutting and trimming of the central cylinder. All residual parts cores, skin and fruit ends are crushed and given a first pressing for juice to be canned as such or prepared as sirup used to fill the cans of fruit, or is utilized in confectionery and beverages, or converted into powdered pineapple extract which has various roles in the food industry. Chlorophyll from the skin and ends imparts a greenish hue that must be eliminated and the juice must be used within 20 hours as it deteriorates quickly. A second pressing yields "skin juice" which can be made into vinegar or mixed with molasses for fermentation and distillation of alcohol.

In Africa, young, tender shoots are eaten in salads. The terminal bud or "cabbage" and the inflorescences are eaten raw or cooked. Young shoots, called *"hijos de pina"* are sold on vegetable markets in Guatemala.

Food Value Per l00 g of Edible Portion*

Moisture	81.3-91.2 g
Ether Extract	0.03 0.29 g
Crude Fiber	0.3-0.6 g
Nitrogen	0.038-0.098 g
Ash	0.21-0.49 g
Calcium	6.2 37.2 mg
Phosphorus	6.6-11.9 mg
Iron	0.27-1.05 mg
Carotene	0.003 0.055 mg
Thiamine	0.048 0.138 mg
Riboflavin	0.011-0.04 mg
Niacin	0.13-0.267 mg
Ascorbic Acid	27.0-165.2 mg

*Analyses of ripe pineapple made in Central America.

Sugar/acid ratio and ascorbic acid content vary considerably with the cultivar. The sugar content may change from 4% to 15% during the final 2 weeks before full ripening.

Toxicity

When unripe, the pineapple is not only inedible but poisonous, irritating the throat and acting as a drastic purgative.

Excessive consumption of pineapple cores has caused the formation of fiber balls (bezoars) in the digestive tract.

Other Uses

Bromelain: The proteolytic enzyme, bromelain, or bromelin, was formerly derived from pineapple juice; now it is gained from the mature plant stems salvaged when fields are being cleared. The yield from 368 lbs (167 kg) of stern juice is 8 lbs (3.6 kg) of bromelain. The enzyme is used like papain from papaya for tenderizing meat and chill proofing beer; is added to gelatin to increase its solubility for drinking; has been used for stabilizing latex paints and in the leather-tanning process. In modern therapy, it is employed as a digestive and for its anti-inflammatory action after surgery, and to reduce swellings in cases of physical injuries; also in the treatment of various other complaints.

Fiber: Pineapple leaves yield a strong, white, silky fiber which was extracted by Filipinos before 1591. Certain cultivars are grown especially for fiber production and their young fruits are removed to give the plant maximum vitality. The 'Perolera' is an ideal cultivar for fiber extraction because its leaves are long, wide and rigid. Chinese people in Kwantgung Province and on the island of Hainan weave the fiber into coarse textiles resembling grass cloth. It was long ago used for thread in Malacca and Borneo. In India the thread is prized by shoemakers and it was formerly used in the Celebes. In West Africa it has been used for stringing jewels and also made into capes and caps worn by tribal chiefs. The people of Guam hand-twist the fiber for making fine casting nets. They also employ the fiber for wrapping or sewing cigars. Pina cloth made on the island of Panay in the Philippines and in Taiwan is highly esteemed. In Taiwan they also make a coarse cloth for farmers' underwear.

The outer, long leaves are preferred. In the manual process, they are first decorticated by beating and rasping and stripping, and then left to ret in water to which chemicals may be added to accelerate the activity of the microorganisms which digest the unwanted tissue and separate the fibers. Retting time has been reduced from 5 days to 26 hours. The rested material is washed clean, dried in the sun and combed. In mechanical processing, the same machine can be used that extracts the fiber from sisal. Estimating 10 leaves to the lb (22 per kg), 22,000 leaves would constitute one ton and would yield 50-60 lbs (22-27 kg) of fiber.

Juice: Pineapple juice has been employed for cleaning machete and knife blades and, with sand, for scrubbing boat decks.

Animal Feed: Pineapple crowns are sometimes fed to horses if not needed for planting. Final pineapple waste from the processing factories may be dehydrated as "bran" and fed to cattle, pigs and chickens. "Bran" is also made from the stumps after bromelain extraction. Expendable plants from old fields can be processed as silage for maintaining cattle when other feed is scarce. The silage is low in protein and high in fiber and is best mixed with urea, molasses and water to improve its nutritional value.

In 1982, public concern in Hawaii was aroused by the detection of heptachlor (a carcinogen) in the milk from cows fed "green chop" leaves from pineapple plants that had been sprayed with the chemical to control the ants that distribute mealybugs. There is supposed to be a one year lapse to allow the heptachlor to become more dilute before sprayed plants are utilized for feed.

Folk Medicine: Pineapple juice is taken as a diuretic and to expedite labor, also as a gargle in cases of sore throat and as an antidote for seasickness. The flesh of very young (toxic) fruits is deliberately ingested to achieve abortion (a little with honey on 3 successive mornings); also to expel intestinal worms; and as a drastic treatment for venereal diseases. In Africa the dried, powdered root is a remedy for edema. The crushed rind is applied on fractures and the rind decoction with rosemary is applied on hemorrhoids. Indians in Panama use the leaf juice as a purgative, emmenagogue and vermifuge.

Ornamental Value

The pineapple fruit with crown intact is often used as a decoration and there are variegated forms of the plant universally grown for their showiness indoors or out. Since 1963, thousands of potted, ethylene treated pineapple plants with fruits have been shipped annually from southern Florida to northern cities as indoor ornamentals.

Morton, J. 1987. Banana. p. 29–46. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Banana

Musa x paridasiaca

The word "banana" is a general term embracing a number of species or hybrids in the genus *Musa* of the family Musaceae. Some species such as *M. Basjoo* Sieb. & Zucc. of Japan and *M. ornata* Roxb., native from Pakistan to Burma, are grown only as ornamental plants or for fiber. *M. textilis* Nee of the Philippines is grown only for its fiber, prized for strong ropes and also for tissue-thin tea bags. The so-called Abyssinian banana, *Ensete ventricosum* Cheesman, formerly *E. edule* Horan, *Musa ensete* Gmel., is cultivated in Ethiopia for fiber and for the staple foods derived from the young shoot, the base of the stem, and the corm.
Most edible-fruited bananas, usually seedless, belong to the species *M. acuminata* Colla (*M. cavendishii* Lamb. ex Paxt., *M. chinensis* Sweet, *M. nana* Auth. NOT Lour., *M. zebrina* Van Houtee ex Planch.), or to the hybrid *M.* X *paradisiaca* L. (*M.* X *sapientum* L.; *M. acumianta* X *M. balbisiana* Colla).

M. balbisiana Colla of southern Asia and the East Indies, bears a seedy fruit but the plant is valued for its disease-resistance and therefore plays an important role as a ";parent"; in the breeding of edible bananas.

M. fehi Bertero ex Vieill. and *M. troglodytarum* L. have been applied to the group of bananas known as fehi or fe'i but taxonomists have yet to make final decisions as to the applicability of these binomials.

To the American consumer, ";banana"; seems a simple name for the yellow fruits so abundantly marketed for consumption raw, and ";plantain"; for the larger, more angular fruits intended for cooking but also edible raw when fully ripe. However, the distinction is not that clear and the terms may even be reversed. The types we call ";banana"; are known by similar or very different names in banana-growing areas. Spanish-speaking people say *banana china* (Paraguay), *banano enano* (Costa Rica), *cambur* or *camburi* (Colombia, Venezuela), *cachaco, colicero, cuatrofilos* (Colombia); *carapi* (Paraguay), *curro* (Panama), guineo (Costa Rico, Puerto Rico, E1 Salvador); *murrapo* (Colombia); *mampurro* (Dominican Republic); *patriota* (Panama); *platano* (Mexico); *platano de seda* (Peru); *platano enano* (Cuba); *suspiro* (Dominican Republic); *zambo* (Honduras). Portuguese names in Brazil are: *banana maca*, *banana de Sao Tome'*, *banana da Prata*. In French islands or areas, the terms may be *bananier nain, bananier de Chine* (Guadaloupe), *figue*, *figue banane, figue naine* (Haiti). Where German is spoken, they say: *echte banane*, *feige*, or *feigenbaum*. In the Sudan, *baranda*.

The types Americans call ";plantain";, Plate IV, may be known as *banaan* (Surinam); *banano macho* (Panama); *banane* or *bananier* (Haiti, Guadeloupe, Martinique); *banane misquette* or *banane musquee*, or *pie banane* (Haiti); *bananeira de terra* (Brazil); *banano indio* (Costa Rica); *barbaro* (Mexico); *butuco* (Honduras); *parichao* (Venezuela); plantain (Guyana, Jamaica, Trinidad); *platano* (Cuba, Puerto Rico, Dominican Republic); *platano burro, platano hembra* (Cuba); *platano macho* (Cuba, Panama); *platano de la isla* (Peru); *topocho* or *yapuru* (Venezuela); *zapolote* (Mexico). Numerous other vernacular names, according to geographical region, are provided by N.W. Simmonds in his textbook, *Bananas*.

In India, there is no distinction between bananas and plantains. All cultivars are merely rated as to whether they are best for dessert or for cooking.

Description

The banana plant, often erroneously referred to as a "tree", is a large herb, with succulent, very juicy stem (properly "pseudostem") which is a cylinder of leaf-petiole sheaths, reaching a height of 20 to 25 ft (6-7.5 m) and arising from a fleshy rhizome or corm. Suckers spring up around the main plant forming a clump or "stool", the eldest sucker replacing the main plant when it fruits and dies, and this process of succession continues indefinitely. Tender, smooth, oblong or elliptic, fleshy-stalked leaves, numbering 4 or 5 to 15, are arranged spirally. They unfurl, as the plant grows, at the rate of one per week in warm weather, and extend upward and outward, becoming as much as 9 ft (2.75 m) long and 2 ft (60 cm) wide. They may be entirely green, green with maroon splotches, or green on the upperside and red purple beneath. The inflorescence, a transformed growing point, is a terminal spike shooting out from the heart in the tip of the stem. At first, it is a large, long-oval, tapering, purple-clad bud. As it opens, it is seen that the slim, nectar-rich, tubular, toothed, white flowers are clustered in whorled double rows along the floral stalk, each cluster covered by a thick, waxy, hoodlike bract, purple outside, deep-red within. Normally, the bract will lift from the first hand in 3 to 10 days. If the plant is weak, opening may not occur until 10 or 15 days. Female flowers occupy the lower 5 to 15 rows; above them may be some rows of hermaphrodite or neuter flowers; male flowers are borne in the upper rows. In some types the inflorescence remains erect but generally, shortly after opening, it begins to bend downward. In about one day after the opening of the flower clusters, the male flowers and their bracts are shed, leaving most of the upper stalk naked except at the very tip where there usually remains an unopened bud containing the last-formed of the male flowers. However, there are some mutants such as 'Dwarf Cavendish' with persistent male flowers and bracts which wither and remain, filling the space between the fruits and the terminal bud.

As the young fruits develop from the female flowers, they look like slender green fingers. The bracts are soon shed and the fully grown fruits in each cluster become a "hand" of bananas, and the stalk droops with the weight until the bunch is upside down. The number of "hands" varies with the species and variety.

The fruit (technically a "berry") turns from deep-green to yellow or red, or, in some forms, green-and white-striped, and may range from 2 1/2 to 12 in (6.4-30 cm) in length and 3/4 to 2 in (1.9-5 cm) in width, and from oblong, cylindrical and blunt to pronouncedly 3-angled, somewhat curved and hornlike. The flesh, ivory-white to yellow or salmon-yellow, may be firm, astringent, even gummy with latex, when unripe, turning tender and slippery, or soft and mellow or rather dry and mealy or starchy when ripe. The flavor may be mild and sweet or subacid with a distinct apple tone. Wild types may be nearly filled with black, hard, rounded or angled seeds 1/8 to 5/8 in (3-16 mm) wide and have scant flesh. The common cultivated types are generally seedless with just minute vestiges of ovules visible as brown specks in the slightly hollow or faintly pithy center, especially when the fruit is overripe. Occasionally, cross-pollination by wild types will result in a number of seeds in a normally seedless variety such as 'Gros Michel', but never in the Cavendish type.

Origin and Distribution

Edible bananas originated in the Indo-Malaysian region reaching to northern Australia. They were known only by hearsay in the Mediterranean region in the 3rd Century B.C., and are believed to have been first carried to Europe in the 10th Century A.D. Early in the 16th Century, Portuguese mariners transported the plant from the West African coast to South America. The types found in cultivation in the Pacific have been traced to eastern Indonesia from where they spread to the Marquesas and by stages to Hawaii.

Bananas and plantains are today grown in every humid tropical region and constitute the 4th largest fruit crop of the world, following the grape, citrus fruits and the apple. World production is estimated to be 28 million tons—65% from Latin America, 27 % from Southeast Asia, and 7 % from Africa. One-fifth of the crop is exported to Europe, Canada, the United States and Japan as fresh fruit. India is the leading banana producer in Asia. The crop from 400,000 acres (161,878 ha) is entirely for domestic consumption. Indonesia produces over 2 million tons annually, the Philippines about 1/2 million tons, exporting mostly to Japan. Taiwan raises over 1/2 million tons for export. Tropical Africa (principally the Ivory Coast and Somalia) grows nearly 9 million tons of bananas each year and exports large quantities to Europe.

Brazil is the leading banana grower in South America—about 3 million tons per year, mostly locally consumed, while Colombia and Ecuador are the leading exporters. Venezuela's crop in 1980 reached 983,000 tons. Large scale commercial production for export to North America is concentrated in Honduras (where banana fields may cover 60 sq mi) and Panama, and, to a lesser extent, Costa Rica. In the West Indies, the Windward Islands of Martinique and Guadeloupe are the main growers and for many years have regularly exported to Europe. Green bananas are the basic food of the people of Western Samoa and large quantities are exported.

In Ghana, the plantain is a staple food but up to the late 1960's the crop was grown only in home gardens or as a shade for cacao. When the cacao trees declined, solid plantings of plantain were established in their place and in newly cleared forest land where the richness of organic matter greatly promotes growth. By 1977, Ghana was harvesting 2,204,000 tons (2,000,000 MT) annually.

The plantain is the most important starchy food of Puerto Rico and is third in monetary value among agricultural crops, being valued at $30,000,000 annually. While improved methods of culture have been adopted in recent years and production has been increased by 15% in 1980, it was still necessary to import 1,328 tons (1,207 MT) to meet local demand. Annual per capita consumption is said to be 65 lbs (29.5 kg). In the past, most of the plantains in Puerto Rico were grown on humid mountainsides. High prices have induced some farmers to develop plantations on level irrigated land formerly devoted to sugarcane.

In tropical zones of Colombia, plantains are not only an important part of the human diet but the fruits and the plants furnish indispensable feed for domestic animals as well. The total plantain area is about 1,037,820 acres (420,000 ha) with a yield of 5,500 lbs per acre (5,500) kg/ha). Mexico grows about 1/6 as much, 35% under irrigation, and the crop is valued at $1,335 US per acre ($3,300 US/ha). Venezuela has somewhat less of a crop 517,000 tons from 146,000 acres (59,000 ha) in 1980—and the Dominican Republic is fourth in order with about 114,600 acres (46,200 ha). Bananas and plantains are casually grown in some home gardens in southern Florida. There are a few small commercial plantations furnishing local markets.

Varieties

Edible bananas are classified into several main groups and subgroups. Simmonds placed first the diploid *M. acuminata* group **'Sucrier'**, represented in Malaya, Indonesia, the Philippines, southern India, East Africa, Burma, Thailand, the West Indies, Colombia and Brazil. The sheaths are dark-brown, the leaves yellowish and nearly free of wax. The bunches are small and the fruits small, thin-skinned and sweet. Cultivars of this group are more important in New Guinea than elsewhere.

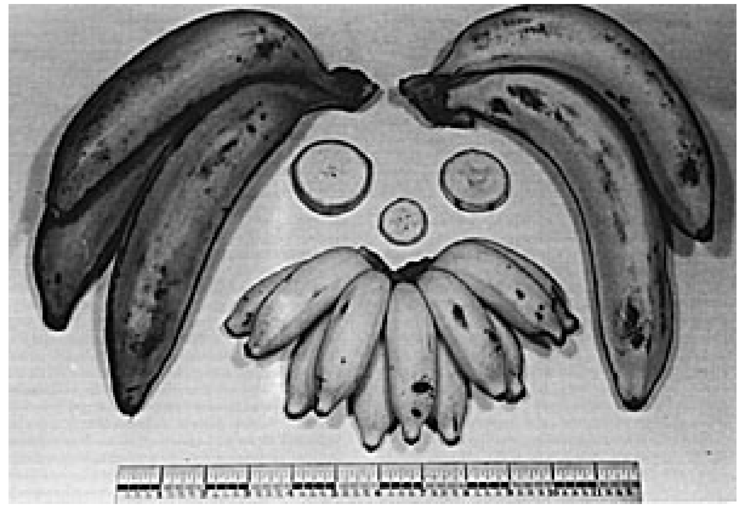

Fig. 8: Green plantains (left), 'Gros Michel' bananas(right) and 'Lady Finger' (center). In: K. and J. Morton, *Fifty Tropical Fruits of Nassau*, 1946.

Here belongs one of the smallest of the well-known bananas, the **'Lady Finger'**, also known as'Date'or'Fig', and, in Spanish, as 'Dedo de Dama', 'Datil', 'Nino', Bocadillo', 'Manices', 'Guineo Blanco', or 'Cambur Titiaro'. The plant reaches 25 ft (7.5 m) in height, has a slender trunk but a heavy root system that fortifies the plant against strong winds. The outer sheaths have streaks or patches of reddish brown. The bunch consists of 10 to 14 hands each of 12 to 20 fingers. The fruit is 4 to 5 in (10-12.5 cm) long, with thin, light-yellow skin and sweet flesh. This cultivar is resistant to drought, Panama disease and the black weevil but subject to Sigatoka (leaf spot). It is common in Latin America and commercial in Queensland and New South Wales.

In second place, there is the group represented by the prominent and widely cultivated **'Gros Michel'** originally from Burma, Thailand, Malaya, Indonesia and Ceylon. It was introduced into Martinique early in the 19th Century by a French naval officer and, a few years later, was taken to Jamaica; from there it was carried to Fiji, Nicaragua, Hawaii and Australia, in that sequence. It is a large, tall plant bearing long bunches of large, yellow fruits, and it was formerly the leading commercial cultivar in Central Africa, Latin America and the Caribbean, but has been phased out because of its great susceptibility to Panama disease. It has given rise to several named sports or mutants.

The Cavendish subgroup includes several important bananas:

a) The **'Dwarf Cavendish'**, Plate III, first known from China and widely cultivated, especially in the Canary Islands, East Africa and South Africa. The plant is from 4 to 7 ft (1.2-2.1 m) tall, with broad leaves on short petioles. It is hardy and wind resistant. The fruit is of medium size, of good quality, but thin-skinned and must be handled and shipped with care. This cultivar is easily recognized because the male bracts and flowers are not shed.

b) The **'Giant Cavendish'**, also known as 'Mons Mari, 'Williams', 'Williams Hybrid', or 'Grand Naine', is of uncertain origin, closely resembles the 'Gros Michel', and has replaced the 'Dwarf' in Colombia, Australia, Martinique, in many Hawaiian plantations, and to some extent in Ecuador. It is the commercial banana of

Taiwan. The plant reaches 10 to 16 ft (2.7-4.9 m). The pseudostem is splashed with darkbrown, the bunch is long and cylindrical, and the fruits are larger than those of the 'Dwarf' and not as delicate. Male bracts and flowers are shed, leaving a space between the fruits and the terminal bud.

Plate III: DWARF CAVENDISH BANANA, *Musa acuminata*

c) **'Pisang masak hijau'**, or 'Bungulan', the triploid Cavendish clone of the Philippines, Indonesia and Malaya, is erroneously called 'Lacatan' in Jamaica where it replaced 'Gros Michel' because of its immunity to Panama disease, though it is subject to Sigatoka (leaf spot). The plant is tall and slender and prone to wind injury. Its fruits ripen unevenly in winter, bruise easily and are inclined to spoil in storage. It is no longer grown commercially in Jamaica and the Windward Islands. The fruits are commonly used as cooking bananas in Jamaican households. Simmonds declares this cultivar is not the true 'Lacatan' of the Philippines. He suggested that 'Pisang masak hijau' may have been the primary source of all the members of the Cavendish group.

d) **'Robusta'**, very similar to the so-called 'Lacatan', has largely replaced that cultivar in Jamaica and the Windward Islands and the 'Gros Michel' in Central America because it is shorter, thick-stemmed, less subject to wind. It is being grown commercially also in Brazil, eastern Australia, Samoa and Fiji. It is resistant to Panama disease but prone to Sigatoka.

e) **'Valery'**, also a triploid Cavendish clone, closely resembles 'Robusta' and some believe it may be the same. However, it is being grown as a successor to 'Robusta'. It is already more widely cultivated than 'Lacatan' for export. As compared with other clones in cooking trials, it has low ratings because cooking hardens the flesh and gives it a waxy texture.

The Banana Breeding Research Scheme in Jamaica has developed a number of tetraploid banana clones with superior disease-resistance and some are equal in dessert quality to the so-called 'Lacatan' and 'Valery'.

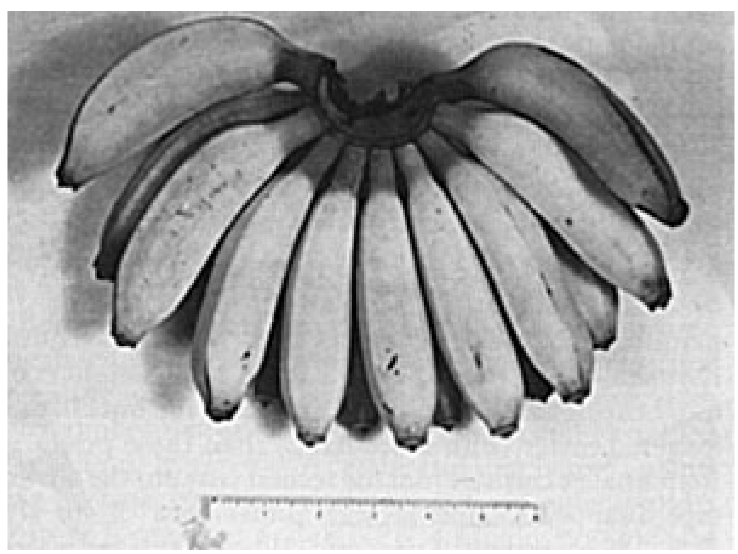

Fig. 9: 'Radja' banana, introduced into Florida by Dr. J.J. Ochse about 1957.

'Bluggoe' (with many other local names) is a cooking banana especially resistant to Panama disease and Sigatoka. It bears a few distinctly separated hands of large, almost straight, starchy fruits, and is of great importance in Burma, Thailand, southern India, East Africa, the Philippines, Samoa, and Grenada.

'Ice Cream' banana of Hawaii ('Cenizo' of Central America and the West Indies; 'Krie' of the Philippines), is a relative of 'Bluggoe'. The plant grows to 10 or 15 ft (3-4.5 m), the leaf midrib is light pink, the flower stalk may be several feet long, but the bunch has only 7 to 9 hands. The fruit is 7 to 9 in (17.5 22.8 cm) long, up to 2 1/2 in (6.25 cm) thick, 4-to 5-angled, bluish with a silvery bloom when young, pale yellow when ripe, The flesh is white, sweetish, and is eaten raw or cooked.

'Mysore', also known as 'Fillbasket' and 'Poovan', is the most important banana type of India, constituting 70% of the total crop. It is sparingly grown in Malaya, Thailand, Ceylon and Burma. It is thought to have been introduced into Dominice in 1900 but the only place where it is of any importance in the New World is Trinidad where it is cultivated as shade for cacao. The plant is large and vigorous, immune to Panama disease and nearly so to Sigatoka; very hardy and drought tolerant. It bears large, compact bunches of medium sized, plump, thin skinned, attractive, bright yellow fruits of subacid flavor.

Other prominent commercial cultivars are **'Salembale'** and **'Rasabale'**, not suitable for canning because of starchy taste and weak flavor. **'Pachabale'** and **'Chandrabale'** are important local varieties preferred for canning. K.C. Naik described 34 cultivars as the more important among the many grown in South India.

'Silk', 'Silk Fig', or 'Apple' ('Manzana' in Spanish), is the most popular dessert banana of the tropics. It is widely distributed around the tropics and subtropics but never grown on a large scale. The plant is 10 to 12 ft (3-3.6m) tall, only medium in vigor, very resistant to Sigatoka but prone to Panama disease. There are only 6 to 12 hands in the bunch, each with 16 to 18 fruits. The plump bananas are 4 to 6 in (10-15 cm) long, slightly curved; astringent when unripe but pleasantly subacid when fully ripe; and apple scented. If left on the bunch until fully developed, the thin skin splits lengthwise and breaks at the stem end causing the fruit to fall, but it is firm and keeps well on hand in the home.

The **'Red'**, 'Red Spanish', 'Red Cuban', 'Colorado', or'Lal Kela' banana may have originated in India, where it is frequently grown, and it has been introduced into all banana growing regions. The plant is large, takes 18 months from planting to harvest. It is highly resistant to disease. The pseudostem, petiole, midrib and fruit peel are all purplish red, but the latter turns to orange yellow when the fruit is fully ripe. The bunch is compact, may contain over 100 fruits of medium size, with thick peel, and flesh of strong flavor. In the mutant called 'Green Red', the plant is variegated green and red, becomes 28 ft (8.5 m) tall with pseudostem to 18 in (45 cm) thick at the base. The bunch bears 4 to 7 hands, the fruits are thick, 5 to 7 in (12.5 17.5 cm) long. The purplish-red peel changes to orange-yellow and the flesh is firm, cream-colored and of good quality.

The **'Fehi'** or 'Fe'i' group, of Polynesia, is distinguished by the erect bunches and the purplish-red or reddish-yellow sap of the plants which has been used as ink and for dyeing. The plants may reach 36 ft (10.9 m) and the leaves are 20 to 30 in (50-75 cm) wide. The bunches have about 6 hands of orange or copper-colored, thick skinned fruits which are starchy, sometimes seedy, of good flavor when boiled or roasted. These plants are often grown as ornamentals in Hawaii.

As a separate group, Simmonds places the 'I.C. 2', or **'Golden Beauty'** banana especially bred at the Imperial College of Tropical Agriculture in Trinidad in 1928 by crossing the 'Gros Michel' with a wild *Musa acuminata*. It is resistant to Panama disease and very resistant to Sigatoka. Though the bunches are small and the fruits short, they ship and ripen well and this cultivar is grown for export in Honduras and has been planted in Hawaii, Samoa and Fiji.

'Orinoco', 'Horse', 'Hog', or 'Burro', banana, a medium tall, sturdy plant, is particularly hardy. The bunch consists of only a few hands of very thick, 3 angled fruits about 6 in (15 cm) long. The flesh has a salmon tint, is firm, edible raw when fully ripe but much better cooked fried, baked or otherwise, as are plantains.

Trials of 5 clones of 'Giant Cavendish' and 9 other cultivars ('Robusta A', 'Robusta B', 'Cocos A', 'Cocos B', 'Golden Beauty', 'Enano Nautia', 'Enano Gigante', 'Enano' and 'Valery') were made between 1976 and 1979 at the Campo Agricola Experimental at Tecoman, Mexico. 'Enano Gigante' is the most widely grown cultivar in that region but the tests showed that 'Enano Nautia' and 'Golden Beauty' bore heavier bunches of better quality fruit, even though 'Enano Gigante' had a greater number of bunches and highest yield per ground area. 'Giant Cavendish' clones 1, 2, 3 and 4, and 'Cocos B' grew very tall, gave low yields and the fruit was of poor quality.

Among the plantains, there are many forms, some with pink, red or dark-brown leaf sheaths, some having also colored midribs or splotches on leaves or fruits. The plants are usually large, vigorous and resistant to Panama disease and Sigatoka but attacked by borers. Major subgroups are known as 'French plantain' and 'Horn plantain', the former with persistent male flowers. The usually large, angled fruits are borne in few hands. All are important sources of food in southern India, East Africa, tropical America and the West Indies. The tall **'Maricongo'** and the **'Common Dwarf'** are leading commercial cultivars. A dwarf mutant is the 'Plantano enano of Puerto Rico (*'banane cochon'* of Haiti). Ordinary plantains are called *'cuadrado'*, *'chato'*, and *'topocho'* in Mexico. The leading commercial cultivars are 'Pelipita' and 'Saba' which are resistant to Black Sigatoka but they do not have the high culinary quality of 'Harton', 'Dominico-Harton', 'Currare', and 'Horn'. 'Laknau' is a fertile plantain that resembles 'Horn' but is of inferior quality. It has opened up possibilities for hybridizing and is being crossed with 'Pelipita' and 'Saba'.

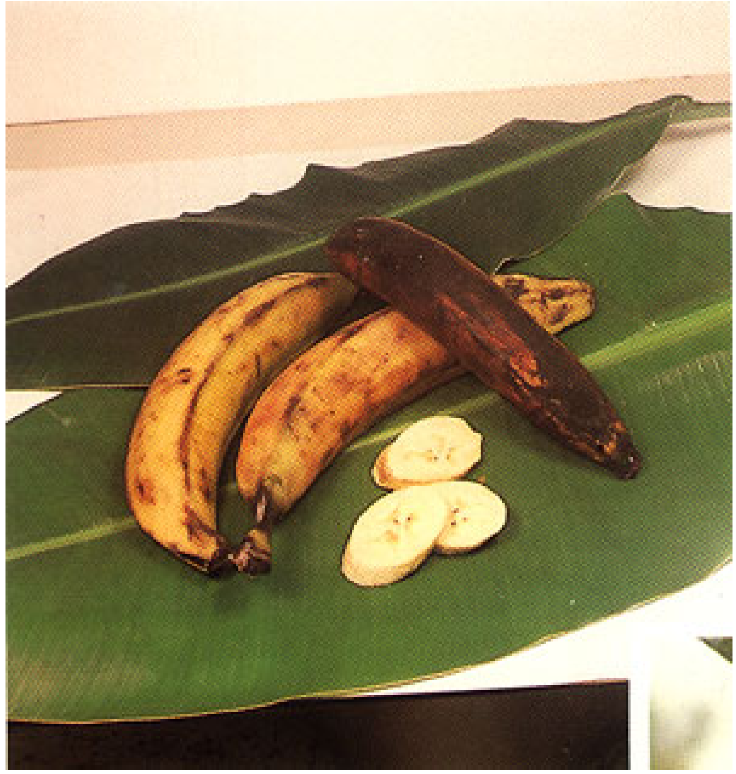

Plate IV: PLANTAIN, *Musa* × *paradisiaca*

Banana and plantain cultivars most often grown in Florida are the 'Dwarf Cavendish', 'Apple', and 'Orinoco' bananas and the 'Macho' plantain. The 'Red' and 'Lady Finger' bananas are very occasionally grown in sheltered locations.

There are five major collections of banana and plantain clones in the world. United Brands maintains a collection of 470 cultivars and 100 species at La Lima, Honduras.

Climate

The edible bananas are restricted to tropical or neartropical regions, roughly the area between latitudes 30°N and 30°S. Within this band, there are varied climates with different lengths of dry season and different degrees and patterns of precipitation. A suitable banana climate is a mean temperature of 80°F (26.67°C) and mean rainfall of 4 in (10 cm) per month. There should not be more than 3 months of dry season.

Cool weather and prolonged drought retard growth. Banana plants produce only one leaf per month in winter, 4 per month in summer. If low temperatures occur just at flowering time, the bud may not be able to emerge from the stem. If fruits have already formed, maturity may be delayed several months or completely suspended. If only the leaves are destroyed, the fruits will be exposed to sunburn. Smudging, by burning dry trash covered with green clippings to create smoke, can raise the temperature 2 to 4 degrees. Flooding the field in advance of a cold snap will keep the ground warm if the chill weather is brief. In Australia, bananas are planted on sunny hill sides at elevations of 200 to 1,000 ft (60 to 300 m) to avoid the cold air that settles at lower levels. Brief frosts kill the plants to the ground but do not destroy the corm. 'Dwarf Cavendish' and the 'Red' banana are particularly sensitive to cold, whereas the dwarf cultivar 'Walha', or 'Kullen', of India is successful up to 4,000 ft (1,220 m) in the outer range of the Western Ghats. 'Vella vazhai' is extensively cultivated in the Lower Pulneys between 3,200 and 5,500 ft (975 and 1,616 m). A cooking banana, 'Plankel', survives winters in home gardens in northern India. In South Africa, the main banana-producing area is along the southeast coast at 3,000 ft (915 m) above sea level with summer rainfall of 35 to 45 in (90-115 cm). The major part of the crop in East Africa is grown between 4,000 and 5,000 ft (1,220 and 1,524 m) and the total range extends from sea-level to 7,500 ft (2,286 m).

Wind is detrimental to banana plants. Light winds shred the leaves, interfering with metabolism; stronger winds may twist and distort the crown. Winds to 30 mph break the petioles; winds to 40 mph will topple a pseudostem that is supporting the weight of a heavy bunch unless the stem is propped, and may cause root damage in non fruiting plants that are not blown down; winds of 60 mph or over will uproot entire plantations, especially when the soil is saturated by rain. Windbreaks are often planted around banana fields to provide some protection from cold and wind. Cyclones and hurricanes are devastating and the latter were the main reason for the shift of large scale banana production from the West Indies to Central America, Colombia and Ecuador. Hail results from powerful convection currents in the tropics, especially in the spring, and does much damage to bananas.

Soil

The banana plant will grow and fruit under very poor conditions but will not flourish and be economically productive without deep, well-drained soil—loam, rocky sand, marl, red laterite, volcanic ash, sandy clay, even heavy clay—but not fine sand which holds water. Over head irrigation is said to improve the filth of heavy clay and has made possible the use of clay soils that would never have been considered for banana culture in the past. Alluvial soils of river valleys are ideal for banana growing. Bananas prefer an acid soil but if the pH is below 5.0 lime should be applied the second year. Low pH makes bananas more susceptible to Panama disease. Where waterlogging is likely, bananas and plantains are grown on raised beds. Low, perennially wet soils require draining and dry soils require irrigation.

Propagation

Banana seeds are employed for propagation only in breeding programs. Corms are customarily used for planting and Mexican studies with 'Giant Cavendish' have shown that those over 17.5 lbs (8 kg) in weight come into bearing early and, in the first year, the bunches are longer, heavier, with more hands than those produced from smaller corms. From the second year on, the advantage disappears. Most growers prefer "bits" 2- to 4-lb (0.9-1.8 kg) sections of the corm. When corms are scarce, smaller sections—1 to 2 lbs (454-908 g) have been utilized and early fertilization applied to compensate for the smaller size. But in Queensland it is specified that "bits" of 'Dwarf Cavendish' shall not be less than 4 x 3 x 3 in (10 x 7.5 x 7.5 cm) and "bits" of 'Lady Finger' and other tall cultivars shall be not less than 5 x 5 x 3 1/2 in (12.5 x 12.5 x 9 cm). The corm has a number of buds, or "eyes", which develop into new shoots. The two upper buds are the youngest and have a pinkish tint. These develop rapidly and become vigorous plants. To obtain the "bits", a selected, healthy banana plant, at least 7 months old but prior to fruiting, is uprooted and cut off about 4 to 5 in (10-12.5 cm) above the corm. The outer layer of leaf bases is peeled off to expose the buds, leaving just a little to protect the buds during handling and transport. The corm is split between the 2 upper buds and trimmed with square sides, removing the lower, inferior buds and any parts affected by pests or disease, usually indicated by discoloration. Then the "bits" are fumigated by immersing for 20 minutes in hot water at about 130°F (54.44°C) or in a commercial nematicide solution. Sometimes it is advisable to apply a fungicide to prevent spoilage. They should then be placed in a sanitary place (away from all diseased trash) in the shade for 48 hrs before planting.

Inasmuch as "bits" are not often available in quantity, the second choice is transplantation of suckers. These should not be too young nor too old.

The sucker first emerges as a conical shoot which opens and releases leaves that are mostly midribs with only vestiges of blade. These juvenile leaves are called "sword", "spear", or "arrow", leaves. Just before the sucker produces wide leaves resembling those of the mature plant but smaller, it has sufficient corm development to be transplanted. Sometimes suckers from old, deteriorating corms have broad leaves from the outset. These are called "water" suckers, are insubstantial, with very little vigor, and are not desirable propagating material. "Maiden" suckers that have passed the "sword"-leaved stage and have developed broad leaves must be large to be acceptably productive. In banana trials at West Bengal, India, suckers 3 to 4 months old with well-developed rhizomes proved to be the best yielders. In comparison, small, medium, or large "sword" suckers develop thicker stems, and give much higher yields of marketable fruits per land parcel. "Bits' grow slowly at first, but in 2 years' time they catch up to plants grown from suckers or "butts" and are much more economical. "Butts" (entire corms, or rhizomes, of mature plants), called "bull heads" in the Windward Islands, are best used to fill in vacancies in a plantation. For quick production, some farmers will use "butts" with several "sword" suckers attached. Very young suckers, called "peepers", are utilized only for establishing nurseries.

Instead of waiting for normal sucker development, multiplication has been artificially stimulated in the field by removing the soil and outer leaf sheaths covering the upper buds of the corm, packing soil around them and harvesting them when they have reached the "sword' sucker stage. A greenhouse technique involves cleaning and injuring a corm to induce callus formation from which many new plants will develop. As many as 180 plantlets have been derived from one corm in this manner.

Diseases are often spread by vegetative propagation of bananas, and this fact has stimulated efforts to create disease-free planting material on a large scale by means of tissue culture. Some commercial banana cultivars have been cultured in Hawaii. A million 'Giant Cavendish' banana plants were produced by meristem culture in Taiwan in 1983. In the field, these laboratory plantlets showed 95% survival, grew faster than suckers in the first 5 months, had bigger stems and more healthy leaves.

Rapid multiplication of 'Philippine Lacatan' and 'Grand Naine' bananas, and the Sigatoka-resistant 'Saba' and 'Pelipita' plantains by shoot-tip culture has been achieved by workers at State University of New York.

Culture

On level land where the soil is compact, deep ploughing is needed to improve aeration and water filtration, whereas on a sloping terrain minimum tillage is advised as well as contouring of rows to minimize erosion. Planting is best done at the end of the dry season and beginning of the wet season for adequate initial moisture and to avoid waterlogging of the young plants. Puerto Rico, because of its favorable climate, is able to make monthly plantings of plantains the year around in order to produce a continuous supply for processing factories. However, some consideration has been given to manipulation of planting dates to avoid a summer surplus (June-September) caused by March and May plantings and to take advantage of higher prices in winter and spring (February to April). To achieve this, it is suggested that plantings be made only in the first or second weeks of January, July, September, November and December. Generally, the banana requires 10 to 12 months from planting to harvest. Summer plantings of plantains in Puerto Rico take 14 to 16 months; winter plantings 17 to 19. In regions where there may be periods of low temperatures in winter, planting time is chosen to allow flowering and fruiting before predictable cold periods.

Spacing varies with the ultimate size of the cultivar, the fertility of the soil, and other factors. Close planting protects plantations exposed to high winds, but results in fewer suckers, hinders disease control, and has been found to be profitable for only the first year. In subsequent years, fruits are shorter, the flesh is softer and bunches ripen prematurely. The standard practice in Puerto Rico is 500 plants of 'Maricongo' plantain per acre (1,235 plants/ha). Increasing to 800 plants/acre (1,976/ha) has increased yield by 4 tons, but elevating density to 1,300 plants/acre (3,212 plants/ha) has not shown any further increase. In Surinam, most of the plantains are grown at a density of 809 to 1,012 plants per acre (2,000-2,500/ha), but density may range from 243 to 1,780 plants per acre (600-4,400/ha).

The higher the number of plants in the field, the larger the volume of fertilizer that must be applied. The crop suffers severely from root competition, for the roots of a fully grown banana plant may extend outward 18 ft (5.5 m). The higher the altitude, the lower the density must be because solar radiation is reduced. Too much space between plants allows excessive evaporation from uncovered soil and increases the weed problem. Growers must determine the most economical balance between sufficient light for good yields and efficient land managemeet. Spacing distances for 'Dwarf Cavendish' range from 10 x 6 ft (3 x 1.8 m) to 15 x 12 ft (4.5 x 3.6 m). A spacing of 12 ft (3.6 m) between rows and 8 ft (2.4 m) between plants allows 450 plants per acre

(1,112 plants/ha). Studies conducted with the so called 'Lacatan' ('Pisang masak hijau') over a 3-year period in Jamaica, demonstrated the optimum density to be 680 plants per acre (2,680/ha). At closer spacings, yield increased but profits declined. Hexagonal spacing gives the maximum number of plants per area. Double- and triple-row plantings provide alleys for mechanical operations and harvesting.

Planting holes should be at least 18 in (45 cm) wide and 15 in (38 cm) deep, but may be as much as 3 ft (0.91 m) wide and 2 ft (0.6 m) deep for extra wind resistance. They should be enriched in advance of planting. On hillsides, suckers are set with the cut surface facing downhill; the bud or "eye" of a "bit" must point uphill; so that the "follower" sucker will emerge on the uphill side where the soil is deepest. A surface cover of about 4 in (10 cm) of soil is trampled down firmly.

Weed control is essential. Geese have been installed as weeders because they do not eat the banana plants. However, they consume mostly grass and fail to eliminate certain broad-leaved weeds which still require cleaning out. Certain herbicides, including Diuron and Ametryne, have been approved for banana fields. They are applied immediately after planting but great care must be taken to minimize adverse effects on the crop. Ametryne has been shown to be relatively safe for the plants and it has a short life in the soil. The most persistent weed is *Cyperus rotundus* L. (nutgrass, yellow nutgrass, purple nutsedge, coqui or coyolillo) which decreases yields and competes with the crop for nitrogen.

In some plantations, a mulch of dry banana leaves is maintained to discourage weeds. Some growers resort to live groundcovers such as *Glycine javanica* L. (Rhodesian kodzu), *Commelina* spp., or *Zebrina pendula* Schnizl. or other creepers, but these tend to climb the banana stems and become a nuisance. Sometimes short-term crops are interplanted in young banana fields, for example, maize, eggplant, peppers, tomatoes, okra, sweetpotato, pineapple or upland rice. A space of at least 3 ft (0.91 m) must be kept clear around each banana plant. However, there are banana authorities who are opposed to interplanting.

Bananas and plantains are heavy feeders. It has been calculated that a harvest of 5 tons of fruit from an acre leaves the soil depleted by 22 lbs (10 kg) nitrogen, 4 lbs (1.8 kg) phosphorus, 55 lbs (25 kg) potash and 11 oz (312 kg) calcium. In general, it can be said that banana plants have high nitrogen and phosphorus requirements and a fertilizer formula of 8:10:8 NPK is usually suitable and normally 1 to 1 1/2 tons/acre (1 1 1/2 MT/ha) may be adequate. One-third of the fertilizer is worked into each planting site when most of the plants appear above ground, one third in a circle about 1 ft (30 cm) out from each plant 2 months later, and one-third at double the distance 2 months after that. Supplementary feedings will depend on signs of deficiencies (often determined by leaf analyses) as the plantation develops. Fertilization needs vary with the soil. In Puerto Rico, most plantains are grown on humid Oxisols and Ultisols in the interior. These soils are well drained but relatively infertile and highly acid, the pH being about 4.8. On such soils, potassium uptake may be too high and N and Mg deficiencies occur. But experts have shown that these soils respond to good fertilization practices and can be very productive. As an example, 224 lbs N per acre (224 kg/ha) applied in circular bands 1.5 ft (0.46 m) from the base of the pseudostem gives a significantly higher yield than broadcast N, and there is good response to Mg applied at time of planting and again 7 months later.

In the humid mountain regions of Puerto Rico, 250 to 325 lbs N per acre (250 325 kg/ha), 125 to 163 lbs phosphorus per acre (125 163 kg/ha), and 500 to 650 lbs potassium per acre (500 650 kg/ha) are recommended for plantains. On lowland sandy clay, phosphorus and magnesium applications appear ineffective. Applications of N at the rate of 168 to 282 lbs/acre (168-282 kg/ha) increase size and number of fruits harvested, but higher rates of N decrease yield because of the number of plants that bend over halfway or are stunted or fail to flower. Applications of 1,121 1bs N per acre (1,121 kg/ha) reduce production by 46%. Potassium at the rate of 405 to 420 lbs/acre (405 420 kg/ha) has the effect of increasing weight and number of fruits. However, there appear to be factors, possibly soil magnesium and calcium, which inhibit the uptake of potassium. One study showed that it took one year for heavy applications of K to reach down to a depth of 8 in (20 cm) where most of the roots were found in a banana plantation on clay loam. One benefit of added potassium is that it makes bananas more buoyant. In cool, dry seasons in Honduras, the fruit tissue is abnormally dense and there is a high rate of "sinkers" when hands are floated through a washing tank. Such fruits have been found deficient in potassium and increased potassium in the fertilizer has reduced the problem. Irrigation by costly overhead sprinkler systems is standard practice in large scale banana culture in Central America. Without such equipment, irrigation basins may be necessary throughout the field and they should be able to hold at least 3 in (7.5 cm) of water. During the first 2 months, the plants should be irrigated every 7 to 10 days; older plants need irrigation only every 3 to 4 weeks in dry seasons. On heavy soils, too frequent irrigations decrease yields. For maximum root development, the water table must be between 14 and 19 in (36 48 cm) below ground level.

To preserve the original density, the plants are pruned; that is, only the most deep seated sucker and one or more of its offshoots ("peepers") are permitted to exist beside each parent plant to serve as replacements and maintain a steady succession. All other suckers are killed to prevent competition with the pseudostem and its "followers", and a bunch of fruits will be ready for harvest every 6 to 8 months. Various methods of de-suckering have been employed: 1) wrenching by hand; 2) cutting at soil level with a banana knife; 3) cutting at soil level and filling the base with kerosene; 4) cutting at soil level and killing the under ground terminal bud by thrusting in and twisting a gouging tool.

As the older leaves wither and droop, they must be removed because they interfere with spraying, they shade the suckers, cause blemishes on the fruits, harbor disease, insects and other creatures, and constitute a fire hazard.

Bearing bananas require propping. This has been done with simple wooden or bamboo poles, forked poles, or two stakes fastened together to form an "X" at the top, a system much less harmful to the pseudostem. Or the plant may be tied back to pickets driven into the ground, to prevent falling with the weight of the bunch.

Various types of covering—dry banana leaves, canvas, drill cloth, sisal sacks, or burlap or so-called "Hessian' bags (made of jute), have been put over banana bunches intended for export, especially to enhance fruit development in winter and avoid blemishes. In 1955, Queensland led the trend toward adoption of tubular poly vinylchloride (PVC), then the cheaper blue polyethylene covers after trials produced record bunches. At first, the transparent covering caused sunburn on the first two hands and it was found necessary to protect these with newspaper before pulling on the plastic sleeve. The use of plastic covers became standard practice not only in Australia but in Africa, India and the American tropics. In 1963, Queensland growers were turning to covers made of High Wet Strength (formaldehyde-treated) kraft paper which was already in use for garbage bags. These bags were easily stapled at the top, prevented sunburn, resisted adverse weather, and were reusable for at least another season. Some growers still prefer the burlap. It is cautioned that the cover should not be put on until the bracts have lifted from the fruits (about 21 days after "shooting") so that the young fingers will be firm enough to resist the friction of the cover.

If bunches are composed of more than 7 hands, debudding, or "de-belling" that is, removal of the

Fig. 10: Immature banana bunch ("stem") in protective plastic cover; Hacienda Secadal, Ecuador.

terminal male bud (which keeps on extending and growing) will result in somewhat fuller bananas, thus increasing bunch weight. The cut should be made several inches below the last hand so that the rotting tip of the severed stalk will not affect the fruits.

Harvesting

Banana bunches are harvested with a curved knife when the fruits are fully developed, that is, 75% mature, the angles are becoming less prominent and the fruits on the upper hands are changing to light green; and the flower remnants (styles) are easily rubbed off the tips. Generally, this stage is reached 75 to 80 days after the opening of the first hand. Cutters must leave attached to the bunch about 6 to 9 in (15-18 cm) of stalk to serve as a handle for carrying. With tall cultivars, the pseudostem must be slashed partway through to cause it to bend and harvesters pull on the leaves to bring the bunch within reach. They must work in pairs to hold and remove the bunch without damaging it. In the early 1960's a "banana bender" was invented in Queensland—an 8-ft pole with a steel rod mounted at the top and shaped with a downward pointing upper hook and an upward-pointing lower hook, the first to pull the pseudostem down after nicking and the second to support the bent pseudostem so that the bunch can be cut at a height of about 4 1/2 ft (1.35 m).

Fig. 11: Mature, newly harvested, banana bunches at Hacienda Secadal, Ecuador.

Formerly, entire bunches were transported to shipping points and exported with considerable loss from inevitable damage. Improved handling methods have greatly reduced bunch injuries. In modern plantations, the bunches are first rested on the padded shoulder of a harvester and then are hung on special racks or on cables operated by pulleys by means of which they can be easily conveyed to roads and by vehicle to nearby packing sheds. Where fields have been located in remote areas lacking adequate highways, transport out has been accomplished by hovercraft flying along riverbeds. In Costa Rica, when rains have prevented truck transport to railway terminals, bananas have been successfully carried in slings suspended from helicopters. Exposure to even moderate light after harvest initiates the ripening process. Therefore the fruits should be protected from light as much as possible until they reach the packing shed.

In India, studies have been made to determine the most feasible disposition of a plant from which a bunch has been harvested. It is normal for it to die and it may be left standing for 3 to 4 months to dehydrate before removal, or the top half may be removed right after harest by means of a tool called a "mattock" (a combined axe and hoe); or the pseudostem may be cut at ground level, split open, and the tender core taken away for culinary purposes. Results indicated that the first two practices have equal effect on production, but the complete felling and removal of the pseudostem lowered the yield of the "follower" significantly. In Jamaica and elsewhere it is considered best to chop and spread as organic matter the felled pseudostem and other plant residue. This returns to the soil 404 lbs N, 101 lbs P and 1, 513 lbs K from an acre of bananas (404 kg, 101 kg and 1,513 kg, respectively, from a hectare). The stump should be covered with hard-packed soil to discourage entrance of pests.

Banana plantations, if managed manually, may survive for 25 years or far longer. The commercial life of a banana "stool" is about 5 or 6 years. From the 4th year on, productivity declines and the field becomes too irregular for mechanical operations. Sanitary regulations require that the old plantings be eradicated. In the past, this has been done by digging out the plants with the mattock, or bringing in cattle to graze on them. In recent years, the old plants and the suckers that arise from the old corms are injected with herbicide until all are thoroughly killed and the field is then cleared. Where bananas or plantains are raised on cleared forest land without sophisticated maintenance practices, they become thoroughly infested with nematodes by the end of the third year and the regrowth of underbrush has begun to take over the field, so it is simply abandoned.

Yield

It is clear that many factors determine the annual yield from a banana or plantain plantation: soil and agronomic practices, the cultivar planted, spacing, the type of propagating material and the management of sucker succession. The 'Gros Michel' banana has yielded 3 to 7 tons per acre (3 to 7 MT/ha) in Central America. A 'Giant Cavendish' bunch may weigh 110 lbs (50 kg) and have a total of 363 marketable fruits. A well-filled bunch of ''Dwarf Cavendish' will have no more than 150 to 200 fruits. Sword suckers of plantains have yielded 54,984 fruits per acre (135,866 fruits /ha); water suckers, 49,021 fruits per acre (121,132 fruits/ha).

With heavy fertilization, the 'Maricongo' plantain in Puerto Rico, planted at the rate of 725 per acre has produced 21,950 fruits per acre (54,238 fruits/ha); at the rate of 1,450 per acre has produced 39,080 fruits per acre (96,369 fruits/ha); in a single year.

In 1981, investigators of the earnings of plantain producers in Puerto Rico found that traditional farmers had costs of $1,568.00 per acre ($3,874.59/ha); gross income of $2,436.90 per acre ($6,021.58/ha); and net profit of $868.88 per acre ($2,146.99/ha). Those farmers who had adopted improved techniques for preparing the field, weeding and control of pests and diseases had a cost of $2,132.14 per acre ($5,268.52/ha); gross income of $4,253.26 per acre ($10,509.81/ha); and net profit of $2,121.12 per acre ($5,241.29/ha).

'Maricongo' plantains spaced at 5 x 5 ft (1.5 x 1.5 m), 1,742 plants/acre (4,303 plants/ha), have produced 33.4 tons per acre (73.5 tons/ha) over a period of 30 months.

Handling and Packing

Banana bunches were formerly padded with leaf trash which absorbed much of the sap and latex from the hervesting operation and the sites of broken off styles, each of which can leak at least 6 drops, especially if bunches are cut early in the morning. In the 1960's, when whole bunches were being exported from the Windward Islands and Jamaica to England, they were wrapped in wadding (paperbacked layers of paper tissue) to absorb the latex, and then encased in plastic sleeves for shipment. Nowadays plastic sleeves left on the bunches help protect them during transport from the field to distant packing sheds and a cushion of banana trash on the floor and against the sides of the truck does much to reduce injury. But the plastic bags increase the problem of staining by the sap/latex which mingles with the condensation inside the bag, becomes more fluid, runs down the inside and stains the peel. When hands are cut off, additional sap/latex mixture oozes from the severed crown. Banana growers and handlers know that this substance oxidizes and makes an indelible dark-brown stain on clothing. It similarly blemishes the fruits. At packing stations, the hands are floated through water tanks to wash it off. (Sodium hydrochlorate is an effective solvent.) Some people maintain that the fruit should remain in the tank for 30 minutes until all oozing of latex ceases. At certain times of the year, up to 5% of the hands may sink to the bottom of the tank, become superficially scarred and no longer exportable. As mentioned earlier, increased potassium in fertilizer mixtures renders the bananas more buoyant and fewer hands sink. In rainy seasons, it may be necessary to apply fungicide on the cut crown surface to avoid rotting, though experiments have shown that some fungicides give an off-flavor to the fruit.

Boxing was experimented with in the late 1920's but abandoned because of various types of spoilage. Modern means of combatting the organisms that cause such problems, as well as better systems of handling and transport, quality control, and good container design, have made carton packing not only feasible but necessary. First, the hands are graded for size and quality and then packed in layers in special ventilated cartons with plastic padding to minimize bruising.

In the past, bananas for export from Fiji to New Zealand were detached individually from the hands and packed tightly in 72-lb (33 kg) wooden boxes, with much bruising of the upper layer and of the fruits in contact with the sides. Reduction of fruit quality was found to offset the economic advantage of filling all the shipping space with fruits. Wooden boxes were abandoned and suppliers were converted to the packing of hands with cushioning material.

Controlled Ripening and Storage

At times, markets may not be able to absorb all the bananas or plantains ready for harvest. Experiments have been conducted to determine the effect of applying gibberellin, either by spraying or in the form of a lanolin paste, on the stalk just above the first hands, or by injection of a solution, powder or tablet into the stalk. In Israel, gibberellin $A_{4}A_{7}$, applied by any of these methods about 2 months before time of normal ripening, had the effect of delaying ripening from 10 to 19 days. If applied too early, the gibberellin treatment has no effect.

Harvested bananas allowed to ripen naturally at room temperature do not become as sweet and flavorful as those ripened artificially. Post harvest ripening is expedited undesirably if bunches or hands are stored in unventilated polyethylene bags. As a substitute for expensive controlled-temperature storage rooms, researchers in Thailand have found that hands treated with fungicide can be stored or shipped over a period of 4 weeks in polyethylene bags if ethylene absorbing vermiculite blocks (treated with a fresh solution of potassium permanganate) are included in the sack. The permanganate solution will be ineffective if exposed to light and oxygen. The blocks must be encased in small polyethylene bags perforated only on one side to avoid staining the fruits.

Bananas are generally ripened in storage rooms with 90 to 95% relative humidity at the outset, later reduced to 85% by ventilation: and at temperatures ranging from 58° to 75°F (14.4°-23.9°C), with 2 to 3 exposures to ethylene gas at 1: 1000, or 6 hourly applications for 1 to 4 days, depending on the speed of ripening desired. The fruit must be kept cool at 56° 60°F (13.3°-15.6°C) and 80 to 85% relative humidity after removal from storage and during delivery to markets to avoid rapid spoilage. Post-ripening storage at 70°F (21°C) in air containing 10 to 100 ppm ethylene accelerates softening but the fruits will remain clear yellow and attractive with few or no superficial brown specks.

Plantains for processing in the ripe stage or marketing fresh must be stored under conditions that will provide the best quality of finished product. Puerto Rican studies have shown that uniform ripening is achieved in 4 to 5 days by storage at 56° to 72°F (13.3°-22.2°C), 95 to 100% relative humidity, and with a single exposure to ethylene gas. The initial 4% starch content is reduced to 1 to 1.74% and sugars increase by about 2%. The ripe fruit can be held another 6 days at 56°F (13.3°C) and still be acceptable for processing.

The manufacture of products from the green, still starchy, plantain is a major industry in Puerto Rico. If held at room temperature, the fruits begin to ripen 7 days after harvest and become fully ripe at the end of 2 more days. Chemically disinfected fruits stored in polyethylene bags with an ethylene absorbent (Purefil wrapped in porous paper) keep 25 days at room temperature of 85°F (29.44°C), and for 55 days under refrigeration at 55°F (12.78°C). Products of such fruits have been found to be as good as or better than those made from freshly harvested green plantains.

The potential benefits of waxing have been considered by various investigators. While it is true that waxing of pre-disinfected fruits prolongs storage life by 60% at room temperature, 78°-92°F (25.56°-33.33°C), and by 28% at 52° to 55°F (11.11°-12.78°C), there is no advantage in waxing if the fruits can be held in gas storage, a combination of waxing and gassing being no better than gassing alone. In fact, waxing may result in uneven ripening after storage.

In the mid 1960's, fumigation by ethylene dibromide (EDB) against fruit fly infestation was authorized to permit export of Hawaiian bananas to the mainland USA. The treatment accelerated ripening and it could not be applied to 'Dwarf Cavendish' without covering the bunch with opaque or semi-opaque material for at least 2 months prior to harvest. EDB is no longer approved for use on food products for marketing within the United States.

Pests

Wherever bananas and plantains are grown, nematodes are a major problem. In Queensland, bananas are attacked by various nematodes that cause rotting of the corms: spiral nematodes—*Scutellonema brachyurum*, *Helicotylenchus multicinctus* and *H. nannus*; banana root-lesion nematode, *Pratylenchus coffaea*, syn. *P. musicola*; and the burrowing nematode, *Radopholus similis* less than 1 mm long, which enters roots and corms, causing red, purple and reddish-black discoloration and providing entry for the fungus *Fusarium oxysporum*. And also prevalent is the root-knot nematode, *Meliodogyne javanica*.

Plantains in Puerto Rico are attacked by 22 species of nematodes. The most injurious is the burrowing nematode and it is the cause of the common black headtoppling disease on land where plantains have been cultivated for a long time. Wherever coffee has been grown, *Pratylenchus coffaea* is the principal nematode, and where plantains have been installed on former sugar cane land, *Meliodogyne incognita* is dominant. These last two are among the three most troublesome nematodes of Surinam, the third being *Helicotylenchus* spp., especially *H. multicinctus*.

Nematicides, properly applied, will protect the crop. Otherwise, the soil must be cleared, plowed and exposed to the sun for a time before planting. Sun destroys nematodes at least in the upper several inches of earth. Some fields may be left fallow for as long as 3 years. Rotating plantains with Pangola grass (*Digitaria decumbens*) controls most of the most important species of nematodes except *Pratylenchus coffaea*. All planting material must be disinfected—corms, or parts of corms, or the bases of suckers. There are various means of accomplishing this. In Hawaii, corms are immersed in water at 122°F (50°C) for 15 minutes and soaked for 5 minutes in 1% sodium hypochlorite. In Puerto Rico, nematodes are combatted by immersing plantain corms in a solution of Nemagon for 5 minutes about 24 hours before planting and, when planting, mixing the soil in the hole with granular Dasanit (Fensulfothion) and every 6 months applying Dasanit in a ring around the pseudostem.

In Queensland, corms are immersed in hot water-131°F (55°C)—for 20 minutes or solutions of nonvolatile Nemacur or Mocap. Hot water and Nemacur are equally effective but hot water has less adverse effects on plant vigor. The Australians believe that nematicidal treatment of corms must be preceded by peeling off 3/8 in (1 cm) of the outer layer (usually discolored) even though this diminishes the vigor of the planting material. However, tests with 'Maricongo' plantain corms in Puerto Rico indicate that immersing for 10 minutes in aqueous solutions of Carbofuran, Dasanit, Ethoprop, or Phenamiphos without the time consuming and possibly detrimental peeling reduces the initial nematode populations by about 95 % and all the nematicides except Carbofuran give adequate post-planting control. Carbofuran apparently does not penetrate deeply enough. The Florida spiral nematode is the most damaging nematode in Brazil and Florida, especially during hot, rainy summers. Ethoprop is the only nematicide registered for use on bananas in Florida but it is not effective against this pest. The hot water treatment must be employed.

The black weevil, *Cosmopolites sordidus*, also called banana stalk borer, banana weevil borer, or corm weevil, is the second most destructive pest of bananas and plantains. It attacks the base of the pseudostem and tunnels upward. A jelly like sap oozes from the point of entry. It was formerly controlled by Aldrin, which is now banned. In Surinam it has been combatted by injecting pesticide into the pseudostem, or spraying the pseudostem with Monocrotophos. In Ghana, they dip planting material in a solution of Monocrotophos and apply dust of Dieldrin or Heptachlor around the base of the pseudostem. Puerto Rican tests of several pesticides have shown that Aldicarb 10G, a nematicide insecticide, applied at the base of plantain plants at the rate of 1 to 1 1/2 oz (30-45 g) every 4 months, or 1 oz (30 g) every 6 months, controls both the burrowing nematode and the black weevil. Biological control of black weevil utilizing a weevil predator, *Piaesius* *javanus*, has not been successful.

The banana rust thrips, *Chaetanophothrips orchidii*; syn. *C. signipennis*, stains the peel, causes it to split and expose the flesh which quickly discolors. The pest is usually partially controlled by the spraying of Dieldrin around the base of the pseudostem to combat the banana weevil borer, because it pupates in the soil. Another measure has been to treat the inside of polyethylene bunch covers with insecticidal dust, especially Diazinon, before slipping them over the bunches. It is recognized that this procedure constitutes a health hazard to the workers. A great improvement is the introduction of polyethylene bags impregnated with 1% of the insecticide Dursban, eliminating the need for dusting. Bunches enclosed in these bags have been found 85.% free of attack by the banana rust thrips. The bags retain their potency for at least a year in storage. Impregnated with 1 to 2% Dursban, they are equal to Diazinon in preventing banana injury by the banana fruit scarring beetle, *Colaspis hypochlora*, also called coquito. This pest invades the bunches when the fruits are very young. It has been very troublesome in Venezuela, and at times from Guyana to Mexico. The banana scab moth, *Nacoleia octasema*, infests the inflorescence from emergence to the time half the bracts have lifted. It is a major pest in North Queensland, Malaysia and the southwest Pacific. Control may be by injection or dusting with pesticide, sometimes with lifting or removal of bracts. Corky scab of bananas in southern Queensland is caused by the banana flowers thrips, *Thrips florum*, especially in hot, dry weather. The infestation is lessened by removal of the terminal male bud which tends to harbor the pest.

Among minor enemies in Queensland is the banana spider mite, *Tetranychus lambi* which moves from beneath the leaves to the fruits in warm weather and creates dull brown specks which may become so numerous as to completely cover the peel, causing it to dehydrate and crack irregularly. The leaves of the plant will wilt. Bi-weekly sprayings of pesticide get rid of the mites.

The banana silvering thrips, *Hercinothrips bicintus*, causes silvery patches on the peel and dots them with shiny black specks of excrement. The rind-chewing caterpillar, *Barnardiella sciaphila*, usually does little damage. Two species of fruit fly—*Strumeta tryoni* and *S. musae* —occasionally attack bananas in North Queensland.

Diseases

The subject of diseases is authoritatively presented by C.W. Wardlaw in the second edition of his textbook, *Banana Diseases, including plantains and abaca*, 1972; 878 pages.

It is appropriate here only to mention the main details of those maladies which are of the greatest concern to banana and plantain growers. Sigatoka, or leaf spot, caused by the fungus *Mycosphaerella musicola* (of which the conidial stage *is Cercospora musae*) was first reported in Java in 1902, next in Fiji in 1913 where it was named after the Sigatoka Valley. It appeared in Queensland 10 years later, and in another 10 years made its appearance in the West Indies and soon spread throughout tropical America. The disease was noticed in East and West Tropical Africa in 1939 and 1940. It was discovered in Ghana in 1954 and ravaged a state farm in 1965. It is most prevalent on shallow, poorly drained soil and in areas where there is heavy dew. The first signs on the leaves are small, pale spots which enlarge to 1/2 in (1.25 cm), become dark purplish black and have gray centers. When the entire plant is affected, it appears as though burned, the bunches will be of poor quality and will not mature uniformly. The fruits will be acid, the plant roots small. Control is achieved by spraying with orchard mineral oil, usuall every 3 weeks, a total of 12 applications of 1 1/2 gals per acre (14.84 liters/ha); or by systemic fungicides applied to the soil or by aerial spraying.

A much more virulent malady, Black Sigatoka, or Black Leaf Streak, caused by *Mycosphaerella fifiensis* var. *difformis*, attacked bananas in Honduras in 1969 and spread to banana plantations in Guatemala and Belize. It appeared in plantations in Honduras in 1972 where there had not been any need to spray against ordinary Sigatoka. It made headway rapidly through plantain fields in Central America to Mexico and about 10 years later was found in the Uruba region of Colombia. The disease struck Fiji in 1963 and became an epidemic. It began spreading in 1973, largely replacing ordinar Sigatoka. Surveys have revealed this previously unrecognized disease on several other South Pacific islands, in Hawaii, the Philippines, Malaysia and Taiwan. It is spread mostly by wind; kills the leaves and exposes the bunches to the sun. Cultivars which are resistant to Sigatoka have shown no resistance to Black Sigatoka. There are vigorous efforts to control the disease by fungicides or intense oil spraying. But it is not completely controlled even by spraying every 10 to 12 days a total of 40 sprayings. The cost of control with fungicides is 3 to 4 times that of controlling ordinary Sigatoka because of the need for more frequent aerial sprayings. It is very difficult to treat properly on islands where bananas are grown mostly in scattered plantings. In Mexico where plantains are extremely important in the diet, and 65% of the production is on non-irrigated land, control efforts have elevated costs of plantain production by 145 to 168%. In the Sula Valley of Honduras, Black Sigatoka has caused annual losses of 3,000,000 boxes of bananas. The great need is for resistant cultivars of high quality.

Panama Disease or Banana Wilt, which arises from infection by the fungus, *Fusarium oxysporum* f. sp. *cubense* originates in the soil, travels to the secondary roots, enters the corm only through fresh injuries, passes into the pseudostem; then, beginning with the oldest leaves, turns them yellow first at the base, secondly along the margins, and lastly in the center. The interior leaves turn bronze and droop. The pseudostem turns brown inside. This plague has seriously affected banana production in Central America, Colombia and the Canary Islands. It started spreading in southern Taiwan in 1967 and has become the leading local banana disease. The 'Cavendish' types have been considered highly resistant but they succumb if planted on land previously occupied by 'Gros Michel'. The disease is transmitted by soil, moving agricultural vehicles or other machinery, flowing water, or by wind. It is combatted by flooding the field for 6 months. Or, if it is not too serious, by planting a cover crop. There are reportedly two races: Race #1 affects 'Gros Michel', 'Manzano', 'Sugar' and 'Lady Finger'; Race #2 attacks 'Bluggoe'. Resistant cultivars are the Jamaican 'Lacatan', 'Monte Cristo', and 'Datil'or'Nino'. Resistant plantains are 'Maricongo', 'Enano' end 'Pelipita'.

Moko Disease, or Moko de Guineo, or Marchites bacteriana, is caused by the bacterium, *Pseudomonas solanacearum*, resulting in internal decay. It has become one of the chief diseases of banana and plantain in the western hemisphere and has seriously reduced production in the leading areas of Colombia. It attacks *Heliconia* species as well. It is transmitted by insects, machetes and other tools, plant residues, soil, and root contact with the roots of sick plants. There are said to be 4 different types transmitted by different means. Efforts at control include covering the male bud with plastic to prevent insects from visiting its mucilaginous excretion; debudding, disinfecting of cutting tools with formaldehyde in water 1: 3; disinfection of planting material; disposal of infected fruits and plant parts; injection of herbicide into infected plants to hasten dehydration, and also seemingly healthy neighboring plants. If the organism is variant SFR, all adjacent plants within a radius of 16.5 ft (5 m) must be destroyed and the area not replanted for 10 to 12 months, for this variant persists in the soil that long. If it is variant B, the plants within 32.8 ft (10 m) must be injected and the area not replanted for 18 months. In either case, the soil must be kept clear of broad leaved weeds that may serve as hosts. In Colombia, there are 12 species of weeds that serve as hosts or "carriers" but only 4 of these are themselves susceptible to the disease. Crop rotation is sometimes resorted to. The only sure defense is to plant resistant cultivars, such as the 'Pelipita' plantain.

Black-end arises from infection by the fungus *Gloeosporium musarum*, of which *Glomerella cingulata* is the perfect form. It causes anthracnose on the plant and attacks the stalk and stalk-end of the fruits forming dark, sunken lesions on the peel, soon penetrating the flesh and developing dark, watery, soft areas. In severe cases, the entire skin turns black and the flesh rots. Very young fruits shrivel and mummify. This fungus is often responsible for the rotting of bananas in storage. Immersing the green fruits in hot water, 131°F (55°C) for 2 minutes before ripening greatly reduces spoilage.

Cigar-tip rot, or Cigar-end disease, *Stachylidium* (*Verticillium*) *theobromae* begins in the flowers and extends to the tips of the fruits and turns them dark, the peel darkens, the flesh becomes fibrous. One remedy is to cut off withered flowers as soon as the fruits are formed and apply copper fungicides to the cut surfaces.

In Surinam, cucumber mosaic virus attacks plantains especially when cocumber is interplanted in the fields.

Also, Chinese cabbage, Cayenne pepper and "bitter greens" (*Cestrum latifolium* Lam.) are hosts for the disease.

Cordana leaf spot (*Cordana musae*), causes oval lesions 3 in (7.5 cm) or more in length, brown with a bright-yellow border. There is progressive dying of the leaves beginning with the oldest, as in Sigatoka, with consequent undersized fruits ripening prematurely. It formerly occurred mainly in sheltered, humid regions of Queensland. Now it is seen mostly as an invader of areas affected by Sigatoka, in various geographical locations.

Bunchy top, an aphid-transmitted virus disease of banana, was unknown in Queensland until about 1913 when it was accidentally introduced in suckers brought in from abroad. In the next 10 years it spread swiftly and threatened to wipe out the banana industry. Drastic measures were taken to destroy affected plants and to protect uninvaded plantations. The disease was found in Western Samoa in 1955 and it eliminated the susceptible 'Dwarf Cavendisht' from commercial plantings. A vigorous eradication and quarantine program was undertaken in 1956 and carried on to 1960. Thereafter, strict inspection and control measures continued. Other crops were provided to farmers in heavily infested areas. Leaves formed after infection are narrow, short, with upturned margins and become stiff and brittle; the leafstalks are short and unbending and remain erect, giving a "rosetted" appearance. The leaves of suckers and the 3 youngest leaves of the mother plant show yellowing and waviness of margins, and the youngest leaves will have very narrow, dark-green, usually interrupted ("dot-and dash") lines on the underside.

Because of the seriousness of Panama disease and Bunchy Top in southern Queensland, the prospective banana planter must obtain a permit from the Queensland Department of Primary Industries. In the Southern Quarantine Area, any plant showing Bunchy Top, as well as its suckers and all plants within a 15 ft (4.6 m) radius must be killed by injecting herbicide or must be dug out completely and cut into pieces no bigger than 2 in (5 cm) wide. In restricted areas, only the immune 'Lady Finger' may be grown. In the Northern Quarantine Area, no plants may be brought in from another area and all plants within a radius of 120 ft (36.5 m) from a diseased plant must be eradicated.

Swelling and splitting of the corm and the base of the pseudostem is caused by saline irrigation water and by overfertilization during periods of drought which builds up soluble salts in the soil.

Food Uses

The ripe banana is utilized in a multitude of ways in the human diet—from simply being peeled and eaten out of-hand to being sliced and served in fruit cups and salads, sandwiches, custards and gelatins; being mashed and incorporated into ice cream, bread, muffins, and cream pies. Ripe bananas are often sliced lengthwise, baked or broiled, and served (perhaps with a garnish of brown sugar or chopped peanuts) as an accompaniment for ham or other meats. Ripe bananas may be thinly sliced and cooked with lemon juice and sugar to make jam or sauce, stirring frequently during 20 or 30 minutes until the mixture jells. Whole, peeled bananas can be spiced by adding them to a mixture of vinegar, sugar, cloves and cinnamon which has boiled long enough to become thick, and then letting them cook for 2 minutes.

In the islands of the South Pacific, unpeeled or peeled, unripe bananas are baked whole on hot stones, or the peeled fruit may be grated or sliced, wrapped, with or without the addition of coconut cream, in banana leaves, and baked in ovens. Ripe bananas are mashed, mixed with coconut cream, scented with *Citrus* leaves, and served as a thick, fragrant beverage.

Banana puree is important as infant food and can be successfully canned by the addition of ascorbic acid to prevent discoloration. The puree is produced on a commercial scale in factories close to banana fields and packed in plastic-lined #10 cans and 55-gallon metal drums for use in baby foods, cake, pie, ice cream, cheesecake, doughnuts, milk shakes and many other products. It is also used for canning half-and-half with applesauce, and is combined with peanut butter as a spread. Banana nectar is prepared from banana puree in which a cellulose gum stabilizer is added. It is homogenized, pasteurized and canned, with or without enrichment with ascorbic acid.

Sliced ripe bananas, canned in sirup, were introduced to the food trade for commercial use in frozen tarts, pies, gelatins and other products. In 1966, the United Fruit Company built a processing plant at La Lima, Honduras, for producing canned and frozen banana puree and canned banana slices. Because of seasonal gluts and perishability and the tonnages of bananas and plantains that are not suitable for marketing or export because of overripeness or stained peel or other defects, there is tremendous interest in the development of modes of processing and preserving these fruits.

In Polynesia, there is a traditional method of preserving large quantities of bananas for years as emergency fare in case of famine. A pit is dug in the ground and lined with banana and *Heliconza* leaves. The peeled bananas are wrapped in *Heliconza* leaves, arranged in layer after layer, then banana leaves are placed on top and soil and rocks heaped over all. The pits remain unopened until the fermented food, called "masi", is needed.

In Costa Rica, ripe bananas from an entire bunch are peeled and boiled slowly for hours to make a thick sirup which is called "honey".

Green bananas, boiled in the skin, are very popular in Cuba, Puerto Rico and other Caribbean islands. In Puerto Rico, the cooked bananas are recooked briefly in a marinating sauce containing black pepper, vinegar, garlic, onions, bay leaves, olive oil and salt and left standing at room temperature for 24 hours before being eaten. Peeled, sliced green bananas are quick-frozen in Puerto Rico for later cooking. If steam treated to facilitate peeling, the enzymes are inactivated only on the surface of the flesh and the interior, when exposed, will turn brown unless sulfited. It is more satisfactory to immerse the whole bananas in water at 200°F (93°C) for 30 minutes which wholly inactivates the enzymes. No sulfite is then needed and no browning occurs.

Much research has been conducted by food technologists at the University of Puerto Rico to determine the best procedures for canning sliced green bananas and plantains to make them readily available for cooking. Enzyme inactivation is necessary and the hot water treatment facilitates the peeling. If peeled raw, green bananas and plantains exude gummy white latex which stains materials. When canning, citric acid in a 2% brine is added, but this method of preservation has not yet met with success because of rapid detinning of the inside of the cans. The problem is not solved by using enamellined cans because the fruit darkens quickly after the cans are opened. Glass jars may prove to be the only suitable containers.

Through experimental work with a view to freezing peeled, blanched, sliced green bananas, it has been found that, with a pulp-to-peel ratio of less than 1:3 the fruits turn gray on exposure to air after processing and this discoloration is believed to be caused by the high iron content (4.28 p/m) of the surface layer of the flesh and its reaction to the tannin normally present in green bananas and plantains. At pulp to peel ratio of 1:0, the tannin level in green bananas is 241.4 mg; at l:3, 151.0 mg, and at 1:5, 112.6 mg, per 100 g. Therefore, it is recommended that for freezing green bananas be harvested at a stage of maturity evidenced by 1:5 pulp-to-peel ratio. Such fruits have a slightly yellowish flesh, higher carotene content, and are free of off-flavors. The slices are cooked by the consumer without thawing.

Completely green plantains are 50% flesh and 50% peel. Plantains for freezing should have a pulp content of at least 60% for maximum quality in the ultimate food product, but a range of 55 to 65% is considered commercially acceptable.

Ripe plantains, held until the skin has turned mostly or wholly black, are commonly peeled, sliced diagonally and fried in olive oil, accompany the main meal daily in the majority of homes in tropical Latin America. In the Dominican Republic, a main dish is made of boiled, mashed ripe plantains mixed with beaten eggs, flour, butter, milk and cloves, and layered in a casserole with ground beef fried with Picalilli and raisins, lastly topped with grated cheese and baked until golden brown. In Guatemala, boiled plantains are usually served with honey.

Green plantains are popular sliced crosswise, fried until partially cooked, pressed into a thickness of 1/2 in (1.25 cm), and fried in deep fat till crisp. The product is called 'tostones" and somewhat resembles French-fried potatoes. Puerto Rican "mofongo" is a ball of fried green plantain mashed with fried pork rind, seasoned with thickened stock, garlic and other condiments. It must be eaten hot before it hardens. "Mofongo" has been successfully frozen in boilable pouches. Slices of nearly ripe plantain (5% starch content) are cooked in sirup and frozen in boilable pouches. Puerto Rican plantains, shipped green to Florida, have been ripened, peeled, quartered, infused with orange juice, frozen and provided to schools for serving as luncheon dessert.

In Ghana, plantains are consumed at 5 different stages of ripeness. Fully ripe plantains are often deep fried or cooked in various dishes. A Ghanian pancake called "fatale" is made of nearly full ripe plantains and fermented whole meal dough of maize, seasoned with onions, ginger, pepper and salt, and fried in palm oil. "Kaklo" is the same mix but thicker and rolled into balls which are deep-fried. Because home preparation is laborious, a commercial dehydrated mix has been developed. In Ghana, green plantains are boiled and eaten in stew or mashed, together with boiled cassava, into a popular plastic product called "fufu" which is eaten with soup. Because of the great surplus of plantains in summer, technologists have developed methods for drying and storing of strips and cubes of plantain for house use in making "fufu" out of season. The cubes can also be ground into plantain flour. Use of infrared, microwave, and extrusion systems has resulted in high-quality finished products. Processing has the added advantage of keeping the peels at factories where they may be converted into useful by-products instead of their adding to the bulk of household garbage.

Banana or plantain flour, or powder, is made domestically by sun-drying slices of unripe fruits and pulverizing. Commercially, it is produced by spray-drying, or drum-drying, the mashed fruits. The flour can be mixed 50-50 with wheat flour for making cupcakes. Two popular Puerto Rican foods are "pasteles" and "alcapurias"; both are pastry stuffed with meat; the first is wrapped in plantain leaves and boiled; the latter is fried. The pastry is made of plantain flour or a mixture of plantain with cassava (*Manihot esculenta* Crantz.) or cocoyam (tanier), *Xanthosoma* spp. The plantain cultivars 'Saba', 'Tundoc' and 'Latundan' are very suitable for making flour.

Commercial production and marketing of fried green plantain and banana chips has been increasing in various parts of the world over the past 25 years and these products are commonly found in retail groceries alongside potato chips and other snack foods. 'Carinosa' and 'Bungulan' bananas are favored for chip-making. In Puerto Rico, the plantain cultivars 'Guayamero Alto' and 'Congo Enano' are chosen for this purpose.

Dried bananas, or so-called "banana figs" are peeled firm-ripe bananas split lengthwise, sulphured, and ovendried to a moisture content of 18 to 20%. Wrapped individually in plastic and then packed by the dozen in polyethylene bags, and encased in cartons, they can be stored for a year at room temperature—75.2° to 86°F (24°-30°C) and they are commonly exported. The product can be eaten as a snack or minced and used together with candied lemon peel in fruit cake and other bakery products. In India the 'Dwarf Cavendish' is preferred for drying; in the Philippines, the true 'Lacatan' or the 'Higo'.

Canadian researchers have developed a system of osmotic dehydration for sliced firm ripe bananas and plantains, especially designed for developing countries with plentiful sugar for the solutions required.

Since the early 1960's, Brazil has produced dehydrated banana flakes for local markets and export to the USA and elsewhere in vacuum sealed cans. The flakes are used on cereal, in baked goods, canapes, meat loaf and curries, desserts, sauces, and other products. In Israel, banana flakes have been made by steam blanching 'Dwarf Cavendish' bananas and drum drying to 2.6% moisture. The flakes, packed in vacuum sealed cans, keep for a year at 75.2° to 86°F (24° 30°C). At temperatures to 95°F (35°C), the flakes darken somewhat and tend to stick together. Israel has also introduced a formula for high-protein flakes made of 70% banana and 30% soybean protein and this development has been adopted in Brazil. The flakes are used by Brazilian food manufacturers in ice cream, and as fillings for cakes and other bakery products. South Africa has produced flakes of 2/3 banana and 1/3 maize meal.

In Africa, ripe bananas are made into beer and wine. The Tropical Products Institute in London has established a simple procedure for preparing an acceptable vinegar from fermented banana rejects.

The terminal male bud of the wild banana, *M. balbisiana*, is marketed in Southeast Asia. It is often boiled whole after soaking an hour in salt water, or with several changes of water to reduce astringency, and eaten as a vegetable. The male bud of cultivated bananas is considered too astringent but it is, nevertheless, sometimes similarly consumed. The flowers may be removed from the bud and prepared separately. They are used in curries in Malaya and eaten with palm oil in West Tropical Africa.

The new shoots of young plants may be cooked as greens. Banana pseudostem core constitutes about 10 to 15% of the whole and contains 1% starch, 0.68% crude fiber and 1% total ash. It is often cooked and eaten as a vegetable in India and is canned with potatoes and tomatoes in a curry sauce. Circular slices about 1/2 in (1.25 cm) thick are treated with citric acid and potassium metabisulphite and candied.

In India, a solution of the ash from burned leaves and pseudostems is used as salt in seasoning vegetable curries. The ash contains roughly (per 100 g): potassium, 255 mg; magnesium, 27 mg; phosphorus, 33 mg; calcium, 6.6 mg; sodium, 51 mg.

Dried green plantains, ground fine and roasted, have been used as a substitute for coffee.

Animal Feed

Reject ripe bananas, supplemented with protein, vitamins and minerals, are commonly fed to swine. Green bananas are also used for fattening hogs but, because of the dryness and astringency and bitter taste due to the tannin content, these animals do not care for them unless they are cooked, which makes the feeding costs too high for most growers. Therefore, dehydrated green banana meal has been developed and, though not equal to grain, can constitute up to 75% of the normal hog diet, 40% of the diet of gestating sows. It is not recommended for lactating sows, nor are ripe bananas, even with a 40% protein supplement.

Beef cattle are very fond of green bananas whether they are whole, chopped or sliced. Because of the fruit's deficiency in protein, urea is added at the rate of 8.8 lbs (4 kg) per ton, with a little molasses mixed in to mask the flavor. But transportation is expensive unless the cattle ranch is located near the banana fields. A minor disadvantage is that the bananas are somewhat laxative and the cattle need to be washed down daily. With dairy cattle, it is recommended that bananas constitute no more than 20% of the feed.

In the Philippines, it has been found that meal made from dehydrated reject bananas can form 14% of total broiler rations without adverse effects. Meal made from green and ripe plantain peels has been experimentally fed to chicks in Nigeria. A flour from unpeeled plantains, developed for human consumption, was fed to chicks in a mixture of 2/3 flour and 1/3 commercial chickfeed and the birds were maintained until they reached the size of fryers. They were found thinner and lighter than those on 100% chickfeed and the gizzard lining peeled in shreds. It was assumed that these effects were the result of protein deficiency in the plantains, but they were more likely the result of the tannin content of the flour which interferes with the utilization of protein.

Leaves, pseudostems, fruit stalks and peels, after chopping, fermentation, and drying, yield a meal somewhat more nutritious than alfalfa presscake. This waste material has been considered for use as organic fertilizer in Somalia. In Malaya, pigs fed the pseudostems are less prone to liver and kidney parasites than those on other diets.

Banana peel contains beta sitosterol, stigmasterol, campesterol, cycloeucalenol, cycloartanol, and 24-methylene cycloartanol. The major constituents are 24-methylene cycloartanol palmitate and an unidentified triterpene ketone.

Food Value Per 100 g of Edible Portion*

Other Uses

Banana leaves are widely used as plates and for lining cooking pits and for wrapping food for cooking or storage. A section of leaf often serves as an eye-shade. In Latin America, it is a common practice during rains to hold a banana leaf by the petiole, upside-down, over one's back as an "umbrella" or "raincoat". The leaves of the 'Fehi' banana are used for thatching, packing, and cigarette wrappers. The pseudostems have been fastened together as rafts.

Split lengthwise, they serve as padding on banana inspection turntables and as cushioning to protect the bunches ("stems") during transport in railway cars and trucks. Seat pads for benches are made of strips of dried banana pseudostems in Ecuador. In West Africa, fiber from the pseudostem is valued for fishing lines. In the Philippines, it is woven into a thin, transparent fabric called "agna" which is the principal material in some regions for women's blouses and men's shirts. It is also used for making handkerchiefs. In Ceylon, it is fashioned into soles for inexpensive shoes and used for floor coverings.

Plantain fiber is said to be superior to that from bananas. In the mid-19th Century, there was quite an active banana fiber industry in Jamaica. Improved processes have made it possible to utilize banana fiber for many purposes such as rope, table mats and handbags. In Kerala, India, a kraft type paper of good strength has been made from crushed, washed and dried banana pseudostems which yield 48 to 51% of unbleached pulp. A good quality paper is made by combining banana fiber with that of the betel nut husk (*Areca catechu* L.). But Australian investigators hold that the yield of banana fiber is too low for extraction to be economical. Only 1 to 4 oz (28-113 g) can be obtained from 40 to 80 lbs (18-36 kg) of green pseudostems; 132 tons of green pseudostems would yield only 1 ton of paper. Their conclusion is that the pseudostem has much greater value as organic matter chopped and left in the field.

Fig. 12 Banana pseudostem pad on inspection-turntable, Hacienda Secadal, Ecuador.

Dried banana peel, because of its 30 to 40% tannin content, is used to blacken leather. The ash from the dried peel of bananas and plantains is rich in potash and used for making soap. That of the burned peel of unripe fruits of certain varieties is used for dyeing.

In the Philippines, the Pinatubo Negritos cut off a banana plant close to the ground, make a hollow in the top of the stump, which then fills with watery sap drunk as an emergency thirst quencher. Central Americans obtain the sap of the red banana in the same manner and take it as an aphrodisiac.

Medicinal Uses: All parts of the banana plant have medicinal applications: the flowers in bronchitis and dysentery and on ulcers; cooked flowers are given to diabetics; the astringent plant sap in cases of hysteria, epilepsy, leprosy, fevers, hemorrhages, acute dysentery and diarrhea, and it is applied on hemorrhoids, insect and other stings and bites; young leaves are placed as poultices on burns and other skin afflictions; the astringent ashes of the unripe peel and of the leaves are taken in dysentery and diarrhea and used for treating malignant ulcers; the roots are administered in digestive disorders, dysentery and other ailments; banana seed mucilage is given in cases of catarrh and diarrhea in India.

Antifungal and antibiotic principles are found in the peel and pulp of fully ripe bananas. The antibiotic acts against *Mycobacteria*. A fungicide in the peel and pulp of green fruits is active against a fungus disease of tomato plants. Norepinephrine, dopamine, and serotonin are also present in the ripe peel and pulp. The first two elevate blood pressure; serotonin inhibits gastric secretion and stimulates the smooth muscle of the intestines.

Alleged hallucinogenic effects of the smoke of burning banana peel have been investigated scientifically and have not been confirmed.

Folklore

The banana plant because of its continuous reproduction is regarded by Hindus as a symbol of fertility and prosperity, and the leaves and fruits are deposited on doorsteps of houses where marriages are taking place. A banana plant is often installed in the corner of a rice field as a protective charm. Malay women bathe with a decoction of banana leaves for 15 days after childbirth. Early Hawaiians used a young plant as a truce flag in wars.

Fig

Ficus carica

While the ancient history of the fig centers around the Mediterranean region, and it is most commonly cultivated in mild-temperate climates, it nevertheless has its place in tropical and subtropical horticulture. Botanically identified as *Ficus carica* L. (family Moraceae), it is unique in a genus embracing perhaps over 1,000 species, mostly giant "rubber trees", and mostly tropical. It is almost universally known simply as fig, common fig, or edible fig. The name is very similar in French (*figue*), German (*feige*), Italian and Portuguese (*figo*). In Spanish it is *higo* or *brevo*. Haitians give it the name, *figue France*, to distinguish it from the small, dried bananas called "figs".

Description

The fig is a tree of small dimensions, 10 to 30 ft (3-9 m) high, with numerous spreading branches and a trunk rarely more than 7 in (17.5 cm) in diameter. It contains copious milky latex. The root system is typically shallow and spreading, sometimes covering 50 ft (15 m) of ground, but in

Plate V: FIG, *Ficus carica*

permeable soil some of the roots may descend to 20 ft (6 m). The deciduous leaves are palmate, deeply divided into 3 to 7 main lobes, these more shallowly lobed and irregularly toothed on the margins. The blade is up to 10 in (25 cm) in length and width, fairly thick, rough on the upper surface, softly hairy on the underside. What is commonly accepted as a "fruit" is technically a synconium, that is, a fleshy, hollow receptacle with a small opening at the apex partly closed by small scales. It may be obovoid, turbinate, or pear-shaped, 1 to 4 in (2.5-10 cm) long, and varies in color from yellowish-green to coppery, bronze, or dark-purple. Tiny flowers are massed on the inside wall. In the case of the common fig discussed here, the flowers are all female and need no pollination. There are 3 other types, the "Caprifig" which has male and female flowers requiring visits by a tiny wasp, *Blastophaga grossorum*; the "Smyrna" fig, needing crosspollination by Caprifigs in order to develop normally; and the "San Pedro" fig which is intermediate, its first crop independent like the common fig, its second crop dependent on pollination. The skin of the fig is thin and tender, the fleshy wall is whitish, pale-yellow, or amber, or more or less pink, rose, red or purple; juicy and sweet when ripe, gummy with latex when unripe. Seeds may be large, medium, small or minute and range in number from 30 to 1,600 per fruit.

Origin and Distribution

The fig is believed to be indigenous to Western Asia and to have been distributed by man throughout the Mediterranean area. It has been cultivated for thousands of years, remnants of figs having been found in excavations of Neolithic sites traced to at least 5,000 B.C. As time went on, the fig-growing territory stretched from Afghanistan to southern Germany and the Canary Islands. Pliny was aware of 29 types. Figs were introduced into England some time between 1525 and 1548. It is not clear when the common fig entered China but by 1550 it was reliably reported to be in Chinese gardens. European types were taken to China, Japan, India, South Africa and Australia.

The first figs in the New World were planted in Mexico in 1560. Figs were introduced into California when the San Diego Mission was established in 1769. Later, many special varieties were received from Europe and the eastern United States where the fig reached Virginia in 1669. The Smyrna fig was brought to California in 1881-82 but it was not until 1900 that the wasp was introduced to serve as the pollinating agent and make commercial fig culture possible. From Virginia, fig culture spread to the Carolinas, Georgia, Florida, Alabama, Mississippi, Louisiana and Texas. The tree was planted in Bermuda in early times and was common around Bahamian plantations in Colonial days. It became a familiar dooryard plant in the West Indies, and at medium and low altitudes in Central America and northern South America. There are fair-sized plantations on mountainsides of Honduras and at low elevations on the Pacific side of Costa Rica. From Florida to northern South America and in India only the common fig is grown. Chile and Argentina grow the types suited to cooler zones.

In Venezuela, the fig is one of the fruits in greatest demand by fruit processors. Because of the inadequate supply, a program was launched in 1960 to encourage commercial plantings. In 1976, fresh figs were regarded as highly desirable luxuries and were selling for $6.35 to $7.25 per lb ($14-$16/kg) in Colombia. The Instituto Colombiano Agropecuario had realized some years earlier that fig growing should be encouraged and had established an experimental plantation in 1973. The results were so favorable that they circulated an advisory bulletin to farmers in 1977, including improved methods of cultivation, costs of production and potential revenue.

Varieties

There are many cultivated varieties in each class of figs. In fact, over 700 varietal names are in use but many are synonyms. Here we need only present those that are suited to warm areas and do not require pollination. Most popular among these are 'Celeste' and 'Brown Turkey', followed by 'Brunswick' and 'Marseilles', described as follows:

'Celeste'—pear-shaped, ribbed, sometimes with a short neck and slender stalk to 3/4 in (2 cm) long; the eye (opening at apex) is closed; the fruit is small to medium; the skin purplish-brown or bronze tinged with purple and covered with bloom; the pulp whitish or pinkish amber, of rich flavor and good quality; almost seedless. Main crop is heavy but of short duration. There is rarely an early, "breba", crop.

'Brown Turkey'—broad-pyriform, usually without neck; medium to large; copper-colored; pulp is whitish shading to pink or light red; of good to very good quality; with few seeds. The tree is prolific. The main crop, beginning in mid-July, is large; the early, breba, crop is small. This cultivar is well adapted to warm climates. It is grown on all the islands of Hawaii.

'Brunswick' ('Magnolia')—leaves narrow-lobed; fruits of main crop are oblique-turbinate, mostly without neck; fruit stalk thick, often swollen; fruit of medium size; bronze or purple-brown; pulp whitish near skin, shading to pink or amber; hollow in center; of fair to good quality; nearly seedless. Ripens over a long season. Breba crop poor; large, bronze-skinned; flesh light-red; coarse.

'Marseilles' ('White Marseilles', or 'Lemon')—fruits of main crop round to oblate without neck; on slender stalks to 1/4 in (6 mm) long; of medium size. Those of breba crop, turbinate with short, thick neck and short stalk; yellow-green with small green flecks; pulp white, sweet; seeds large, conspicuous. Of fair quality.

In Queensland, 'Brown Turkey', 'Adriatic', 'Genoa' and 'Purple Genoa' perform very well.

'Adriatic' ('White Adriatic', or 'Grosse Verte')—turbinate with short, thick neck and short stalk; above medium size; green to yellowish-green with red pulp; of distinctive flavor and very good quality. In early, minor, breba crop the fruits are oblique-pyriform, large, green, often tinged with purplish-red with dark-red pulp and strong flavor.

'Genoa' ('White Genoa')—pyriform or turbinate, very faintly ribbed; neck thick and short, or absent; above medium in size; skin downy, greenish-yellow; pulp greenish-white near skin, mostly amber tinged with red; hollow; of fair quality. Fruits of breba crop oblique-obovate with thick neck and short stalk; yellowish-green externally; pulp light-red; of fair to good quality.

'Purple Genca' ('Black Genoa'; 'Black Spanish') oblong, broad at apex, narrow at base; large; very dark-purple with thick blue bloom; pulp yellowish becoming reddish to red at the center; juicy, with sweet, rich flavor.

At Saharanpur, India, 'Brown Turkey', 'Bangalore', 'Black Ischia' and 'Lucknow' are successfully grown. Around Bombay, there is only one variety, 'Poona'.

'Black Ischia' ('Blue Ischia')—an Italian variety; main crop is elongated pear shaped with many noticeable rlbs; short neck and short to medium stalk; large, 2 1/2 in (6.35 cm) long and 1 1/2 in (3.8 cm) wide; dark purple-black except at the apex where it is lighter and greenish; there are many golden flecks; skin is wholly coated with thin, dark-blue bloom; eye open, with red-violet scales; pulp is violet-red, of good quality. In the breba crop, there are few rlbs and mostly indistinct; the fruit is small, about 1 1/2 in (3.8 cm) long and of the same width at the apex; the pulp is red to greenish-amber; of poor flavor. The tree is particularly ornamental and the leaves are glossy, only shallowly 3 lobed. A heavy bearer.

'Poona'-bell-shaped, of medium size, weighing about 1 1/2 oz (42 g); thin-skinned; light-purple with red flesh, of sweet, good flavor.

We have no descriptions of 'Bangalore' and 'Lucknow'.

Climate

In southern India, 'Marseilles' flourishes on hills above 5,000 ft (1,525 m). In tropical areas generally, figs thrive between 2,600 and 5,900 ft (800-1,800 m). The tree can tolerate 10° to 20° of frost in favorable sites. It should have a dry climate with light early spring rains if it is intended for the production of fresh fruit. Rains during fruit development and ripening are detrimental to the crop, causing the fruits to split. The semi arid tropical and subtropical regions of the world are ideal for fig-growing if means of irrigation are available. But very hot, dry spells will cause fruit-drop even if the trees are irrigated.

Soil

The fig can be grown on a wide range of soils; light sand, rich loam, heavy clay or limestone, providing there is sufficient depth and food drainage. Sandy soil that is medium-dry and contains a good deal of lime is preferred when the crop is intended for drying. Highly acid soils are unsuitable. The pH should be between 6.0 and 6.5. The tree is fairly tolerant of moderate salinity.

Propagation

Fig trees have been raised from seed, even seed extracted from commercial dried fruits. Ground- or air-layering can be done satisfactorily, and rapid mass multiplication by tissue culture has been achieved in Greece, but the tree is commonly propagated by cuttings of mature wood 2 to 3 years of age, 1/2 to 3/4 in (1.25-2 cm) thick and 8 to 12 in (20-30 cm) long. Planting must be done within 24 hours but, first, the upper, slanting end of the cutting should be treated with a sealant to protect it from disease, and the lower, flat, end with a root-promoting hormone. Trees of unsatisfactory varieties can be topworked by shield- or patch-budding, or cleft- or bark-grafting.

Culture

Cuttings are raised in nursery beds and are set out in the field after 12 or 15 months. They may be spaced from 6 to 25 ft (1.8-7.5 m) apart depending on the cultivar and the fertility of the soil. A spacing of 13 x 13 ft (4x4 m) allows 260 trees/acre (625 trees/ha). In Colombia, growers are advised to set the trees at 10 x 10 ft (3x3 m) on level land, 10 x 13 ft (3x4 m) on slopes. Fruiting will commence in less than a year from planting out. Young plants will benefit from shading with palm fronds or other material until they are well established. A fertilizer formula of 10-30-10 or 10-20-20 NPK is recommended 2 oz (about 60 g) each for young plants and 1/5 lb (100 g) each for adults, plus minor elements at the rate of 1 oz (30 g) per tree every 6 months.

Fig trees are cut back severely in fall or winter, depending on whether the crop is desired the following summer or fall. Branches are often notched to induce lateral branching and increase the yield. If there are heavy rains, drainage ditches should be dug to prevent water-logging. Fig trees remain productive up to 12 or 15 years of age and thereafter the crop declines though the trees may live to a very advanced age.

Season

Fig trees usually bear 2 crops a year, the early season ("breba") fruits being inferior and frequently too acid, and only those of the second, or main, crop of actual value.

In Colombia and Venezuela, some fruits are borne throughout the year but there are 2 principal crops, one in May and June and the other in December and January.

Large-scale fig producers in California spray ethephon to speed up ripening and then wind-machines are drawn past the trees or helicopter overflights are made to hasten fruit drop, thus shortening the harvest period by as much as 10 days in order to avoid impending rain and insect attack. Proper timing of the growth regulator is crucial to fruit quality.

Harvesting and Yield

The fruits may be picked from the tree or gathered normally or by mechanical sweepers after they fall to the ground. 'Brunswick' is so tender it must be picked when slightly unripe in order to be firm enough for processing. Workers must wear gloves and protective clothing because of the latex. Harvested fruits are spread out in the shade for a day so that the latex will dry a little. Then they are transported to processing plants in wooden boxes holding 22 to 33 lbs (10-15 kg). In India, a fig tree bears 180 to 360 fruits per year. Venezuelan growers expect 132 to 176 lbs (6-8 kg) per tree.

Keeping Quality

Fresh figs are very perishable. At 40° to 43°F (4.44°-6.11°C) and 75% relative humidity, figs remain in good condition for 8 days but have a shelf life of only 1 to 2 days when removed from storage. At 50°F (10°C) and relative humidity of 85%, figs can be kept no longer than 21 days. They remain in good condition for 30 days when stored at 32° to 35° F (0°-1.67° C). If frozen whole, they can be maintained for several months.

Pests and Diseases

Fig trees are prone to attack by nematodes (especially *Meloidogyne* spp.) and, in the tropics, have been traditionally planted close to a wall or building so that the roots can go underneath and escape damage. A heavy mulch will serve equally well. Today, control is possible with proper application of nematicides.

In India, a stem-borer, *Batocera rufomaculata*, feeds on the branches and may kill the tree. Lepidopterous pests in Venezuela include the fig borer, *Azochis gripusalis*, the larvae of which feed on the new growth, tunnel down through the trees to the roots and kill the tree. Another, called *cachudo de la higuera*, has prominently horned larvae up to 3 1/8 in (8 cm) long that can destroy a fig tree in a few days. There are also coleopterous insects of the genera *Epitrix* and *Colaspis* that perforate and severely damage the leaves and shoots. Scale insects include *Asterolecanium* sp. which attacks the bark of trees weakened by excessive humidity or prolonged drought, and the lesser enemy, *Saissetia haemispherica.*

A common and widespread problem is leaf rust caused by *Cerotelium fici*; bringing about premature leaf fall and reducing yields. It is most prevalent in rainy seasons. Leaf spot results from infection by *Cylindrocladium scoparium* or *Cercospora fici*. Fig mosaic is caused by a virus and is incurable. Affected trees must be destroyed.

The dried fruit beetle, or sour bug, *Carpophilus* spp., enters the fruit through the eye and leads to souring and smut caused by *Aspergillus niger*. This fungus may attack ripening fruits.

Food Uses

Some people peel the skin back from the stem end to expose the flesh for eating out of-hand. The more fastidious eater holds the fruit by the stem end, cuts the fruit into quarters from the apex, spreads the sections apart and lifts the flesh from the skin with a knife blade, discarding the stem and skin. Commercially, figs are peeled by immersion for 1 minute in boiling lye water or a boiling solution of sodium bicarbonate. In warm, humid climates, figs are generally eaten fresh and raw without peeling, and they are often served with cream and sugar. Peeled or unpeeled, the fruits may be merely stewed or cooked in various ways, as in pies, puddings, cakes, bread or other bakery products, or added to ice cream mix. Home owners preserve the whole fruits in sugar sirup or prepare them as jam, marmalade, or paste. Fig paste (with added wheat and corn flour, whey, sirup, oils and other ingredients) forms the filling for the well known bakery product, "Fig Newton". The fruits are sometimes candied whole commercially. In Europe; western Asia, northern Africa and California, commercial canning and drying of figs are industries of great importance.

Some drying is done in Poona, India, and there is currently interest in solar-drying in Guatemala. Usually, the fruits are allowed to fully ripen and partially dehydrate on the tree, then are exposed to sulphur fumes for about a half hour, placed out in the sun and turned daily to achieve uniform drying, and pressed flat during the 5- to 7-day process. 'Black Mission' and 'Kadota' figs are suitable for freezing whole in sirup, or sliced and layered with sugar.

Dried cull figs have been roasted and ground as a coffee substitute. In Mediterranean countries, low-grade figs are converted into alcohol. An alcoholic extract of dried figs has been used as a flavoring for liqueurs and tobacco.

Toxicity

The latex of the unripe fruits and of any part of the tree may be severely irritating to the skin if not removed promptly. It is an occupational hazard not only to fig harvesters and packers but also to workers in food industries, and to those who employ the latex to treat skin diseases.

Other Uses

Seed oil: Dried seeds contain 30% of a fixed oil containing the fatty acids: oleic, 18.99%; linoleic, 33.72%; linolenic, 32.95%; palmitic, 5.23%; stearic, 2.1 8%; arachidic, 1.05%. It is an edible oil and can be used as a lubricant.

Leaves: Fig leaves are used for fodder in India. They are plucked after the fruit harvest. Analyses show: moisture, 67.6%; protein, 4.3%; fat, 1.7%; crude fiber, 4.7%; ash, 5.3%; N-free extract, 16.4%; pentosans, 3.6%; carotene on a dry weight basis, 0.002%. Also present are bergaptene, stigmasterol, sitosterol, and tyrosine.

In southern France, there is some use of fig leaves as a source of perfume material called "fig-leaf absolute"—a dark-green to brownish-green, semi-solid mass or thick liquid of herbaceous-woody-mossy odor, employed in creating woodland scents.

Latex: The latex contains caoutchouc (2.4%), resin, albumin, cerin, sugar and malic acid, rennin, proteolytic enzymes, diastase, esterase, lipase, catalase, and peroxidase. It is collected at its peak of activity in early morning, dried and powdered for use in coagulating milk to make cheese and junket. From it can be isolated the protein-digesting enzyme *ficin* which is used for tenderizing meat, rendering fat, and clarifying beverages.

In tropical America, the latex is often used for washing dishes, pots and pans. It was an ingredient in some of the early commercial detergents for household use but was abandoned after many reports of irritated or inflamed hands in housewives.

Medicinal Uses: The latex is widely applied on warts, skin ulcers and sores, and taken as a purgative and vermifuge, but with considerable risk. In Latin America, figs are much employed as folk remedies. A decoction of the fruits is gargled to relieve sore throat; figs boiled in milk are repeatedly packed against swollen gums; the fruits are much used as poultices on tumors and other abnormal growths. The leaf decoction is taken as a remedy for diabetes and calcifications in the kidneys and liver. Fresh and dried figs have long been appreciated for their laxative action.

Food Value Per 100 g of Edible Portion*

	Fresh	*Dried*
Calories	80	274
Moisture	77.5-86.8g	23.0g

Morton, J. 1987. Breadfruit. p. 50–58. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Breadfruit

Artocarpus altilis

One of the great food producers in its realm and widely known, at least by name, through its romanticized and dramatized history, the breadfruit, *Artocarpus altilis* Fosb. (syns. *A. communis* J.R. and G. Forst.; *A. incisus* L.f.) belongs to the mulberry family, Moraceae. The common name is almost universal, in English, or tanslated into Spanish as *fruta de pan* (fruit), or *arbor de pan*, *arbor del pan* (tree), or *pan de pobre*; into French, as *fruit a pain* (seedless), *chataignier* (withseeds), *arbre a pain* (tree); Portuguese, *fruta pao*, or *pao de massa*; Dutch, *broodvrucht* (fruit), *broodboom* (tree). InVenezuela it may be called *pan de ano*, *pan de todo el ano*, *pan de palo*, *pan de name*, *topan*, or *tupan*; in Guatemale and Honduras, *mazapan* (seedless), *castana* (with seeds); in Peru, *marure*; in Yucatan, *castano de Malabar* (with seeds); in Puerto Rico, *panapen* (seedless), *pana de pepitas* (with seeds). In Malaya and Java, it is *suku* or *sukun* (seedless); *kulur*, *kelur*, or *kulor* (with seeds); in Thailand, *sa-ke*, in the Philippines, *rimas* (seedless); in Hawaii, *ulu*. The type with seeds is sometimes called "breadnut", a name better limited to *Brosimum alicastrum* Swartz, an edible-seeded tree of Yucatan, Central America and nearby areas. Its Spanish name is *ramon* and the seeds, leaves and twigs are prized as stock feed.

Description

Fig. 13: Ripe breadfruit (*Artocarpus altilis*). In: K. & J. Morton, *Fifty Tropical Fruits of Nassau*, 1946.

The breadfruit tree is handsome and fast growing, reaching 85 ft (26 m) in height, often with a clear trunk to 20 ft (6 m) becoming 2 to 6 ft (0.6-1.8 m) in width and often buttressed at the base, though some varieties may never exceed 1/4 or 1/2 of these dimensions. There are many spreading branches, some thick with lateral foliage-bearing branchlets, others long and slender with foliage clustered only at their tips. The leaves, evergreen or deciduous depending on climatic conditions, on thick, yellow petioles to 1 1/2 in (3.8 cm) long, are ovate, 9 to 36 in (22.8-90 cm) long, 8 to 20 in (20-50 cm) wide, entire at the base, then more or less deeply cut into 5 to 11 pointed lobes. They are bright-green and glossy on the upper surface, with conspicuous yellow veins; dull, yellowish and coated with minute, stiff hairs on the underside.

The tree bears a multitude of tiny flowers, the male densely set on a drooping, cylindrical or club-shaped spike 5 to 12 in (12.5-30 cm) long and 1 to 1 1/2 in (2.5-3.75 cm) thick, yellowish at first and becoming brown. The female are massed in a somewhat rounded or elliptic, green, prickly head, 2 1/2 in (6.35 cm) long and 1 1/2 in (3.8 cm) across, which develops into the compound fruit (or syncarp), oblong, cylindrical, ovoid, rounded or pearshaped, 3 1/2 to 18 in (9-45 cm) in length and 2 to 12 in (5-30 cm) in diameter. The thin rind is patterned with irregular, 4- to 6-sided faces, in some "smooth" fruits level with the surface, in others conical; in some, there may rise from the center of each face a sharp, black point, or a green, pliable spine to 1/8 in (3 mm) long or longer. Some fruits may have a harsh, sandpaper-like rind. Generally the rind is green at first, turning yellowish-green, yellow or yellow-brown when ripe, though one variety is lavender.

In the green stage, the fruit is hard and the interior is white, starchy and somewhat fibrous. When fully ripe, the fruit is somewhat soft, the interior is cream colored or yellow and pasty, also sweetly fragrant. The seeds are irregularly oval, rounded at one end, pointed at the other, about 3/4 in (2 cm) long, dull-brown with darker stripes. In the center of seedless fruits there is a cylindrical or oblong core, in some types covered with hairs bearing flat, brown, abortive seeds about 1/8 in (3 mm) long. The fruit is borne singly or in clusters of 2 or 3 at the branch tips. The fruit stalk (pedicel) varies from 1 to 5 in (2.5-12.5 cm) long.

All parts of the tree, including the unripe fruit, are rich in milky, gummy latex. There are two main types: the normal, "wild" type (cultivated in some areas) with seeds and little pulp, and the "cultivated" (more widely grown) seedless type, but occasionally a few fully developed seeds are found in usually seedless cultivars. Some forms with entire leaves and with both seeds and edible pulp have been classified by Dr. F.R. Fosberg as belonging to a separate species, *A. mariannensis* Trecul. but these commonly integrate with *A. altilis* and some other botanists regard them as included in that highly variable species.

Fig. 14 Breadfruit is borne singly or in 2's or 3's at the branch tips of this handsome, large-leaved tree.

Origin and Distribution

The breadfruit is believed to be native to a vast area extending from New Guinea through the Indo-Malayan Archipelago to Western Micronesia. It is said to have been widely spread in the Pacific area by migrating Polynesians, and Hawaiians believed that it was brought from the Samoan island of Upalu to Oahu in the 12th Century A.D. It is said to have been first seen by Europeans in the Marquesas in 1595, then in Tahiti in 1606. At the beginning of the 18th Century, the early English explorers were loud in its praises, and its fame, together with several periods of famine in Jamaica between 1780 and 1786, inspired plantation owners in the British West Indies to petition King George III to import seedless breadfruit trees to provide food for their slaves.

There is good evidence that the French navigator Sonnerat in 1772 obtained the seeded breadfruit in the Philippines and brought it to the French West Indies. It seems also that some seedless and seeded breadfruit plants reached Jamaica from a French ship bound for Martinique but captured by the British in 1782. There were at least two plants of the seeded breadfruit in Jamaica in 1784 and distributions were quickly made to the other islands. There is a record of a plant having been sent from Martinique to the St. Vincent Botanical Garden before 1793. The story of Captain Thigh's first voyage to Tahiti, in 1787, and the loss of his cargo of 1,015 potted breadfruit plants on his disastrous return voyage is well known. He set out again in 1791 and delivered 5 different kinds totalling 2,126 plants to Jamaica in February 1793. On that island, the seedless breadfruit flourished and it came to be commonly planted in other islands of the West Indies, in the lowlands of Central America and northern South America. In some areas, only the seedless type is grown, in others, particularly Haiti, the seeded is more common. Jamaica is by far the leading producer of the seedless type, followed by St. Lucia. In New Guinea, only the seeded type is grown for food.

It has been suggested that the seeded breadfruit was carried by Spaniards from the Philippines to Mexico and Central America long before any reached the West Indies. On the Pacific coast of Central America, the seeded type is common and standard fare for domestic swine. On the Atlantic Coast, seedless varieties are much consumed by people of African origin. The breadfruit tree is much grown for shade in Yucatan. It is very common in the lowlands of Colombia, a popular food in the Cauca Valley, the Choco, and the San Andres Islands; mostly fed to live stock in other areas. In Guyana, in 1978, about 1,000 new breadfruit trees were being produced each year but not nearly enough to fill requests for plants. There and in Trinidad, because of many Asians in the population, both seeded and seedless breadfruits are much appreciated as a regular article of the diet; in some other areas of the Caribbean, breadfruit is regarded merely as a food for the poor for use only in emergencies. Nowadays, it is attracting the attention of gourmets and some islands are making small shipments to the United States, Canada and Europe for specialized ethnic markets. In the Palau Islands of the South Pacific, breadfruit is being outclassed by cassava and imported flour and rice. For some time breadfruit was losing ground to taro (*Colocasia esculenta* Schott.) in Hawaii, but now land for taro is limited and its culture is static.

The United States Department of Agriculture brought in breadfruit plants from the Canal Zone, Panama, in 1906 (S.P.I. #19228). For many years there have been a number of seedless breadfruit trees in Key West, Florida, and there is now at least one on Vaca Key about 50 miles to the northeast. On the mainland of Florida, the tree can be maintained outdoors for a few years with mild winters but, unless protected with plastic covering to prevent dehydration, it ultimately succumbs. A few have been kept alive in greenhouses or conservatories such as the Rare Plant House of Fairchild Tropical Garden, and the indoor garden of the Jamaica Inn on Key Biscayne.

Varieties

An unpublished report of 1921 covered 200 cultivars of breadfruit in the Marquesas. The South Pacific Commission published the results of a breadfruit survey in 1966. In it, there were described 166 named sorts from Tonga, Niue, Western and American Samoa, Papua and New Guinea, New Hebrides and Rotuma. There are 70 named varieties of seeded and seedless breadfruits in Fiji. They are locally separated into 8 classes by leaf form. The following, briefly presented, are those that are recorded as "very good". It will be noted that some varietal names are reported under more than one class.

Class I: Leaf entire, or with one or two, occasionally, three lobes.

'Koqo'— round; 4 in (10 cm) wide; seedless; does not deteriorate quickly.

'Tamaikora'—gourd shaped (constricted around middle); to 4 1/2 in (11.5 cm) long, 3 in (7.5 cm) wide; with many seeds. Can be eaten raw when ripe. Highly perishable. Tree to 40 or 45 ft (12-13.5 m).

Class II: Leaf dissected at apex.

'Temaipo'—round; 3 1/2 in (9 cm) long; seedless. Can be eaten raw when ripe. There is also an oblong form with many seeds.

Class III: Leaf moderately deeply dissected at apex.

'Uto Kuro'—round; 5 in (12.5 cm) long; does not deteriorate quickly.

Class IV: Leaf moderately deeply dissected on upper half.

'Samoa'—('Kasa Balavu') round; 4 to 6 in (10-15 cm) long; seeds sparse to many.

'Uto Yalewa'—oblong; to 8 in (20 cm) long and 6 in (15 cm) wide; seedless.

'Kulu Dina'—oblong; to 16 in (40 cm) long and 13 in (33 cm) wide; seedless. Need not be peeled after cooking. Tree bears all year.

'Sogasoga'—oblong; to 9 in (23 cm) long and 6 1/2 in (16.5 cm) wide; seedless.

'Uto Dina'—oblong; to 6 in (15 cm) long and 3 to 3 1/2 in (7.5-9 cm) wide; seedless; need not be peeled after cooking. Tree 60 to 70 ft (18-21 m) high.

'Buco Ni Viti'—oblong; 11 to 14 in (28-35.5 cm) long, 6 to 7 in (15-18 cm) wide; seedless; one of the best cultivars.

'Tamaikora'—oblong; 7 to 9 in (18-23 cm) long, 5 to 6 1/2 in (12.5-16.5 cm) wide; seeds sparse; pulp eaten raw when ripe. Tree to 75 or 85 ft (23-26 m) high; bears 2 crops per year.

'Kulu Mabomabo'—oval; 6 to 8 in (15-20 cm) long, 4 to 5 1/2 in (10-14 cm) wide; seedless.

Class V: Leaf moderately deeply dissected; shape of leaf base variable.

'Uto Dina'—round; 4 1/2 to 5 in (11.5-12.5 cm) wide; seed less. Highly recommended. Tree is 25-30 ft (7.5-9 m) tall.

'Balekana Ni Samoa'—round; 4 to 5 in (10-12.5 cm) long; seeds sparse. Best of all Samoan varieties. There is an oval form by the same name; seedless; deteriorates very quickly.

'Balekana Ni Vita'—round; 3 1/2 to 4 in (9-10 cm) long; seedless. Does not deteriorate quickly.

'Balekana Dina'—oval; 6 to 8 in (15-20 cm) long, 3 to 5 in (7.5-12.5 cm) wide; seeds sparse. One of the best, especially when boiled.

'Tabukiraro'—round; 8 in (20 cm) long; seedless; skin sometimes eaten after cooking.

'Sici Ni Samoa'—oval; 5 to 6 in (12.5-15 cm) long, 3 to 3 1/2 in (7.5-9 cm) wide; seedless. One of the highly recommended Samoan varieties.

'Uto Me'—oval; 5 to 6 3/4 in (12.5-17 cm) long, 4 1/2 to 5 in (11.5 cm) wide; with many seeds; does not deteriorate quickly.

'Uto Wa'—oval; 6 to 7 1/2 in (15-19 cm) long, 5 to 5 1/2 in (12.5-14 cm) wide. The variety most recommended.

'Kulu Vawiri'—oval; 9 to 12 in (22-30 cm) long, 8 to 9 in (20-22 cm) wide; especially good when boiled.

Class VI: Leaf deeply dissected.

'Kulu Dina'—round; 3 to 4 in (7.5-10 cm) long; seedless. Need not be peeled after boiling. Highly recommended.

'Balekana'—oval; 4 in (10 cm) long, 3 in (7.5 cm) wide; of the best quality. Tree 70 to 80 ft (21-24 m) high.

'Balekana Ni Samoa'—round; 3 in (7.5 cm) long; seeds sparse. Best of all Samoan varieties.

'Balekana Ni Viti'—oblong; 5 to 6 in (12.5-15 cm) long, 3 to 4 in (7.5-10 cm) wide; seedless. The best native-type variety.

'Uto Dina'—('Kasa Leka') round; 4 in (10 cm) long; seedless.

'Uto Matala'—round; 3 to 4 in (7.5-10 cm) long. Especially fine when boiled. Tree bears 3 times a year.

Class VII: Leaf deeply dissected; apex pointed.

'Balekana Ni Samoa'—round; 5 to 5 1/2 in (12.5-14 cm) long; seeds sparse. Best of all Samoan varieties.

'Kulu Dina'—('Kasa Balavu') oval; 6 to 7 in (15-18 cm) long, 4 to 5 in (10-12.5 cm) wide; seedless.

'Uto Dina'—(Large) oval; 8 to 9 in (20-22 cm) long, 4 to 7 in (10-18 cm) wide; seedless. Also, by the same name, a form with only moderately dissected leaves.

'Bokasi'—round; 4 in (10 cm) long, 3 in (7.5 cm) wide.

Class VIII: Leaf deeply dissected, wide spaces between lobes.

'Savisavi Ni Samoa'—oval; 4 to 5 in (10-12.5 cm) long, 3 to 3 1/2 in (7.5-9 cm) wide. Ranks with best Samoan varieties.

'Savisavi Ni Viti'—oblong; 6 to 8 in(16-20 cm) long, 4 to 6 in (10-15 cm) wide; seedless; especially good when boiled.

'Savisavi'—round; 3 to 3 1/2 in (7.5-9 cm) wide; especially good when boiled.

'Balawa Ni Viti'—oval; 6 to 7 in (15-18 cm) long, 3 1/2 to 4 in (9-10 cm) wide; seedless.

'Uto Kasekasei'—round; 4 to 5 in (10-12.5 cm) long; seeds sparse.

'Via Loa'—oblong; 6 to 7 in (15-18 cm) long, 4 to 5 in (10-12.5 cm) wide; seedless; does not deteriorate quickly.

Koroieveibau provides a key to the 8 classes illustrated by leaf and fruit outline sketches.

P.J. Wester, in 1928, published descriptions of 52 breadfruit cultivars of the Pacific Islands. In the book, *The Breadfruit of Tahiti*; by G.P. Wilder, there are detailed descriptions and close-up, black-and-white photographic illustrations of the foliage and fruit of 30 named varieties, and of the foliage only of one which did not have mature fruit at the time of writing. One 'Aata', an oblong fruit, is described as of poor quality and eaten by humans only when better breadfruits are scarce, but it is important as feed for pigs and horses. The tree bears heavily. Among the best are:

'Aravei'—fruit ellipsoidal; large, 8 to 12 in (10-30 cm) long, 6 to 9 in (15-22 cm) wide; rind yellowish-green with brown spots on the sunny side; rough, with sharp points which are shed on maturity. Pulp is light-yellow, dry or flaky and of delicious flavor after cooking which takes very little time. Core long, slim, with many abortive seeds.

'Havana'—fruit oval-round; the rind yellowish-green, spiny; pulp golden-yellow, moist, pasty, separates into loose flakes when cooked; very sweet with excellent flavor; core oval, large, with a row of abortive seeds. Very perishable; must be used within 2 days; cooks quickly over fire. Fruit borne in 2's and 3's. Popularly claimed to be one of the best breadfruits.

'Maohi'—fruit round; 6 in (15 cm) wide; rind bright yellow-green with patches of red-brown; rough, with spines, and often bears much exuded latex. Pulp cream-colored and smooth when cooked; of very good flavor; slow cooking, needs even heat. Core is large. Fruit is borne in 2's and 3's. Tree a heavy bearer. This is the most common breadfruit of Tahiti.

'Paea'—ellipsoidal; very large, to 11 in (28 cm) long and 9 in (22.8 cm) wide; rind yellowish-green, spiny; core oblong, thick, with a row of brown, abortive seeds; pulp bright-yellow, moist, slightly pasty, separating into flakes when cooked; agreeable but only one of its forms, 'Paea Maaroaro', is really sweet. Formerly, 'Paea' was reserved for chiefs only. Needs one hour to roast on open fire. The tree is tall, especially well formed and elegant.

'Pei'—broad-ellipsoidal; large; rind light-green, relatively smooth; pulp light-yellow and flaky when cooked, aromatic, of sweet, delicious "fruity" flavor; cooks quickly. Ripens earlier than others. When the breadfruit crop is scant, the fruits of this cultivar are stored by burying in the ground until needed, even for a year, then taken up, wrapped in *Cordyline* leaves and boiled.

'Pucro'—fruit spherical or elongated; large; rind yellow-green with small brown spots, very rough, spiny, thin; pulp light-yellow and smooth, of excellent flavor. Cooks quickly. Highly esteemed, ranked with the very best breadfruits. There are two oblong forms, one with a large, hairy core.

'Rare'—fruit broad-ovoid; to 7 in (17.5 cm) long, rind bright-green, rough, spiny; pulp of deep-cream tone, fine-grained, smooth, flaky when cooked; of very sweet, excellent flavor. Core is small with a great many small abortive seeds. Must be cooked for about one hour. There are 3 forms that are well recognized. Fruits are borne singly on a tall, open, short branched tree.

'Rare Aumee'—fruit round; 6 1/2 in (16.5 cm) across; rind bright-green with red-brown splotches, fairly smooth at the base but rough at the apex; pulp deep-ivory, firm, smooth when cooked; not very sweet but of excellent flavor. Cooks quickly. Highly prized; in scarce supply because the tall, few branched tree bears scantily.

'Rare Autia'—fruit round; 6 in (15 cm) across; rind dull-green with red-brown markings. Pulp light-yellow when cooked and separates into chunks; has excellent flavor. Core is large with small abortive seeds all around. This cultivar is so superior it was restricted to royalty and high chiefs in olden times.

'Tatara'—fruit broad-ellipsoid; verylarge, up to 10 lbs(4.5 kg) in weight; rind has prominent faces with long green spines; pulp light-yellow, smooth when cooked and of pleasant flavor. Core is oblong. This variety is greatly esteemed. The tree is found only in a small coastal valley where there is heavy rainfall. It is of large dimensions and high-branching and it is difficult to harvest the fruits.

'Vai Paere'—fruit is obovoid; 10 to 12 in (25-30 cm) long, 7 to 8 in (17.5-20 cm) wide; rind is yellow-green with red-brown splotches and there is a short raised point at the center of each face; pulp light-yellow, firm, smooth, a little dryish when cooked, with a slightly acid, but excellent flavor. Core is oblong, large, with a few abortive seeds attached. Fruit cooks easily. Tree is very tall, bears fruit in clusters. Grows at sea level in fairly dry locations.

There are at least 50 cultivars on Ponape and about the same number on Truk. In Samoa, a variety known as **'Maopo'**, with leaves that are almost entire or sometimes very shallowly lobed, is very common and considered one of the best.

'Puou' is another choice and much planted variety since early times. It has deeply cut leaves and nearly round fruits 6 in (15 cm) long. 'Ulu Ea', with leaves even more deeply lobed, has oblong fruits to 6 1/8 in (15.5 cm) long and 5 in (12.5 cm) wide; is a longtime favorite.

In the past three decades there has been an awakening to the possibilities of increasing the food supply of tropical countries by more plantings of selected varieties of seedless breadfruit. In 1958, many appealing varieties (some early, some late in season) were collected around the South Pacific region and transferred to Western Samoa, Tahiti and Fiji for comparative trials. Two years later, plans were made to introduce Polynesian varieties into Micronesia, and propagating material of 36 Micronesian types was distributed to other areas.

Climate

The breadfruit is ultra-tropical, much tenderer than the mango tree. It has been reported that it requires a temperature range of 60° to 100°F (15.56°-37.78°C), an annual rainfall of 80 to 100 in (203-254 cm), and a relative humidity of 70 to 80%. However, in southern India, it is cultivated at sea level and up humid slopes to an altitude of 3,500 ft (1,065 m), also in thickets in dry regions where it can be irrigated. In the "equatorial dry climate" of the Marquesas, where the breadfruit is an essential crop, there is an average rainfall of only 40 to 60 in (100-150 cm) and frequent droughts. In Central America, it is grown only below 2,000 ft (600 m).

Soil

According to many reports, the breadfruit tree must have deep, fertile, well-drained soil. But some of the best authorities on South Pacific plants point out that the seedless breadfruit does well on sandy coral soils, and seeded types grow naturally on "coraline limestone" islands in Micronesia. In New Guinea, the breadfruit tree occurs wild along waterways and on the margins of forests in the flood plain, and often in freshwater swamps. It is believed that there is great variation in the adaptability of different strains to climatic and soil conditions, and that each should be matched with its proper environment. The Tahitian 'Manitarvaka' is known to be drought-resistant. The variety 'Mai-Tarika', of the Gilbert Islands, is salt-tolerant. 'Mejwaan', a seeded variety of the Marshall Islands, is not harmed by brackish water nor salt spray and has been introduced into Western Samoa and Tahiti.

Propagation

The seeded breadfruit is always grown from seeds, which must be planted when fairly fresh as they lose viability in a few weeks. The seedless breadfruit is often propagated by transplanting suckers which spring up naturally from the roots. One can deliberately induce suckers by uncovering and injuring a root. Pruning the parent tree will increase the number of suckers, and root pruning each sucker several times over a period of months before taking it up will contribute to its survival when transplanted. For multiplication in quantity, it is better to make root cuttings about 1 to 2 1/2 in (2.5-6.35 cm) thick and 9 in (22 cm) long. The ends may be dipped into a solution of potassium permanganate to coagulate the latex, and the cuttings are planted close together horizontally in sand. They should be shaded and watered daily, unless it is possible to apply intermittent mist. Calluses may form in 6 weeks (though rooting time may vary from 2 to 5 months) and the cuttings are transplanted to pots, at a slant, and watered once or twice a day for several months or until the plants are 2 ft (60 cm) high. A refined method of rapid propagation uses stem cuttings taken from root shoots. In Puerto Rico, the cuttings are transplanted into plastic bags containing a mixture of soil, peat and sand, kept under mist for a week, then under 65% shade, and given liquid fertilizer and regular waterings. When the root system is well developed, they are allowed full sun until time to set out in the field.

In India, it is reported that breadfruit scions can be successfully grafted or budded onto seedlings of wild jackfruit trees.

Culture

Young breadfruit trees are planted in well-enriched holes 15 in (40 cm) deep and 3 ft (0. 9m) wide that are first prepared by burning trash in them to sterilize the soil and then insecticide is mixed with the soil to protect the roots and shoots from grubs. The trees are spaced 25 to 40 ft (7.5-12 m) apart in plantations. Usually there are about 25 trees per acre (84/ha). Those grown from root suckers will bear in 5 years and will be productive for 50 years. Some growers recommend pruning of branches that have borne fruit and would normally die back, because this practice stimulates new shoots and also tends to keep the tree from being too tall for convenient harvesting.

Standard mixtures of NPK are applied seasonally. When the trees reach bearing age, they each receive, in addition, 4.4 lbs (2 kg) superphosphate per year to increase the size and quality of the fruits.

Season

In the South Seas, the tree fruits more or less continuously, fruit in all stages of development being present on the tree the year around, but there are two or three main fruiting periods. In the Caroline Islands and the Gilbert Islands, the main ripening season is May to July or September; in the Society Islands and New Hebrides, from November to April, the secondary crop being in July and August. Breadfruits are most abundant in Hawaiian markets off and on from July to February. Flowering starts in March in northern India and fruits are ready for harvest in about 3 months. Seeded breadfruits growing in the Eastern Caroline Islands fruit only once a year but the season is 3 months long—from December to March. Seedless varieties introduced from Ponape bear 2 to 3 times a year. In the Bahamas, breadfruit is available mainly from June to November, but some fruits may mature at other times during the year.

Harvesting and Yield

Breadfruits are picked when maturity is indicated by the appearance of small drops of latex on the surface. Harvesters climb the trees and break the fruit stalk with a forked stick so that the fruit will fall. Even though this may cause some bruising or splitting, it is considered better than catching the fruits by hand because the broken pedicel leaks much latex. They are packed in cartons in which they are separated individually by dividers.

In the South Pacific, the trees yield 50 to 150 fruits per year. In southern India, normal production is 150 to 200 fruits annually. Productivity varies between wet and dry areas. In the West Indies, a conservative estimate is 25 fruits per tree. Studies in Barbados indicate a reasonable potential of 6.7 to 13.4 tons per acre (16-32 tons/ha). Much higher yields have been forecasted, but experts are skeptical and view these as unrealistic.

Keeping Quality

In Jamaica, surplus breadfruits are often kept under water until needed. Fully ripe fruits that have fallen from the tree can be wrapped in polyethylene, or put into polyethylene bags, and kept for 10 days in storage at a temperature of 53.6°F (12°C). At lower temperature, the fruit shows chilling injury. Slightly unripe fruits that have been caught by hand when knocked down can be maintained for 15 days under the same conditions. The thickness of the polyethylene is important: 38-or even 50-micrometer bags are beneficial, but not 25-micrometer.

Some Jamaican exporters partly roast the whole fruits to coagulate the latex, let them cool, and then ship them by sea to New York and Europe. Various means of preserving breadfruit for future local use are mentioned under "Food Uses", q.v.

Pests and Diseases

Soft-scales and mealybugs are found on breadfruit trees in the West Indies and ants infest branches that die back after fruiting. In southern India, the fruits on the tree are subject to soft rot. This fungus disease can be controlled by two sprays of Bordeaux mixture, one month apart. Young breadfruit trees in Trinidad have been killed by a disease caused by *Rosellinia* sp. In the Pacific Islands *Fusarium* sp. is believed to be the cause of die back, and *Pythium* sp. is suspected in cases of root rot. A mysterious malady, called "Pingalap disease", killed thousands of trees from 1957 to 1960 in the Gilbert and Ellice Islands, the Caroline Islands, Marshalls and Mariannas. The foliage wilts and then the branch dies back. Sometimes the whole tree is affected and killed to the roots; occasionally only half of a tree declines. The fungus, *Phytophthora palmivora*, attacks the fruit on the island of Truk. *Phomopsis, Dothiorella* and *Phylospora* cause stem-end rot.

Food Uses

Like the banana and plantain, the breadfruit may be eaten ripe as a fruit or underripe as a vegetable. For the latter purpose, it is picked while still starchy and is boiled or, in the traditional Pacific Island fashion, roasted in an underground oven on pre-heated rocks. Sometimes it is cored and stuffed with coconut before roasting. Malayans peel firm-ripe fruits, slice the pulp and fry it in sirup or palm sugar until it is crisp and brown. Filipinos enjoy the cooked fruit with coconut and sugar.

Fully ripe fruits, being sweeter, are baked whole with a little water in the pan. Some cooks remove the stem and core before cooking and put butter and sugar in the cavity, and serve with more of the same. Others may serve the baked fruit with butter, salt and pepper. Ripe fruits may be halved or quartered and steamed for 1 or 2 hours and seasoned in the same manner as baked fruits. The steamed fruit is sometimes sliced, rolled in flour and fried in deep fat. In Hawaii, underripe fruits are diced, boiled, and served with butter and sugar, or salt and pepper, or diced and cooked with other vegetables, bacon and milk as a chowder. In the Bahamas, breadfruit soup is made by boiling underripe chunks of breadfruit in water until the liquid begins to thicken, then adding cooked salt pork, chopped onion, white pepper and salt, stirring till thick, then adding milk and butter, straining, adding a bit of sherry and simmering until ready to serve.

The pulp scraped from soft, ripe breadfruits is combined with coconut milk (not coconut water), salt and sugar and baked to make a pudding. A more elaborate dessert is concocted of mashed ripe breadfruit, with butter, 2 beaten eggs, sugar, nutmeg, cinnamon and rosewater, a dash of sherry or brandy, blended and boiled. There are numerous other dishes peculiar to different areas. Breadfruit is also candied, or sometimes prepared as a sweet pickle.

In Micronesia, the peel is scraped off with a sharpened cowrie shell, or the fruits are peeled with a knife, cored, cut up and put into sacks or baskets, soaked in the sea for about 2 hours while being beaten or trampled; allowed to drain on shore for a few days; then packed in banana leaf-lined boxes to ferment for a month or much longer, the leaves being changed weekly.

In Polynesia and Micronesia, a large number of fruits are baked in a native oven and left there to ferment. Over a period of a few weeks, batches are taken out as needed. In the New Hebrides, peeled breadfruits are wrapped in leaves and placed to ferment in piles of stones on open beaches where they will be flooded at high tide. In Samoa, seeded breadfruits are skinned, washed, quartered and left to ferment in a pit lined and covered with layers of banana and *Heliconia* leaves, and topped with earth and rocks. The fruits ferment for long periods, sometimes for several years, and form a pasty mass called *masi*. The seeds are squeezed out, the paste is wrapped in *Heliconia* leaves smeared with coconut cream and the product is baked for 2 hours. There is a strong, cheese-like odor, but it is much relished by the natives.

The original method of poi making involved peeling, washing and halving the fruit, discarding the core, placing the fruits in stone pits lined with leaves of Cordylme terminalis Kunth, alternating the layers of fruit with old fermented pod, covering the upper layer with leaves, topping the pit with soil and rocks and leaving the contents to ferment, which acidifies and preserves the breadfruit for several years.

Modern poi is made from firm-ripe fruits, boiled whole until tender, cored, sliced, ground, pounded to a paste, kneaded with added water to thin it, strained through cloth, and eaten. If it is to be kept in the refrigerator for 2 days, only a little water is added in kneading; more is added and it is strained just before serving. Food value and digestibility are improved by mixing with poi made from taro which is rated highly as a non-allergenic food. In the Seychelles, the seedless breadfruit is cut into slices 1/2 in (1.25 cm) thick, dried for 4 days at 120°F (48.89°C). In some Pacific Islands, the fruits are partly roasted, then peeled, dried and formed into loaves for long-time storage. The Ceylonese dip breadfruit slices into a salt solution, then blanch them in boiling water for 5 minutes, dry them at 158°F (70°C) for 4 to 6 hours before storing. The slices will keep in good condition for 8 to 10 months. In Guam, cooked fruits may be mashed to a paste which is spread out thin, dried in the sun, and wrapped in leaves for storage. It is soaked in water to soften it for eating. This might be called "breadfruit leather". On the small Kapingamarangi Atoll in the Caroline Islands, the cooked paste is pressed into sheets 5 ft (1.5 m) long and 20 in (50 cm) wide, dried in the sun on coconut leaf mats, then rolled into cylinders, wrapped in *Pandanus* leaves and stored for at least 3 years.

The dried fruit has been made into flour and improved methods have been explored in Barbados and Brazil with a view to substituting breadfruit in part for wheat flour in breadmaking. The combination has been found more nutritious than wheat flour alone. Breadfruit flour is much richer than wheat flour in lysine and other essential amino acids. In Jamaica, the flour is boiled, sweetened, and eaten as porridge for breakfast.

Soft or overripe breadfruit is best for making chips and these are being manufactured commercially in Trinidad and Barbados. Some breadfruit is canned in Dominica and Trinidad for shipment to London and New York.

In Jamaica, Puerto Rico and the South Pacific, fallen male flower spikes are boiled, peeled and eaten as vegetables or are candied by recooking, for 2-3 hours, in sirup; then rolled in powdered sugar and sun-dried.

The seeds are boiled, steamed, roasted over a fire or in hot coals and eaten with salt. In West Africa, they are sometimes made into a puree. In Costa Rica, the cooked seeds are sold by street vendors.

Underripe fruits are cooked for feeding to pigs. Soft-ripe fruits need not be cooked and constitute a large part of the animal feed in many breadfruit-growing areas of the Old and New World. Breadfruit has been investigated as potential material for chickfeed but has been found to produce less weight gain than cassava or maize despite higher intake, and it also causes delayed maturity.

Experiments by technologists at the United States Department of Agriculture's Western Regional Research Laboratory in Berkeley, California, have demonstrated that breadfruit can be commercially dehydrated by tunnel drying or freeze-drying and the waste from these processes constitutes a highly-digestible stock feed.

Food Value Per 100 g of Edible Portion*

	Fruit (underripe, raw)	*Ripe (cooked)*	*Seeds (fresh)*	*Seeds (roasted)*	*Seeds (dried)*
Calories	105-109

*A composite of analyses made in Central America, Mexico, Colombia, Africa and India.

Note: There are reportedly two enzymes in the breadfruit—*papayotin* and *artocarpine*.

Negron de Bravo and colleagues in Puerto Rico show niacin content up to 8.33 mg in dried, ground seeds collected locally.

It will be seen from the above that the seedless breadfruit is low in protein, the seeds considerably higher, and therefore the seeded breadfruit is actually of more value as food.

Breadfruit flour contains 4.05% protein; 76.70% carbohydrates, and 331 calories, while cassava flour contains,1.16% protein, 83.83% carbobydrates, and 347 calories per 100 g.

Toxicity

Most varieties of breadfruit are purgative if eaten raw. Some varieties are boiled twice and the water thrown away, to avoid unpleasant effects, while there are a few named cultivars that can be safely eaten without cooking.

The cyclopropane-containing sterol, *cycloartenol*, has been isolated from the fresh fruit. It contitutes 12% of the non-saponifiable extract.

Other Uses

Leaves: Breadfruit leaves are eagerly eaten by domestic livestock. In India, they are fed to cattle and goats; in Guam, to cattle, horses and pigs. Horses are apt to eat the bark of young trees as well, so new plantings must be protected from them.

Latex: Breadfruit latex has been used in the past as birdlime on the tips of posts to catch birds. The early Hawaiians plucked the feathers for their ceremonial cloaks, then removed the gummy substance from the birds' feet with oil from the candlenut, *Aleurites moluccana* Willd., or with sugarcane juice, and released them.

After boiling with coconut oil, the latex serves for caulking boats and, mixed with colored earth, is used as a paint for boats.

Wood: The wood is yellowish or yellow-gray with dark markings or orange speckles; light in weight; not very hard but strong, elastic and termite resistant (except for drywood termites) and is used for construction and furniture. In Samoa, it is the standard material for house-posts and for the rounded roof-ends of native houses. The wood of the Samoan variety 'Aveloloa' which has deeply cut leaves, is most preferred for house-building, but that of 'Puou', an ancient variety, is also utilized. In Guam and Puerto Rico the wood is used for interior partitions. Because of its lightness, the wood is in demand for surfboards. Traditional Hawaiian drums are made from sections of breadfruit trunks 2 ft (60 cm) long and 1 ft (30 cm) in width, and these are played with the palms of the hands during Hula dances. After seasoning by burying in mud, the wood is valued for making household articles. These are rough-sanded by coral and lava, but the final smoothing is accomplished with the dried stipules of the breadfruit tree itself.

Fiber: Fiber from the bark is difficult to extract but highly durable. Malaysians fashioned it into clothing. Material for tape cloth is obtained from the inner bark of young trees and branches. In the Philippines, it is made into harnesses for water buffalo.

Flowers: The male flower spike used to be blended with the fiber of the paper mulberry, *Broussonetia papyrifera* Vent. to make elegant loincloths. When thoroughly dry, the flower spikes also serve as tinder.

Medicinal Uses: In Trinidad and the Bahamas, a decoction of the breadfruit leaf is believed to lower blood pressure, and is also said to relieve asthma. Crushed leaves are applied on the tongue as a treatment for thrush. The leaf juice is employed as ear-drops. Ashes of burned leaves are used on skin infections. A powder of roasted leaves is employed as a remedy for enlarged spleen. The crushed fruit is poulticed on tumors to "ripen" them. Toasted flowers are rubbed on the gums around an aching tooth. The latex is used on skin diseases and is bandaged on the spine to relieve sciatica. Diluted latex is taken internally to overcome diarrhea.

Morton, J. 1987. Jackfruit. p. 58–64. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Jackfruit

Artocarpus heterophyllus

The jackfruit, *Artocarpus heterophyllus* Lam. (syns. *A. integrifolius* Auct. NOT L. f.; *A integrifolia* L. f.; *A. integra* Merr.; *Rademachia integra* Thunb.), of the family Moraceae, is also called jak-fruit, jak, jaca, and, in Malaysia and the Philippines, *nangka*; in Thailand, *khanun*; in Cambodia, *khnor*; in Laos, *mak mi* or *may mi*; in Vietnam, *mit*. It is an excellent example of a food prized in some areas of the world and allowed to go to waste in others. O.W. Barrett wrote in 1928: ";The jaks . . . are such large and interesting fruits and the trees so well-behaved that it is difficult to explain the general lack of knowledge concerning them.";

Description

The tree is handsome and stately, 30 to 70 ft (9-21 m) tall, with evergreen, alternate, glossy, somewhat leathery leaves to 9 in (22.5 cm) long, oval on mature wood, sometimes oblong or deeply lobed on young shoots. All parts contain a sticky, white latex. Short, stout flowering twigs emerge from the trunk and large branches, or even from the soil-covered base of very old trees. The tree is monoecious: tiny male flowers are borne in oblong clusters 2 to 4 in (5-10 cm) in length; the female flower clusters are elliptic or rounded. Largest of all tree-borne fruits, the jackfruit may be 8 in to 3 ft (20-90 cm) long and 6 to 20 in (15-50 cm) wide, and the weight ranges from 10 to 60 or even as much as 110 lbs (4.5-20 or 50 kg). The "rind' or exterior of the compound or aggregate fruit is green or yellow when ripe and composed of numerous hard, cone-like points attached to a thick and rubbery, pale yellow or whitish wall. The interior consists of large "bulbs" (fully developed perianths) of yellow, banana-flavored flesh, massed among narrow ribbons of thin, tough undeveloped perianths (or perigones), and a central, pithy core. Each bulb encloses a smooth, oval, light-brown "seed" (endocarp) covered by a thin white membrane (exocarp). The seed is 3/4 to 1 1/2 in (2-4 cm) long and 1/2 to 3/4 in (1.25-2 cm) thick and is white and crisp within. There may be 100 or up to 500 seeds in a single fruit. When fully ripe, the unopened jackfruit emits a strong disagreeable odor, resembling that of decayed onions, while the pulp of the opened fruit smells of pineapple and banana.

Plate 6: JACKFRUIT, *Artocarpus heterophyllus*

Origin and Distribution

No one knows the jackfruit's place of origin but it is believed indigenous to the rainforests of the Western Ghats. It is cultivated at low elevations throughout India, Burma, Ceylon, southern China, Malaya, and the

East Indies. It is common in the Philippines, both cultivated and naturalized. It is grown to a limited extent in Queensland and Mauritius. In Africa, it is often planted in Kenya, Uganda and former Zanzibar. Though planted in Hawaii prior to 1888, it is still rare there and in other Pactfic islands, as it is in most of tropical America and the West Indies. It was introduced into northern Brazil in the mid-19th Century and is more popular there and in Surinam than elsewhere in the New World.

In 1782, plants from a captured French ship destined for Martinique were taken to Jamaica where the tree is now common, and about 100 years later, the jackfruit made its appearance in Florida, presumably imported by the Reasoner's Nursery from Ceylon. The United States Department of Agriculture's *Report on the Conditions of Tropical and Semitropical Fruits in the United States in 1887* states: "There are but few specimens in the State. Mr. Bidwell, at Orlando, has a healthy young tree, which was killed back to the ground, however, by the freeze of 1886. " There are today less than a dozen bearing jackfruit trees in South Florida and these are valued mainly as curiosities. Many seeds have been planted over the years but few seedlings have survived, though the jackfruit is hardier than its close relative, the breadfruit (q.v.).

In South India, the jackfruit is a popular food ranking next to the mango and banana in total annual production. There are more than 100,000 trees in backyards and grown for shade in betelnut, coffee, pepper and cardamom plantations. The total area planted to jackfruit in all India is calculated at 14,826 acres (26,000 ha). Government horticulturists promote the planting of jackfruit trees along highways, waterways and railroads to add to the country's food supply.

There are over 11,000 acres (4,452 ha) planted to jack fruit in Ceylon, mainly for timber, with the fruit a much-appreciated by-product. The tree is commonly cultivated throughout Thailand for its fruit. Away from the Far East, the jackfruit has never gained the acceptance accorded the breadfruit (except in settlements of people of East Indian origin). This is due largely to the odor of the ripe fruit and to traditional preference for the breadfruit.

Varieties

In South India, jackfruits are classified as of two general types: 1) *Koozha chakka*, the fruits of which have small, fibrous, soft, mushy, but very sweet carpels; 2) *Koozha pazham*, more important commercially, with crisp carpers of high quality known as *Varika*. These types are apparently known in different areas by other names such as *Barka*, or *Berka* (soft, sweet and broken open with the hands), and *Kapa* or *Kapiya* (crisp and cut open with a knife). The equivalent types are known as *Kha-nun nang* (firm; best) and *Kha-nun lamoud* (soft) in Thailand; and as *Vela* (soft) and *Varaka*, or *Waraka* (firm) in Ceylon. *The Peniwaraka*, or honey jak, has sweet pulp, and some have claimed it the best of all. The *Kuruwaraka* has small, rounded fruits. Dr. David Fairchild, writing of the honey jak in Ceylon, describes the rind as dark-green in contrast to the golden yellow pulp when cut open for eating, but the fruits of his own tree in Coconut Grove and those of the Matheson tree which he maintained were honey jaks are definitely yellow when ripe. The *Vela* type predominates in the West Indies.

Firminger described two types: the *Khuja* (green, hard and smooth, with juicy pulp and small seeds); the *Ghila* (rough, soft, with thin pulp, not very juicy, and large seeds). Dutta says *Khujja*, or *Karcha*, has pale-brown or occcasionally pale-green rind, and pulp as hard as an apple; *Ghila*, or *Ghula*, is usually light-green, occasionally brownish, and has soft pulp, sweet or acidulously sweet. He describes 8 varieties, only one with a name. This is *Hazari*; similar to *Rudrakshi*; which has a relatively smooth rind and flesh of inferior quality.

The **'Singapore'**, or **'Ceylon'**, jack, a remarkably early bearer producing fruit in 18 months to 2 1/2 years from transplanting, was introduced into India from Ceylon and planted extensively in 1949. The fruit is of medium size with small, fibrous carpers which are very sweet. In addition to the summer crop (June and July), there is a second crop from October to December. In 1961, the Horticultural Research Institute at Saharanpur, India, reported the acquisition of air-layered plants of the excellent varieties, **'Safeda'**, **'Khaja'**, **'Bhusila'**, **'Bhadaiyan'** and **'Handia'** and others. The Fruit Experimental Station at Burliar, established a collection of 54 jackfruit clones from all producing countries, and ultimately selected **'T Nagar Jack'** as the best in quality and yield. The Fruit Experimental Station at Kallar, began breeding work in 1952 with a view to developing short, compact, many-branched trees, precocious and productive, bearing large, yellow, high quality fruits, 1/2 in the main season, 1/2 late. 'Singapore Jack' was chosen as the female parent because of its early and late crops; and, as the male parent, **'Velipala'**, a local selection from the forest having large fruits with large carpers of superior quality, and borne regularly in the main summer season. After 25 years of testing, one hybrid was rated as outstanding for precocity, fruit size, off-season as well as main season production, and yield excelling its parents. It had not been named when reported on by Chellappan and Roche in 1982. In Assam, nurserymen have given names such as 'Mammoth', 'Everbearer', and 'Rose-scented' to preferred types.

Pollination

Horticulturists in Madras have found that hand-pollination produces fruits with more of the fully developed bulbs than does normal wind-pollination.

Climate

The jackfruit is adapted only to humid tropical and near-tropical climates. It is sensitive to frost in its early life and cannot tolerate drought. If rainfall is deficient, the tree must be irrigated. In India, it thrives in the Himalayan foothills and from sea-level to an altitude of 5,000 ft (1,500 m) in the south. It is stated that jackfruits grown above 4,000 ft (1,200 m) are of poor quality and usable only for cooking. The tree ascends to about 800 ft (244 m) in Kwangtung, China.

Soil

The jackfruit tree flourishes in rich, deep soil of medium or open texture, sometimes on deep gravelly or laterite soil. It will grow, but more slowly and not as tall in shallow limestone. In India, they say that the tree grows tall and thin on sand, short and thick on stony land. It cannot tolerate "wet feet". If the roots touch water, the tree will not bear fruit or may die.

Propagation

Propagation is usually by seeds which can be kept no longer than a month before planting. Germination requires 3 to 8 weeks but is expedited by soaking seeds in water for 24 hours. Soaking in a 10% solution of gibberellic acid results in 100% germination. The seeds may be sown *in situ* or may be nursery-germinated and moved when no more than 4 leaves have appeared. A more advanced seedling, with its long and delicate tap root, is very difficult to transplant successfully. Budding and grafting attempts have often been unsuccessful, though Ochse considers the modified Forkert method of budding feasible. Either jackfruit or champedak (q.v.) seedlings may serve as rootstocks and the grafting may be done at any time of year. Inarching has been practiced and advocated but presents the same problem of transplanting after separation from the scion parent. To avoid this and yet achieve consistently early bearing of fruits of known quality, air-layers produced with the aid of growth promoting hormones are being distributed in India. In Florida cuttings of young wood have been rooted under mist. At Calcutta University, cuttings have been successfully rooted only with forced and etiolated shoots treated with indole butyric acid (preferably at 5,000 mg/l) and kept under mist. Tissue culture experiments have been conducted at the Indian Institute of Horticultural Research, Bangalore.

Culture

Soaking one-month-old seedlings in a gibberellic acid solution (25-200 ppm) enhances shoot growth. Gibberellic acid spray and paste increase root growth. In plantations, the trees are set 30 to 40 ft (9-12 m) apart. Young plantings require protection from sunscald and from grazing animals, hares, deer, etc. Seeds in the field may be eaten by rats. Firminger describes the quaint practice of raising a young seedling in a 3 to 4 ft (0.9-1.2 m) bamboo tube, then bending over and coiling the pliant stem beneath the soil, with only the tip showing. In 5 years, such a plant is said to produce large and fine fruits on the spiral underground. In Travancore, the whole fruit is buried, the many seedlings which spring up are bound together with straw and they gradually fuse into one tree which bears in 6 to 7 years. Seedlings may ordinarily take 4 to 14 years to come into bearing, though certain precocious cultivars may begin to bear in 2 1/2 to 3 1/2 years. The jackfruit is a fairly rapid grower, reaching 58 ft (17.5 m) in height and 28 in (70 cm) around the trunk in 20 years in Ceylon. It is said to live as long as 100 years. However, productivity declines with age. In Thailand, it is recommended that alternate rows be planted every 10 years so that 20-year-old trees may be routinely removed from the plantation and replaced by a new generation. Little attention has been given to the tree's fertilizer requirements. Severe symptoms of manganese deficiency have been observed in India.

After harvesting, the fruiting twigs may be cut back to the trunk or branch to induce flowering the next season. In the Cachar district of Assam, production of female flowers is said to be stimulated by slashing the tree with a hatchet, the shoots emerging from the wounds; and branches are lopped every 3 to 4 years to maintain fruitfulness. On the other hand, studies at the University of Kalyani, West Bengal, showed that neither scoring nor pruning of shoots increases fruit set and that ringing enhances fruit set only the first year, production declining in the second year.

Season

In Asia, jackfruits ripen principally from March to June, April to September, orJune to August, depending on the climatic region, with some off-season crops from September to December, or a few fruits at other times of the year. In the West Indies, I have seen many ripening in June; in Florida, the season is late summer and fall.

Harvesting

Fruits mature 3 to 8 months from flowering. In Jamaica, an "X" is sometimes cut in the apex of the fruit to speed ripening and improve flavor.

Yield

In India, a good yield is 150 large fruits per tree annually, though some trees bear as many as 250 and a fully mature tree may produce 500, these probably of medium or small size.

Fig. 16: Much white, gummy latex flows from the jackfruit stalk when the slightly underripe fruit is harvested.

Storage

Jackfruits turn brown and deteriorate quickly after ripening. Cold storage trials indicate that ripe fruits can be kept for 3 to 6 weeks at 52° to 55°F (11.11°-12.78°C) and relative humidity of 85 to 95%.

Pests and Diseases

Principal insect pests in India are the shoot-borer caterpillar, *Diaphania caesalis*; mealybugs. *Nipaecoccus viridis, Pseudococcus corymbatus*, and *Ferrisia virgata*, the spittle bug, *Cosmoscarta relata*, and jack scale, *Ceroplastes rubina*. The most destructive and widespread bark borers are *Indarbela tetraonis* and *Batocera rufomaculata*. Other major pests are the stem and fruit borer, *Margaronia caecalis*, and the brown bud-weevil, *Ochyromera artocarpio*. In southern China, the larvae of the longicorn beetles, including *Apriona germarri*; *Pterolophia discalis, Xenolea tomenlosa asiatica*, and *Olenecamptus bilobus* seriously damage the fruit stem. The caterpillar of the leaf webbers, *Perina nuda* and *Diaphania bivitralis*, is a minor problem, as are aphids, *Greenidea artocarpi* and *Toxoptera aurantii*; and thrips, *Pseudodendrothrips dwivarna*.

Diseases of importance include pink disease, *Pelliculana (Corticium) salmonicolor*, stem rot, fruit rot and male inflorescence rot caused by *Rhizopus artocarpi*; and leafspot due to *Phomopsis artocarpina*, *Colletotrichum lagenarium*, *Septoria artocarpi*, and other fungi. Gray blight, *Pestalotia elasticola*, charcoal rot, *Ustilana zonata*, collar rot, *Rosellinia arcuata*, and rust, *Uredo artocarpi*, occur on jackfruit in some regions.

The fruits may be covered with paper sacks when very young to protect them from pests and diseases. Burkill says the bags encourage ants to swarm over the fruit and guard it from its enemies.

Food Uses

Westerners generally will find the jackfruit most acceptable in the full-grown but unripe stage, when it has no objectionable odor and excels cooked green breadfruit and plantain. The fruit at this time is simply cut into large chunks for cooking, the only handicap being its copious gummy latex which accumulates on the knife and the hands unless they are first rubbed with salad oil. The chunks are boiled in lightly salted water until tender, when the really delicious flesh is cut from the rind and served as a vegetable, including the seeds which, if thoroughly cooked, are mealy and agreeable. The latex clinging to the pot may be removed by rubbing with oil. The flesh of the unripe fruit has been experimentally canned in brine or with curry. It may also be dried and kept in tins for a year. Cross sections of dried, unripe jackfruit are sold in native markets in Thailand. Tender young fruits may be pickled with or without spices.

Fig. 17: Dried slices of peeled unripe jackfruit are commonly marketed in Southeast Asia

If the jackfruit is allowed to ripen, the bulbs and seeds may be extracted outdoors; or, if indoors, the odorous residue should be removed from the kitchen at once. The bulbs may then be enjoyed raw or cooked (with coconut milk or otherwise); or made into ice cream, chutney, jam, jelly, paste, "leather" or *papad*, or canned in sirup made with sugar or honey with citric acid added. The crisp types of jackfruit are preferred for canning. The canned product is more attractive than the fresh pulp and is sometimes called "vegetable meat". The ripe bulbs are mechanically pulped to make jackfruit nectar or reduced to concentrate or powder. The addition of synthetic flavoring—ethyl and *n*-butyl esters of 4-hydroxybutyric acid at 120 ppm and 100 ppm, respectively greatly improves the flavor of the canned fruit and the nectar.

Fig 18: Jackfruit seeds, salvaged from the ripe fruits, are sold for boiling or roasting like chestnuts.

If the bulbs are boiled in milk, the latter when drained off and cooled will congeal and form a pleasant, orange colored custard. By a method patented in India, the ripe bulbs may be dried, fried in oil and salted for eating like potato chips. Candied jackfruit pulp in boxes was being marketed in Brazil in 1917. Improved methods of preserving and candying jackfruit pulp have been devised at the Central Food Technological Research Institute, Mysore, India. Ripe bulbs, sliced and packed in sirup with added citric acid, and frozen, retain good color, flavor and texture for one year. Canned jackfruit retains quality for 63 weeks at room temperature—75° to 80°F (23.89°-26.67°C), with only 3% loss of B-carotene. When frozen, the canned pulp keeps well for 2 years.

In Malaya, where the odor of the ripe fruit is not avoided, small jackfruits are cut in half, seeded, chilled, and brought to the table filled with ice cream.

The ripe bulbs, fermented and then distilled, produce a potent liquor.

The seeds, which appeal to all tastes, may be boiled or roasted and eaten, or boiled and preserved in sirup like chestnuts. They have also been successfully canned in brine, in curry, and, like baked beans, in tomato sauce. They are often included in curried dishes. Roasted, dried seeds are ground to make a flour which is blended with wheat flour for baking.

Where large quantities of jackfruit are available, it is worthwhile to utilize the inedible portion, and the rind has been found to yield a fair jelly with citric acid. A pectin extract can be made from the peel, undeveloped perianths and core, or just from the inner rind; and this waste also yields a sirup used for tobacco curing.

Tender jackfruit leaves and young male flower clusters may be cooked and served as vegetables.

Food Value Per 100 g of Edible Portion

	Pulp (ripe-fresh)	Seeds (fresh)	Seeds (dried)
Calories	98		
Moisture	72.0-77.2 g	51.6-57.77 g	
Protein	1.3-1.9 g	6.6 g	
Fat	0.1-0.3 g	0.4 g	
Carbohydrates	18.9-25.4 g	38.4 g	
Fiber	1.0-1.1 g	1.5 g	
Ash	0.8-1.0 g	1.25-1.50 g	2.96%
Calcium	22 mg	0.05-0.55 mg	0.13%
Phosphorus	38 mg	0.13-0.23 mg	0.54%
Iron	0.5 mg	0.002-1.2 mg	0.005%
Sodium	2 mg		
Potassium	407 mg		
Vitamin A	540 I.U.		
Thiamine	0.03 mg		
Niacin	4 mg		
Ascorbic Acid	8-10 mg		

The pulp constitutes 25-40% of the fruit's weight.

In general, fresh seeds are considered to be high in starch, low in calcium and iron; good sources of vitamins B_1 and B2.

Toxicity

Even in India there is some resistance to the jackfruit, attributed to the belief that overindulgence in it causes digestive ailments. Burkill declares that it is the raw, unripe fruit that is astringent and indigestible. The ripe fruit is somewhat laxative; if eaten in excess it will cause diarrhea. Raw jackfruit seeds are indigestible due to the presence of a powerful trypsin inhibitor. This element is destroyed by boiling or baking.

Other Uses

Fruit: In some areas, the jackfruit is fed to cattle. The tree is even planted in pastures so that the animals can avail themselves of the fallen fruits. Surplus jackfruit rind is considered a good stock food.

Leaves: Young leaves are readily eaten by cattle and other livestock and are said to be fattening. In India, the leaves are used as food wrappers in cooking, and they are also fastened together for use as plates.

Latex: The latex serves as birdlime, alone or mixed with *Ficus* sap and oil from *Schleichera trijuga* Willd. The heated latex is employed as a household cement for mending chinaware and earthenware, and to caulk boats and holes in buckets. The chemical constituents of the latex have been reported by Tanchico and Magpanlay. It is not a substitue for rubber but contains 82.6 to 86.4% resins which may have value in varnishes. Its bacteriolytic activity is equal to that of papaya latex.

Wood: Jackwood is an important timber in Ceylon and, to a lesser extent, in India; some is exported to Europe. It changes with age from orange or yellow to brown or dark-red; is termite proof, fairly resistant to fungal and bacterial decay, seasons without difficulty, resembles mahogany and is superior to teak for furniture, construction, turnery, masts, oars, implements, brush backs and musical instruments. Palaces were built of jackwood in Bali and Macassar, and the limited supply was once reserved for temples in Indochina. Its strength is 75 to 80% that of teak. Though sharp tools are needed to achieve a smooth surface, it polishes beautifully. Roots of old trees are greatly prized for carving and picture framing. Dried branches are employed to produce fire by friction in religious ceremonies in Malabar.

From the sawdust of jackwood or chips of the heartwood, boiled with alum, there is derived a rich yellow dye commonly used for dyeing silk and the cotton robes of Buddhist priests. In Indonesia, splinters of the wood are put into the bamboo tubes collecting coconut toddy in order to impart a yellow tone to the sugar. Besides the yellow colorant, *morin*, the wood contains the colorless *cyanomaclurin* and a new yellow coloring matter, *artocarpin*, was reported by workers in Bombay in 1955. Six other flavonoids have been isolated at the National Chemical Laboratory, Poona.

Bark: There is only 3.3% tannin in the bark which is occasionally made into cordage or cloth.

Medicinal Uses: The Chinese consider jackfruit pulp and seeds tonic, cooling and nutritious, and to be "useful in overcoming the influence of alcohol on the system." The seed starch is given to relieve biliousness and the roasted seeds are regarded as aphrodisiac. The ash of jackfruit leaves, burned with corn and coconut shells, is used alone or mixed with coconut oil to heal ulcers. The dried latex yields artostenone, convertible to artosterone, a compound with marked androgenic action. Mixed with vinegar, the latex promotes healing of abscesses, snakebite and glandular swellings. The root is a remedy for skin diseases and asthma. An extract of the root is taken in cases of fever and diarrhea. The bark is made into poultices. Heated leaves are placed on wounds. The wood has a sedative property; its pith is said to produce abortion.

Related Species

The **Champedak**, *A. integer* Merr. (syns. *A. champeden* Spreng., *A. polyphena* Pers.), is also known as *chempedak, cempedak, sempedak, temedak* in Malaya; *cham-pa-da in* Thailand, *tjampedak* in Indonesia; *lemasa* in the Philippines. The wild form in Malaya is called *bangkong* or *baroh*. The fruit is borne by a deciduous tree, reaching about 60 ft (18 m) in cultivation, up to 100 or 150 ft (30-45.5 m) in the wild. It is easy to distinguish from the jackfruit by the long, stiff, brown hairs on young branchlets, leaves, buds and peduncles. The leaves, often 3-lobed when young, are obovate oblong or elliptical when mature and 6 to 11 in (15-28 cm) long. The male flower spikes are only 2 in (5 cm) long and the fruit cylindrical or irregular, no more than 14 in (35.5 cm) long and 6 in (15 cm) thick, mustard-yellow to golden-brown, reticulated, warty, and highly odoriferous when ripe. In fact, it is described as having the "strongest and richest smell of any fruit in creation." The rind is thinner than that of the jackfruit and the seeds and surrounding pulp can be extracted by cutting open the base and pulling on the fruit stalk. The pulp is deep-yellow, tender, slimy, juicy and sweet. That of the wild form is thin, subacid and odorless.

The tree is native and common in the wild in Malaya up to an altitude of 4,200 ft (1,300 m) and is cultivated throughout Malaysia and by many preferred to jackfruit. It is grown from seed or budded onto self-seedlings or jackfruit or other *Artocarpus* species. Seedlings bear in 5 years. The pulp is eaten with rice and the seeds are roasted and eaten. The wood is strong and durable and yields yellow dye, and the bark is rich in tannin.

The **Lakoocha**, *A. lakoocha* Roxb., is also known as monkey jack or *lakuchi* in India; *tampang* and other similar native names in Malaya; as *lokhat* in Thailand. The tree is 20 to 30 ft (6-9 m) tall with deciduous, large, leathery leaves, downy on the underside. Male and female flowers are borne on the same tree, the former orange-yellow, the latter reddish. The fruits are nearly round or irregular, 2 to 5 in (5-12.5 cm) wide, velvety, dull-yellow tinged with pink, with sweet sour pulp which is occasionally eaten raw but mostly made into curries or chutney. The male flower spike, acid and astringent, is pickled.

A native of the humid sub-Himalayan region of India, up to 4,000 ft (1,200 m), also Malaya and Ceylon, it is sometimes grown for shade or for its fruit. Seedlings come into production in 5 years. A specimen was planted at the Federal Experiment Station, Mayaguez, Puerto Rico, in 1921. There was a large tree in Bermuda in 1918.

The wood, sold as *lakuch*, is heavier than that of the jackfruit, similar to teak, durable outdoors and under water, but does not polish well. It is used for piles, and in construction; for boats, furniture and cabinetwork. The bark contains 8.5% tannin and is chewed like betelnut. It yields a fiber for cordage. The wood and roots yield a dye of richer color than that obtained from the jackfruit. Both seeds and milky latex are purgative. The bark is applied on skin ailments. The fruit is believed to act as a tonic for the liver.

The **Kwai Muk**, possibly *A. lingnanensis* Merr., was introduced into Florida as *A. hypargyraea* Hance, or *A. hypargyraeus* Hance ex Benth. The tree is a slow-growing, slender, erect ornamental 20 to 50 ft (6-15 m) tall, with much milky latex and evergreen leaves 2 to 5 in (5-12.5 cm) long. Tiny male and female flowers are yellowish and borne on the same tree, the female in globular heads to 3/8 in (1 cm) long.

The fruits are more or less oblate and irregular, 1 to 2 in (2.5-5 cm) wide, with velvety, brownish, thin, tender skin and replete with latex when unripe. When ripe, the pulp is orange-red or red, soft, of agreeable subacid to acid flavor and may be seedless or contain 1 to 7 small, pale seeds. The pulp is edible raw; can be preserved in sirup or dried. Ripens from August to October in Florida.

The tree is native from Kwangtung, China, to Hong Kong, and has been introduced sparingly abroad. It was planted experimentally in Florida in 1927 and was thriving in Puerto Rico in 1929. It grows at an altitude of 500 ft (152 m) in China. Young trees are injured by brief drops in temperature to 28° to 30°F (-2.22°-1.11°C). Mature trees have endured 25° to 26°F (-3.89°-3.33°C) in Homestead, Florida; have been killed by 20°F (-6.67°C) in central Florida.

Morton, J. 1987. Cherimoya. p. 65–69. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Cherimoya

Annona cherimola

Certainly the most esteemed of the fruits of the genus *Annona* (family Annonaceae), the cherimoya, *A. cherimola* Mill., because of its limited distribution, has acquired few colloquial names, and most are merely local variations in spelling, such as *chirimoya, cherimolia, chirimolla*, *cherimolier*, *cherimoyer*. In Venezuela, it is called *chirimorrinon*; in Brazil, *graveola*, *graviola*, or *grabiola*; and in Mexico, *pox* or *poox*; in Belize, *tukib*; in El Salvador it is sometimes known as *anona poshte*; and elsewhere merely as *anona*, or *anona blanca*. In France, it is *anone*; in Haiti, *cachiman la Chine*. Indian names in Guatemala include *pac*, *pap*, *tsummy* and *tzumux*. The name, *cherimoya*, is sometimes misapplied to the less-esteemed custard apple, *A. reticulata* L. In Australia it is often applied to the atemoya (a cherimoya-sugar apple hybrid).

Description

The tree is erect but low branched and somewhat shrubby or spreading; ranging from 16 to 30 ft (5 to 9 m) in height; and its young branchlets are rusty-hairy. The leaves are briefly deciduous (just

Plate 7: CHERIMOYA, *Annona cherimola*

before spring flowering), alternate, 2-ranked, with minutely hairy petioles 1/4 to 1/2 in (6 to 12.5 mm) long; ovate to elliptic or ovate-lanceolate, short blunt-pointed at the apex; slightly hairy on the upper surface, velvety on the underside; 3 to 6 in (7.5-15 cm) long, 1 1/2 to 3 1/2 in (3.8-8.9 cm) wide.

Fragrant flowers, solitary or in groups of 2 or 3, on short, hairy stalks along the branches, have 3 outer, greenish, fleshy, oblong, downy petals to 1 1/4 in (3 cm) long and 3 smaller, pinkish inner petals. A compound fruit, the cherimoya is conical or somewhat heart-shaped, 4 to 8 in (10 to 20 cm) long and up to 4 in (10 cm) in width, weighing on the average 5 1/2 to 18 oz (150-500 g) but extra large specimens may weigh 6 lbs (2.7 kg) or more. The skin, thin or thick, may be smooth with fingerprint like markings or covered with conical or rounded protuberances. The fruit is easily broken or cut open, exposing the snow-white, juicy flesh, of pleasing aroma and delicious, subacid flavor; and containing numerous hard, brown or black, beanlike, glossy seeds, 1/2 to 3/4 in (1.25 to 2 cm) long.

Origin and Distribution

The cherimoya is believed indigenous to the interandean valleys of Ecuador, Colombia and Bolivia. In Bolivia, it flourishes best around Mizque and Ayopaya, in the Department of Cochabamba, and around Luribay, Sapahaqui and Rio Abajo in the Department of La Paz. Its cultivation must have spread in ancient times to Chile and Brazil for it has become naturalized in highlands throughout these countries. Many authors include Peru as a center of origin but others assert that the fruit was unknown in Peru until after seeds were sent by P. Bernabe Cobo from Guatemala in 1629 and that thirteen years after this introduction the cherimoya was observed in cultivation and sold in the markets of Lima. The often-cited representations of the cherimoya on ancient Peruvian pottery are actually images of the soursop, *A. muricata* L. Cobo sent seeds to Mexico also in 1629. There it thrives between 4,000 and 5,000 ft (1312-1640 m) elevations.

It is commonly grown and naturalized in temperate areas of Costa Rica and other countries of Central America. In Argentina, the cherimoya is mostly grown in the Province of Tucuman. In 1757, it was carried to Spain where it remained a dooryard tree until the 1940's and 1950's when it gained importance in the Province of Granada, in the Sierra Nevada mountains, as a replacement for the many orange trees that succumbed to disease and had to be taken out. By 1953, there were 262 acres (106 ha) of cherimoyas in this region.

In 1790 the cherimoya was introduced into Hawaii by Don Francisco de Paulo Marin. It is still casually grown in the islands and naturalized in dry upland forests. In 1785, it reached Jamaica, where it is cultivated and occurs as an escape on hillsides between 3,500 and 5,000 ft (1,066-1,524 m). It found its way to Haiti sometime later. The first planting in Italy was in 1797 and it became a favored crop in the Province of Reggio Calabria. The tree has been tried several times in the

Botanic Gardens, Singapore first around 1878—but has always failed to survive because of the tropical climate. In the Philippines, it does well in the Mountain Province at an altitude above 2,460 ft (750 m). It was introduced into India and Ceylon in 1880 and there is small-scale culture in both countries at elevations between 1,500 and 7,000 ft (457-2,134 m). The tree was planted in Madeira in 1897, then in the Canary Islands, Algiers, Egypt and, probably via Italy, in Libya, Eritrea and Somalia.

The United States Department of Agriculture imported a number of lots of cherimoya seeds from Madeira in 1907 (S.P.I. Nos. 19853, 19854, 19855, 19898, 19901, 19904, 19905).

Seeds from Mexico were planted in California in 1871. There were 9,000 trees in that state in 1936 but many of them were killed by a freeze in 1937. Several small commercial orchards were established in the 1940's. At present there may be less than 100 acres (42 ha) in the milder parts of San Diego County. Seeds, seedlings and grafted trees from California and elsewhere have been planted in Florida many times but none has done well. Any fruits produced have been of poor quality.

Varieties

In Peru, cherimoyas are classed according to degree of surface irregularity, as: **'Lisa'**, almost smooth; **'Impresa'**, with "fingerprint" depressions; **'Umbonada'**, with rounded protrusions; **'Papilonado'**, or **'Tetilado'**, with fleshy, nipple-like protrusions; **'Tuberculada'**, with conical protrusions having wartlike tips. At the Agricultural Experiment Station "La Molina", several named and unnamed selections collected in northern Peru are maintained and evaluated. Among the more important are: #1, **'Chavez'**, fruits up to 3.3 lbs (1 1/2 kg); February to May; #2, **'Names'**, fruits January to April; #3, **'Sander'**, fruits with moderate number of seeds; July and early August; #4, fruit nearly smooth, not many seeds, 1.1 to 2.2 lbs (1/2-1 kg), June to August; #5, nearly smooth, very sweet, 2.2 Ibs (1 kg), March to June; #6, fruit with small protuberances, 1.1 to 2.2 Ibs (1/2-1 kg), not many seeds; #7 fruit small, very sweet, many seeds, March to May; #8, fruit very sweet, 1.1 to 2.2 Ibs (1/2 1 kg), with very few seeds, February to April.

In the Department of Antioquia, Colombia, a cultivar called **'Rio Negro'** has heart shaped fruits weighing 1 3/4 to 2.2 Ibs (0.8-1 kg). The cherimoyas of Mizque, Cochabamba, Bolivia, are locally famed for their size and quality. **'Concha Lisa'** and **'Bronceada'** are grown commercially in Chile. Other cultivars mentioned in Chilean literature are **'Concha Picuda'** and **'Terciopelo'.**

Dr. Ernesto Saavedra, University of Chile, after ex perimenting with growth regulators for 4 years, developed a super cherimoya, 4 to 6 in (10-15 cm) wide and weighing up to 4 Ibs (1.8 kg); symmetrical, easy to peel and seedless, hence having 25% more flesh than an ordinary cherimoya. However, the larger fruits are subject to cracking.

The leading commercial cultivars in Spain are **'Pinchua'** (thin-skinned) and **'Baste'** (thick-skinned.)

Named cultivars in California include:

'Bays'—rounded, fingerprinted, light green, medium to large, of excellent flavor; good bearer; early.

'Whaley'—long-conical, sometimes shouldered at the base, slightly and irregularly tuberculate, with fairly thick, downy skin. Of good flavor, but membranous sac around each seed may adhere to flesh. Bears well; grown commercially; early.

'Deliciosa'—long-conical, prominently papillate; skin tbin, slightly downy; variable in flavor; only fair in quality; generally bears well but doesn't ship well; cold-resistant. Midseason.

'Booth'—short-conical, fingerprinted, medium to large; of good flavor; next to 'Deliciosa in hardiness. Late.

'McPherson'—short conical, fingerprinted but umbonate at the base; medium to large; of high quality; bears well. Midseason.

'Carter'—long-conical, but not shouldered; smooth or faintly fingerprinted; skin green to bronze; bears well. Late. Leaves wavy or twisted.

'Ryerson'—long-conical, smooth or fingerprinted, with tbick, tough, green or yellow green skin; of fair quality; ships well. Leaves wavy or twisted.

'White'—short-conical with rounded apex; slightly papil late to umbonate; medium to large; skin medium thick; of good flavor; doesn t bear well near the coast.

'Chaffey'—introduced in 1940s; rounded, short, finger printed; of medium size; excellent quality; bears well, even without hand-pollination.

'Ott'—(Patent #656)—introduced in 1940's; long conical to heart shaped, slightly tuberculate; of excellent flavor; ships well.

Among others that have been planted in California but considered inferior are: **'Horton'**, **'Golden Russet'**, **'Loma'**, **'Mire Vista'**, **'Sallmon'**.

Pollination

A problem with the cherimoya is inadequate natural pollination because the male and female structures of each flower do not mature simultaneously. Few insects visit the flowers. Therefore, hand-pollination is highly desirable and must be done in a 6- to 8-hour period when the stigmas are white and sticky. It has been found in Chile that in the first flowers to open the pollen grains are loaded with starch, whereas flowers that open later have more abundant pollen, no starch grains, and the pollen germinates readily. Partly-opened flowers are collected in the afternoon and kept in a paper bag overnight. The next morning the shed pollen is put, together with moist paper, in a vial and transferred by brush to the receptive stigmas. Usually only a few of the flowers on a tree are pollinated each time, the operation being repeated every 4 or 5 days in order to extend the season of ripening. The closely related *A. senegalensis* Pers., if available, is a good source of abundant pollen for pollinating the cherimoya. The pollen of the sugar apple is not satisfactory. Fruits from hand-pollinated flowers will be superior in form and size.

Climate

The cherimoya is subtropical or mild-temperate and does not succeed in the lowland tropics. It requires long days. In Colombia and Ecuador, it grows naturally at elevations between 4,600 and

6,600 ft (1,400-2,000 m) where the temperature ranges between 62.6° and 68°F (17°-20°C). In Peru, the ideal climate for the cherimoya is said to lie between 64.5° and 77°F (18°-25°C) in the summer and 64.5° and 41°F (18°-5°C) in winter. In Guatemala, naturalized trees are common between 4,000 and 8,200 ft (1,200-2,500 m) though the tree produces best between 4,000 and 5,900 ft (1,200-1,800 m) and can be grown at elevations as low as 2,950 ft (900 m). The tree cannot survive the cold in the Valle de Mexico at 7,200 ft (2,195 m). In Argentina, young trees are wrapped with dry grass or burlap during the winter. The cherimoya can tolerate light frosts. Young trees can withstand a temperature of 26°F (-3.33°C), but a few degrees lower will severely injure or kill mature trees. In February 1949, a small scale commercial grower (B. E. Needham) in Glendora, California, reported that most of his crop was lost because of frost and snow, the cherimoya suffering more cold damage than his avocados, oranges or lemons.

The tree prefers a rather dry environment as in southern Guatemala where the rainfall is 50 in (127 cm) and there is a long dry season. It is not adaptable to northern Guatemala where the 100 inch (254 cm) rainfall is spread throughout the year.

Finally, the tree should be protected from strong winds which interfere with pollination and fruit set.

Soil

The cherimoya tree performs well on a wide range of soil types from light to heavy, but seems to do best on a medium soil of moderate fertility. In Argentina, it makes excellent growth on rockstrewn, loose, sandy loam 2 to 3 ft (0.6-0.9 m) above a gravel subsoil. The optimum pH ranges from 6.5 to 7.6. A greenhouse trial in sand has demonstrated that the first nutritional deficiency evoked in such soil is lack of calcium.

Propagation

Cherimoya seeds, if kept dry, will remain viable for several years. While the tree is traditionally grown from seed in Latin America, the tendency of seedlings to produce inferior fruits has given impetus to vegetative propagation.

Seeds for rootstocks are first soaked in water for 1 to 4 days and those that float are discarded. Then planting is done directly in the nursery row unless the soil is too cool, in which case the seeds must be placed in sand peat seedbeds, covered with 1 in (2.5 cm) of soil and kept in a greenhouse. They will germinate in 3 to 5 weeks and when the plants are 3 to 4 in (7.5-10 cm) high, they are transplanted to pots or the nursery plot with 20 in (50 cm) between rows. When 12 to 24 months old and dormant, they are budded or grafted and then allowed to grow to 3 or 4 ft (0.9-1.2 m) high before setting out in the field. Large seedlings and old trees can be topworked by cleft-grafting. It is necessary to protect the trunk of topped trees to avoid sunburn.

The cherimoya can also be grafted onto the custard apple (*A. reticulata*). In India this rootstock has given 90% success. Cuttings of mature wood of healthy cherimoya trees have rooted in coral sand with bottom heat in 28 days.

Culture

The young trees should be spaced 25 to 30 ft (7.5-9 m) apart each way in pits 20 to 24 in (50-60 cm) wide, enriched with organic material. In Colombia, corn (maize), vegetables, ornamental foliage plants, roses or annual flowers for market are interplanted during the first few years. In Spain, the trees are originally spaced 16.5 ft (5 m) apart with the intention of later thinning them out. Thinning is not always done and around the village of Jete, where the finest cherimoyas are produced, the trees have grown so close together as to form a forest. In the early years they are interplanted with corn, beans and potatoes.

Pruning to eliminate low branches, providing a clean trunk up to 32 in (80 cm), to improve form, and open up to sunlight and pesticide control, is done preferably during dormancy. After 6 months, fertilizer (10-8-6 N, P, K) is applied at the rate of 1/2 lb (227 g) per tree and again 6 months later at 1 lb (454 g) per tree. In the 3rd year, the fertilizer formula is changed to 6-10-8 N,P,K and each year thereafter the amount per tree is increased by 1 lb (454 g) until the level of 5 lbs (2.27 kg) is reached. Thenceforth this amount is continued each year per tree. The fertilizer is applied in trenches 6 in (15 cm) deep and 8 in (20 cm) wide dug around each tree at a distance of 5 ft (1.5 m) from the base, at first; later, at an appropriately greater distance.

Young trees are irrigated every 15 to 20 days for the first few years except during the winter when they must be allowed to go dormant—ideally for 4 months. When the first leafbuds appear, irrigation is resumed. With bearing trees, watering is discontinued as soon as the fruits are full-grown.

In Chile, attempts to increase fruit set with chemical growth regulators have been disappointing. Spraying flowers with gibberellic acid has increased fruit set and improved form and size but induces deep cracking prior to full maturity, far beyond the normal rate of cracking in fruits from natural or hand-pollinated flowers.

Cropping and Yield

The cherimoya begins to bear when 3 1/2 to 5 years old and production steadily increases from the 5th to the 10th year, when there should be a yield of 25 fruits per tree—2,024 per acre (5,000 per ha). Yields of individual trees have been reported by eyewitnesses as a dozen, 85, or even 300 fruits annually. In Colombia, the average yield is 25 fruits; as many as 80 is exceptional. In Italy, trees 30 to 35 years old produce 230 to 280 fruits annually.

The fruits must be picked when full grown but still firm and just beginning to show a slight hint of yellowish-green and perhaps a bronze cast. Bolivians judge that a fruit is at full maturity by shaking it and listening for the sound of loose seeds. Italians usually wait for the yellowish hue and the sweet aroma noticeable at a distance, picking the fruits only 24 to 28 hours prior to consumption. However, if the fruits must travel to markets in central Italy, they are harvested when the skin turns from dark-green to lighter green.

In harvesting, the fruits must be clipped from the branch so as to leave only a very short stem attached to the fruit to avoid stem caused damage to the fruits in handling, packing and shipping.

Keeping Quality and Storage

Firm fruits should be held at a temperature of 50°F (10°C) to retard softening. When transferred to normal room temperature, they will become soft and ready to eat in 3 to 4 days. Then they can be kept chilled in the home refrigerator if not to be consumed immediately. A California grower has shipped cherimoyas ('Deliciosa' and 'Booth') packed in excelsior in 12 lb (5.5-kg) boxes to Boston and New York quite satisfactorily. And the fruit has been shipped from Madeira to London for many years.

In Bolivia, fruits for home use are wrapped in woollen cloth as soon as picked and kept at room temperature so that they can be eaten 3 days later.

Pests and Diseases

The cherimoya tree is resistant to nematodes. Very few problems have been noted in California except for infestations of mealybugs, especially at the base of the fruit, and these can be flushed off. In Colombia, on the other hand, it is said that a perfectly healthy tree is a rarity. In the Valle de Tenza, formerly an important center of production, lack of control of pests greatly reduced the plantations before 1960 when programs were launched to improve cherimoya culture here and in various other regions of the country.

Caterpillars (*Thecla* sp. and Oiketicus kubeyi) may defoliate the tree. A scale insect, *Conchaspis angraeci* attacks the trunk and branches. Prime enemies are reported to be fruit flies (*Anastrepha* s p.); leaf miners (*Leucoptera* sp.), particularly in the Valle de Tenza, which necessitate the collection and burning of affected leaves plus the application of systemic insecticides; and the seed borer (*Bephrata maculicollis*). The latter pest deposits eggs on the surface of the developing fruits, the larvae invade the fruit and consume the seeds, causing premature and defective ripening and rendering the fruits susceptible to fungal diseases. This pest is difficult to combat. Borers attack the tree in Argentina reducing its life span from 60 to 30 years.

The coccid, *Pseudococcus filamentosus* attacks the fruit in Hawaii, and *Aulacaspis miranda* and *Ceropute yuccae* in Mexico. In Spain, the thin-skinned cultivar 'Pinchua' is subject to attack by the Mediterranean fruit-fly, *Ceratitis capitata*.

Stored seeds for planting are subject to attack by weevils. To avoid damping-off of young seedlings, dusting of seeds with fungicide is recommended. The tree may succumb to root-rot in clay soils or where there is too much moisture and insufficient drainage. Sooty mold may occur on leaves and fruits where ants, aphids and other insects have deposited honeydew.

Fig. 19: Cherimoyas (Annona cherimola) from the highlands are sold at fruit stands along Venezuelan roadways.

Food Uses

The flesh of the ripe cherimoya is most commonly eaten out of-hand or scooped with a spoon from the cut open fruit. It really needs no embellishment but some people in Mexico like to add a few drops of lime juice. Occasionally it is seeded and added to fruit salads or used for making sherbet or ice cream. Colombians strain out the juice, add a slice of lemon and dilute with ice-water to make a refreshing soft drink. The fruit has been fermented to produce an alcoholic beverage.

Food Value Per 100 g of Edible Portion

Analysis of cherimoyas in Ecuador		*Colombian Analysis*

Riboflavin	0.112 mg	Thiamine	0.10 mg
Niacin	1.02 mg	Riboflavin	0.14 mg
Ascorbic Acid	16.8 mg	Niacin	0.9 mg
		Ascorbic Acid	5.0 mg

Toxicity

The seeds, like those of other *Annona* species, are crushed and used as insecticide. Paul Allen, in his *Poisonous and Injurious Plants of Panama*, (see Bibliography), implies personal knowledge of a case of blindness resulting from "the juice of the crushed seeds coming in contact with the eyes. " The seeds contain several alkaloids: caffeine, (+)-reticuline, (-)-anonaine, liriodenine, and lanuginosine.

Human ingestion of 0.15 g of the dark-yellow resin isolated from the seeds produces dilated pupils, intense photophobia, vomiting, nausea, dryness of the mouth, burning in the throat, flatulence, and other symptoms resembling the effects of atropine. A dose of 0.5 g, injected into a medium-sized dog, caused profuse vomiting.

Wilson Popenoe wrote that hogs feed on the fallen fruits in southern Ecuador where there are many cherimoya trees and few people. One wonders whether the hogs swallow the hard seeds whole and avoid injury.

The twigs possess the same alkaloids as the seeds plus michelalbine. A team of pharmacognosists in Spain and France has reported 8 alkaloids in the leaves: (+)-isoboldine, (-)-stepholidine, (+)-corytuberine, (+) nornantenine, (+)-reticuline, (-)-anonaine, liriodenine, and lanuginosine.

Other Uses

In Jamaica, the dried flowers have been used as flavoring for snuff.

Medicinal Uses: In Mexico, rural people toast, peel and pulverize 1 or 2 seeds and take the powder with water or milk as a potent emetic and cathartic. Mixed with grease, the powder is used to kill lice and is applied on parasitic skin disorders. A decoction of the skin of the fruit is taken to relieve pneumonia.

Morton, J. 1987. Sugar Apple. p. 69–72. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Sugar Apple

Annona squamosa

The most widely grown of all the species of *Annona*, the sugar apple, *A. squamosa* L., has acquired various regional names: *anon* (Bolivia, Costa Rica, Cuba, Panama); *anon de azucar*, *anon domestico, hanon, mocuyo* (Colombia); *anona blanca* (Honduras, Guatemala, Dominican Republic); *anona de castilla* (El Salvador); *anona de Guatemala* (Nicaragua); applebush (Grenadines); *ata, fruta do conde, fruta de condessa, frutiera deconde, pinha, araticutitaia*, or *ati* (Brazil); *ates* or *atis* (Philippines); *atte* (Gabon); *chirimoya* (Guatemala, Ecuador); *cachiman* (Argentina); *cachiman cannelle* (Haiti); *kaneelappel* (Surinam); *pomme cannelle* (Guadeloupe, French Guiana, French West Africa); *rinon* (Venezuela); *saramulla, saramuya, ahate* (Mexico); *scopappel* (Netherlands Antilles); sweetsop (Jamaica, Bahamas); *ata, luna, meba, sharifa, sarifa, sitaphal, sita pandu*, custard apple, scaly custard apple (India); *bnah nona, nona, seri kaya* (Malaya) *manonah, noinah, pomme cannelle du Cap* (Thailand); *qu a na* (Vietnam); *mang cau ta* (Cambodia); *mak khbieb* (Laos); *fan-li-chi* (China).

Description

Plate 8: SUGAR APPLE, *Annona squamosa*

The sugar apple tree ranges from 10 to 20 ft (3-6 m) in height with open crown of irregular branches, and some-what zigzag twigs. Deciduous leaves, alternately arranged on short, hairy petioles, are lanceolate or oblong, blunt tipped, 2 to 6 in (5-15 cm) long and 3/4 to 2 in (2-5 cm) wide; dull-green on the upperside, pale, with a bloom, below; slightly hairy when young; aromatic when crushed. Along the branch tips, opposite the leaves, the fragrant flowers are borne singly or in groups of 2 to 4. They are oblong, 1 to 1 1/2 in (2.5-3.8 cm) long, never fully open; with 1 in (2.5 cm) long, drooping stalks, and 3 fleshy outer petals, yellow-green on the outside and pale-yellow inside with a purple or dark-red spot at the base. The 3 inner petals are merely tiny scales. The compound fruit is nearly round, ovoid, or conical; 2 1/3 to 4 in (6-10 cm) long; its thick rind composed of knobby segments, pale-green, gray-green, bluish-green, or, in one form, dull, deep-pink externally (nearly always with a bloom); separating when the fruit is ripe and revealing the mass of conically segmented, creamy-white, glistening, delightfully fragrant, juicy, sweet, delicious flesh. Many of the segments enclose a single oblong-cylindric, black or dark-brown seed about 1/2 in (1.25 cm) long. There may be a total of 20 to 38, or perhaps more, seeds in the average fruit. Some trees, however, bear seedless fruits.

Origin and Distribution

The original home of the sugar apple is unknown. It is commonly cultivated in tropical South America, not often in Central America, very frequently in southern Mexico, the West Indies, Bahamas and Bermuda, and occasionally in southern Florida. In Jamaica, Puerto Rico, Barbados, and in dry regions of North Queensland, Australia, it has escaped from cultivation and is found wild in pastures, forests and along roadsides.

The Spaniards probably carried seeds from the New World to the Philippines and the Portuguese are assumed to have introduced the sugar apple to southern India before 1590. It was growing in Indonesia early in the 17 th century and has been widely adopted in southern China, Queensland, Australia, Polynesia, Hawaii, tropical Africa, Egypt and the lowlands of Palestine. Cultivation is most extensive in India where the tree is also very common as an escape and the fruit exceedingly popular and abundant in markets. The sugar apple is one of the most important fruits in the interior of Brazil and is conspicuous in the markets of Bahia.

Cultivars

The **'Seedless Cuban'** sugar apple was introduced into Florida in 1955, has produced scant crops of slightly malformed fruits with mere vestiges of undeveloped seeds. The flavor is less appealing than that of normal fruits but it is vegetatively propagated and distributed as a novelty. Another seedless type was introduced from Brazil.

Indian horticulturists have studied the diverse wild and cultivated sugar apples of that country and recognize ten different types: **'Red'** (A. *squamosa* var. *Sangareddyiz*)—red-tinted foliage and flowers, deep-pink rind, mostly non-reducing sugars, insipid, with small, blackish-pink seeds; poor quality; comes true from seed. **'Red-speckled'**—having red spots on green rind. **'Crimson'**—conspicuous red-toned foliage and flowers, deep-pink rind, pink flesh. **'Yellow'**; **'White-stemmed'**; **'Mammoth'** (A. *squamosa* var. *mammoth*)—pale yellow petals, smooth, broad, thick, round rind segments that are light russet green; fruits lopsided, pulp soft, white, very sweet; comes true from seed. **'Balangar'**—large, with green rind having rough, warty [tuberculate], fairly thick rind segments with creamy margins; sweet; high yielding. **'Kakarlapahad'**—very high yielding. **'Washington'**—acute tuberculate rind segments, orange-yellow margins; high yielding; late in season, 20 days after others. **'Barbados'** and **'British Guiana'**—having green rind, orange-yellow margins; high-yielding; late.

Named cultivars growing at the Sabahia Experiment Station, Alexandria, Egypt, include: **'Beni Mazar'**—nearly round, large, 5 1/4 to 6 1/2 oz (150-180 g); 56-60% flesh; 15 30 seeds. **'Abd El Razik'**—light-green or reddish rind; nearly round, large, maximum 8 1/3 oz (236.3 g); 69.5% flesh; 14 seeds.

Climate

The sugar apple tree requires a tropical or near-tropical climate. It does not succeed in California because of the cool winters though in Israel it has survived several degrees below freezing. Generally, it does best in dry areas and it has high drought tolerance. However, in Ceylon it flourishes in the wet as well as the dry zones from sea level to 3,500 ft (1,066 m) elevation. During the blooming season, drought interferes with pollination and it is, therefore, concluded that the sugar apple should have high atmospheric humidity but no rain when flowering. In severe droughts, the tree sheds its leaves and the fruit rind hardens and will split with the advent of rain.

Soil

The sugar apple is not particular as to soil and has performed well on sand, oolitic limestone and heavy loam with good drainage. Water-logging is intolerable. The tree is shallow-rooted and doesn't need deep soil. Irrigation water containing over 300 ppm chlorine has done the tree no harm.

Propagation

Sugar apple seeds have a relatively long life, having kept well for 3 to 4 years. They germinate better a week after removal from the fruit than when perfectly fresh. Germination may take 30 days or more but can be hastened by soaking for 3 days or by scarifying. The percentage of germination is said to be better in unsoaked seeds. While the tree is generally grown from seed, vegetative propagation is practiced where the crop is important and early fruiting is a distinct advantage.

Seedlings may be budded or grafted when one-year old. In India, selected clones grafted on *A.*

reticulata seedlings have flowered within 4 months and fruited in 8 months after planting out, compared with 2 to 4 years in seedlings. The grafted trees are vigorous, the fruits less seedy and more uniform in size. *A. senegalensis* is employed as a rootstock in Egypt. *A. glabra* is suitable but less hardy. The sugar apple itself ranks next after *A. reticulata* as a rootstock. In India, budding is best done in January, March and June. Results are poor if done inJuly, August, November or December unless the scions are defoliated and debudded in advance and cut only after the petioles have dehisced. Side-grafting can be done only from December to May, requires much skill and the rate of success has not exceeded 58.33%. Shield-budding gives 75% success and is the only commercially feasible method.

Inarching is 100% successful. Cuttings, layers, airlayers have a low rate of success, and trees grown by these techniques have shallow root systems and cannot endure drought as well as seedlings do.

Culture

In Egypt, sugar apple trees are spaced at 10 x 10 ft (3x3 m) in order to elevate atmospheric humidity and improve pollination. Palestinian growers were spacing at 16 x 16 ft (5x5 m) but changed to 16 x 10 ft (5x3 m) as more feasible. On light soils, they apply 132 to 176 lbs (60-80 kg) manure per tree annually and they recommend the addition of nitrogen. Commercial fertilizer containing 3% N, 10 % P and 10% K significantly increases flowering, fruit set and yield. Judicious pruning to improve shape and strength of tree must be done only in spring when the sap is rising, otherwise pruning may kill the tree. Irrigation during the dry season and once during ripening will increase fruit size.

Cropping and Yield

Seedlings 5 years old may yield 50 fruits per tree in late summer and fall. Older trees rarely exceed 100 fruits per tree unless hand-pollinated. With age, the fruits become smaller and it is considered best to replace the trees after 10 to 20 years. The fruits will not ripen but just turn black and dry if picked before the white, yellowish or red tint appears between the rind segments, the first signs of separation. If allowed to ripen on the tree, the fruit falls apart.

Keeping Quality

In India, mature fruits treated with 50-60 g carbide ripened in 2 days and thereafter remained in good condition only 2 days at room temperature, while those packed in straw ripened in 5-6 days and kept well for 4 days.

Storage trials in Malaya indicate that the ripening of sugar apples can be delayed by storage at temperatures between 59° and 68°F (15°-20°C) and 85-90% relative humidity, with low O2 and C2 H2. To speed ripening at the same temperature and relative humidity, levels of O2 and CO2 should be high. Storing at 39.2°F (4°C) for 5 days resulted in chilling injury.

In Egypt, of 'Beni Mazar' fruits, picked when fullgrown, ll5 days from set, and held at room temperature, 86°,to ripened in 10 days. Of 'Abd E1 Razik' fruits, 140 days from set, 56% were ripe in 15 days. Therefore, 'Abd E1 Razik' is better adapted to Upper Egypt where the climate should promote normal ripening.

Pests and Diseases

In Florida and the Caribbean, a seed borer (chalcid fly), *Bephratelloides cubensis*, infests the seeds and an associated fungus mummifies the partly grown fruits on the tree. This has discouraged many from growing the sugar apple, though in the past it was a fairly common dooryard fruit tree. Similar damage is caused by *B. maculicollis* in Colombia, Venezuela and Surinam, by *B. ruficollis* in Panama, and *B. paraguayensis* in Paraguay. The soft scale, *Philephedra* sp., attacks leaves and twigs and deposits honeydew on which sooty mold develops. Ambrosia beetles lay eggs on young stems and the larvae induce dieback during the winter.

The mealybug is the main pest in Queensland, Australia, but is easily controlled. The green tree ant is a nuisance because of the nests it makes in the tree. Bird and animal predators force Indian growers to cover the tree with netting or pick the fruits prematurely and ripen them in straw.

A serious leaf blight in India is caused by the fungus *Colletotrichum annonicola*. In 1978 a new fruit rot of sugar apple was observed in India, beginning with discoloration at one end which turns brown or black in 4 or 5 days, and 2 or 3 days later the entire fruit starts to rot. Later, the fruit is covered with gray-black mycelium and spherical bodies. The isolated fungus was identified as the *Colletotrichum* state of *Glomerella cingulata*.

Food Uses

The ripe sugar apple is usually broken open and the flesh segments enjoyed while the hard seeds are separated in the mouth and spat out. It is so luscious that it is well worth the trouble. In Malaya, the flesh is pressed through a sieve to eliminate the seeds and is then added to ice cream or blended with milk to make a cool beverage. It is never cooked.

Toxicity

The seeds are acrid and poisonous. Bark, leaves and seeds contain the alkaloid, anonaine. Six other aporphine alkaloids have been isolated from the leaves and stems: corydine, roemerine, norcorydine, norisocarydine, isocorydine and glaucine. Aporphine, norlaureline and dienone may be present also. Powdered seeds, also pounded dried fruits serve as fish poison and insecticides in India. A paste of the seed powder has been applied to the head to kill lice but must be kept away from the eyes as it is highly irritant and can cause blindness. If applied to the uterus, it induces abortion. Heat-extracted oil from the seeds has been employed against agricultural pests. Studies have shown the ether extract of the seeds to have no residual toxicity after 2 days. High concentrations are potent for 2 days and weaken steadily, all activity being lost after 8 days. In Mexico, the leaves are rubbed on floors and put in hen's nests to repel lice.

Other Uses

The **seed kernels** contain 14-49% of whitish or yellowish, non-drying oil with saponification index of 186.40. It has been proposed as a substitute for peanut oil in the manufacture of soap and can be detoxified by an alkali treatment and used for edible purposes. The leaves yield an excellent oil rich in terpenes and sesquiterpenes, mainly B-caryophyllene, which finds limited use in perfumes, giving a woody spicy accent.

Fiber extracted from the bark has been employed for cordage. The **tree** serves as host for lac-excreting insects.

Medicinal Uses: In India the crushed leaves are sniffed to overcome hysteria and fainting spells; they are also applied on ulcers and wounds and a leaf decoction is taken in cases of dysentery. Throughout tropical America, a decoction of the leaves alone or with those of other plants is imbibed either as an emmenagogue, febrifuge, tonic, cold remedy, digestive, or to clarify the urine. The leaf decoction is also employed in baths to alleviate rheumatic pain. The green fruit, very astringent, is employed against diarrhea in El Salvador. In India, the crushed ripe fruit, mixed with salt, is applied on tumors. The bark and roots are both highly astringent. The bark decoction is given as a tonic and to halt diarrhea. The root, because of its strong purgative action, is administered as a drastic treatment for dysentery and other ailments.

Morton, J. 1987. Atemoya. p. 72–75. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Atemoya

Annona squamosa × Annona cherimola

The atemoya, *Annona squamosa* × *A. cherimola*, is a hybrid of the sugar apple and cherimoya, qq.v. It was for many years mistakenly called custard apple or cherimoya in Queensland and New South Wales. The name applied in Venezuela is *chirimorinon*.

Description

The tree closely resembles that of the cherimoya; is fast-growing; may reach 25 to 30 ft (7.5-9 m) and is short-bunked, the branches typically drooping and the lowest touching the ground. The leaves are deciduous, alternate, elliptical, leathery, less hairy than those of the cherimoya; and up to 6 in (15 cm) in length. The flowers are long-stalked, triangular, yellow, 2 3/8 in (6 cm) long and 1 1/2 to 2 in (4-5 cm) wide. The fruit is conical or heart-shaped, generally to 4 in (10 cm) long and to 3 3/4 in(9.5 cm) wide; some weighing as much as 5 lbs(2.25 kg); pale bluish-green or pea-green, and slightly yellowish between the areoles. The rind, 1/8 in (3 mm) thick, is composed of fused areoles more prominent and angular than those of the sugar apple, with tips that are rounded or slightly upturned; firm, pliable, and indehiscent. The fragrant flesh is snowy-white, of fine texture, almost solid, not conspicuously divided into segments, with fewer seeds than the sugar apple; sweet and subacid at the same time and resemblirig the cherimoya in flavor. The seeds are cylindrical, 3/4 in (2 cm) long and 5/16 in (8 mm) wide; so dark a brown as to appear black; hard and smooth.

Plate 9: ATEMOYA, *Annona squamosa* × *Annona cherimola*

Origin and Distribution

The first cross was made by the horticulturist, P.J. Wester, at the United States Department of Agriculture's subtropical laboratory, Miami, in 1908. Seedlings were planted out in 1910. Other crosses made in 1910 fruited in 1911 and seeds were taken by Wester to the Philippines. The hybrids grew there to 7 1/2 ft (2.3 m) high in one year, had to be moved to another location; one bloomed in 1913 and was pollinated by the custard apple, q.v. The rest of the plants fruited in 1914. Resulting fruits were superior in quality to the sugar apple and were given the name "atemoya", a combinetion of "ate", an old Mexican name for sugar apple, and "moya" from cherimoya. Cuttings of 9 of the hybrids were sent by Wester to the United States Department of Agriculture in January of 1915. (S.P.I. Nos. 39808-39816), #39809 representing the hybrid tree pollinated by the custard apple. In 1917, Wester sent cuttings of #39809 under the name "cuatemoya" to the United States Department of Agriculture (S.P.I. Nos. 44671-44673). In the meantime, Edward Simmons, at the Plant Introduction Field Station, Miami, had successfully grown hybrids and they had survived an early February 1917 drop in temperature to 26.5ºF (-3.10ºC), showing the hardiness derived from the cherimoya. Another introduction was received from the Philippines in 1918 (S.P.I. #45571).

A few experimental growers in southern Florida maintained atemoya trees (apparently distributed by the United States Department of Agriculture) for many years while there was a general lapse of interest in this fruit. Today, there are a few small commercial plantings and the fruits are being sent to some northern fruit dealers.

In the early 1930's or 1940's, what were apparently chance hybrids between adjacent sugar apple and cherimoya orchards attracted attention in Israel and work was begun to choose and standardize the best of these for vegetative propagation.

Varieties

One of the first named selections of atemoya was the **'Page'**, so-named by Roy Page of Coral Gables who took budwood from superior atemoya trees on the property of Morrison Page in the Redlands. Perhaps the second was the **'Bradley'** which the Newcomb Nursery sold grafted onto custard apple.

An early hybrid that arose in Queensland after the introduction of cherimoya seeds from South America, was named **'Mammoth'** (or 'Pink's Prolific', or 'Pink's Mammoth') and became the basis of the commercial production of atemoyas there and on the north coast of New South Wales, though the flesh of this cultivar immediately below the rind is usually brownish and bitter. **'Island Beauty'**, a vigorous selection with excellent fruit quality was grown to a lesser extent. 'Mammoth' was introduced into Hawaii from Queensland in 1960 and grafted plants were soon being distributed by agricultural stations of the University of Hawaii in Kona and Hilo, and being sold by nurseries in Honolulu.

'African Pride' is an improved clone that originated in South Africa. It was introduced into Queensland by Langbecker Nurseries and 3,000 trees were released for commercial planting in July 1961. It was quickly adopted as a replacement for 'Mammoth' as it was free of the discoloration and bitterness next to the skin. In 1963, 6 plants of 'African Pride' were obtained from Landbecker's by private experimenters and planted at several locations in southern Florida. They began fruiting in 1965. The fruits appeared to be superior in quality to the 'Page' and 'Bradley'.

Israeli selections tried at the University of Florida's Agricultural Research and Education Center, Homestead, and the United States Department of Agriculture's Subtropical Horticulture Research Unit, Miami, are **'Geffner'**, **'Malamud'**, **'Bernitski'**, **'Kabri'** and **'Malai #1'**. Other named selections that have been grown in Florida over the years are **'Caves'**, **Chirimorinon** A, B and C, **'Island Gem'**, **'Keller'**, **'Lindstrom'**, **'Priestly'** and **'Stermer'**. 'Geffner' is being propagated at the AREC, Homestead; 'Priestly' by the Zill Nursery in Boynton Beach. None of the others have outstanding features; some develop hard spots in the flesh. In 'Keller' there is frequently a black membrane around each seed-containing carper.

'Cherimata' and **'Finny'** are Egyptian clones. 'Finny' is somewhat cylindrical, is more productive than'Cherimata', has been grown in Egypt for many years and is considered the best for commercial production in coastal districts.

Pollination

The atemoya and other annona trees bear hermaphroditic protogynous flowers and self-pollination is rare. Atemoyas are sometimes misshapen, underdeveloped on one side, as the result of inadequate pollination. The flower, in its female stage, opens between 2 and 4 o'clock in the afternoon. Between 3 and 5 o'clock on the following afternoon, the flower converts to its male stage. In cold and humid climates it releases pollen even though it is sticky. Where the climate is hot and the humidity low at the blooming season, the carpers are short lived and the stigmatic surface soon dries up and insects are necessary to transfer the pollen. Studies in Israel have identified the principal insect pollinators as nitidulid beetles—*Carpophilus hemipterus*, C. *mutilatus*, *Haptoncus luteolus*, and *Uroporus humeralis*. Even where these beetles are present, hand-pollination will enhance fruit-setting and this is commonly practiced in Egypt. Spraying the flowers several times with gibberellin at 1,000 ppm has increased fruit yield. The resulting fruits are seedless but smaller and less flavorful than fruits with seeds.

Climate

The atemoya is slightly hardier than the sugar apple but still is limited to tropical or near-tropical lowlands. In New South Wales, it is said to do best near the coast where rainfall and humidity are high and winters are warm. Rainy weather during the ripening season, however, may cause the fruits to split.

Soil

The tree thrives in various types of soil, from sandy loam to red basalt or heavy clay, but best growth and productivity occur in deep, rich loam of medium texture, with good organic content and a moderate amount of moisture. Good drainage is essential; waterlogging is fatal.

Propagation

Atemoyas for rootstocks are raised from seeds which germinate in about 4 weeks in seedbeds. Seedlings are transplanted to nursery rows when they are a year old and they are placed 18 in (45 cm) apart in rows 3 ft (90 cm) apart. Grafting is done in the spring, using the whip- or tongue-graft. If older trees are top worked, it is done by cleft- or bark-grafting. Scion wood is taken from selected cultivars after the leaves have fallen. In Florida and India, the atemoya is usually grafted onto the custard apple or sugar apple. Cherimoya is used as a rootstock in Israel.

Culture

When transferred to the field at the near-dormant period, grafted plants are spaced 28 to 30 ft (8.5-9 m) apart each way and cut back to a height of 24 to 30 in (60-75 cm). Weeds are eliminated to avoid competition with the spreading, shallow root system. During the next 2 or 3 years, the trees are kept pruned to form a strong frame. Thereafter, only light pruning is done. No fertilizer is applied until after the trees are well established, since the young roots are very sensitive. A 6-10-16 formula is recommended for broadcasting over the root area, the amount gradually increased to 10 to 12 lbs (4.5-5.4 kg) annually for mature trees. Half is given in the spring a month before flowering. Irrigation during flowering and fruit setting improves yield and fruit quality.

Season

In Florida, the atemoya ripens in the fall. In Queensland, the main blooming period is October and November and the fruits mature in April and May. If there is light fruit set in October/November, flowering may continue to February and the fruit from such late blooms may have to be picked prematurely and ripened artificially to avoid cold night temperatures, but it will not develop the highest quality.

Harvesting

The fruits must be clipped from the branch, taking care that the stalk left on the fruit does not protrude beyond the shoulders. Frequent picking is necessary to harvest the fruit at the ideal stage, that is, when creamy lines appear around the areoles showing that the spaces between them are widening. If picked too soon, the fruit will not ripen but will darken and shrivel.

Fruits colonized by mealybugs have to be cleaned by brushing or the use of compressed air before marketing. The fruits should not be wrapped because this will speed ripening, but they need to be packed in boxes with padding between layers. Because of the irregular form, the fruits must be carefully fitted together with the base of each fruit against the wall of the container and the more delicate apex inward.

Yield

The atemoya is a shy yielder, mainly for the reason mentioned under "Pollination". Trees 5 years old are expected to bear 50 fruits annually. In Queensland, commercial groves have produced 5 bushels of fruit per tree—67 bushels per acre (165.5 bu/ha). An exceptionally large atemoya tree in Florida yielded 11 bushels of fruits in the 1972 season.

Keeping Quality

Atemoyas keep very well in cool, shady, well-ventilated storage for at least 3 weeks. The rind may darken before the interior shows any signs of spoilage. The ideal temperature for refrigerated storage is 68ºF (20ºC), though an acceptable temperature range is 59º to 77ºF (15º-25ºC). Lower temperatures cause chilling injury.

Pests and Diseases

The citrus mealybug, *Planococcus citri*; which congregates around the base of the fruit, is the most common pest, and sooty mold develops on its exodate.

In Queensland, the protective activities of the natural enemies of the mealybug are disrupted by the coastal brown ant, *Pheidole megacephala*, which carries mealybugs up the trunk and around between the fruits. Australian growers have tried sticky-banding the trunks and this has reduced the numbers of ants but not sufficiently.

The chalcid fly that lays eggs in the seeds and makes exit holes in the fruit permitting entrance of fungi, occasionally causes mummification of the atemoya. White wax, pink wax, and brown olive scales may be found on the foliage but are shed along with the leaves.

A condition called "littleleaf" is not a disease but zinc deficiency which can be corrected by foliar spraying.

Atemoyas are prone to collar rot (*Phytophthora* sp.), the first sign being an exudation of gum near the base of the trunk and on the crown roots.

*Analyses made in Florida, the Philippines and at the University of New South Wales.

Food Uses

The atemoya, preferably chilled, is one of the most delicious of fruits. It needs no seasoning. It may be simply cut in half or quartered and the flesh eaten from the "shell" with a spoon. Slices or cubes of the pulp may be added to fruit cups or salads or various dessert recipes. Some people blend the pulp with orange juice, lime juice and cream and freeze as ice cream.

Toxicity

The seeds, like those of all *Annona* species, are toxic and care should be taken to seed the pulp before it is mechanically blended.

Morton, J. 1987. Soursop. p. 75–80. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Soursop

Annona muricata

Of the 60 or more species of the genus *Annona*, family Annonaceae, the soursop, *A. muricata* L., is the most tropical, the largest-fruited, and the only one lending itself well to preserving and processing.

It is generally known in most Spanish-speaking countries as *guanabana*; in E1 Salvador, as *guanaba*; in Guatemala, as *huanaba*; in Mexico, often as *zopote de viejas*, or *cabeza de negro*; in Venezuela, as *catoche* or *catuche*; in Argentina, as *anona de puntitas* or *anona de broquel*; in Bolivia, *sinini*; in Brazil, *araticum do grande, graviola*, or *jaca do Para*; in the Netherlands Antilles, *sorsaka* or *zunrzak*, the latter name also used in Surinam andJava; in French-speaking areas of the West Indies, West Africa, and Southeast Asia, especially North Vietnam, it is known as *corossol, grand corossol, corossol epineux*, or *cachiman epineux*. In Malaya it may be called *durian belanda, durian maki*; or *seri kaya belanda*; in Thailand, *thu-rian-khack*.

In 1951, Prof. Clery Salazar, who was encouraging the development of soursop products at the

College of Agriculture at Mayaguez, Puerto Rico, told me that they would like to adopt an English name more appealing than the word "soursop", and not as likely as *guanabana* to be mispronounced. To date, no altematives have been chosen.

Description

The soursop tree is low-branching and bushy but slender because of its upturned limbs, and reaches a height of 25 or 30 ft (7.5-9 m). Young branchlets are rusty-hairy. The malodorous leaves, normally evergreen, are alternate, smooth, glossy, dark green on the upper surface, lighter beneath; oblong, elliptic or narrowobovate, pointed at both ends, 2 1/2 to 8 in (6.25-20 cm) long and 1 to 2 1/2 in (2.5-6.25 cm) wide. The flowers, which are borne singly, may emerge anywhere on the trunk, branches or twigs. They are short stalked, 1 1/2 to 2 in (4 5 cm) long, plump, and triangular-conical, the 3 fleshy, slightly spreading, outer petals yellow-green, the 3 close-set inner petals pale-yellow.

Plate 10: SOURSOP, *Annona muricata*

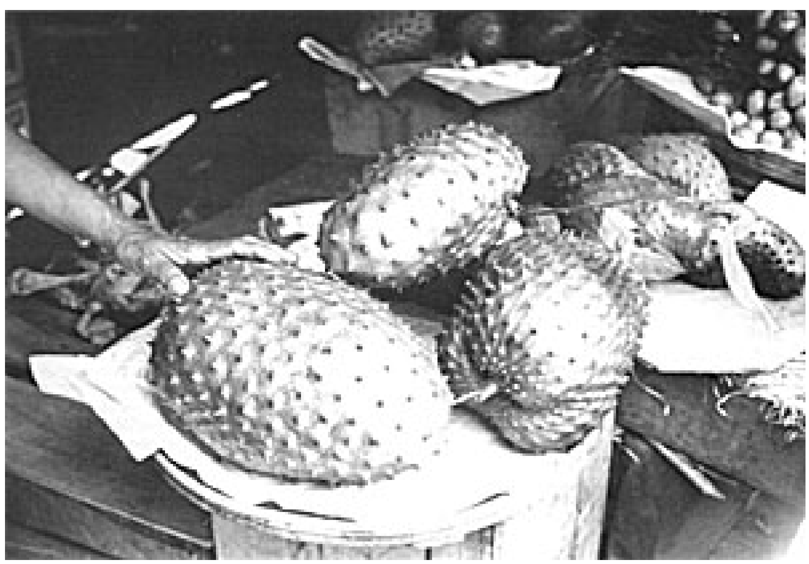

Fig. 20: Exceptionally large and well-formed soursops (*Annona muricata*) in a Saigon market, 1968.

The fruit is more or less oval or heart-shaped, some times irregular, lopsided or curved, due to improper carper development or insect injury. The size ranges from 4 to 12 in (10-30 cm) long and up to 6 in (15 cm) in width, and the weight may be up to 10 or 15 lbs (4.5-6.8 kg). The fruit is compound and covered with a reticulated, leathery-appearing but tender, inedible, bitter skin from which protrude few or many stubby, or more elongated and curved, soft, pliable "spines". The tips break off easily when the fruit is fully ripe. The skin is dark-green in the immature fruit, becoming slightly yellowish-green before the mature fruit is soft to the touch. Its inner surface is cream-colored and granular and separates easily from the mass of snow-white, fibrous, juicy segments—much like flakes of raw fish—surrounding the central, soft-pithy core. In aroma, the pulp is somewhat pineapple-like, but its musky, subacid to acid flavor is unique. Most of the closely-packed segments are seedless. In each fertile segment there is a single oval, smooth, hard, black seed, l/2 to 3/4 in (1.25-2 cm) long; and a large fruit may contain from a few dozen to 200 or more seeds.

Origin and Distribution

Oviedo, in 1526, described the soursop as abundant in the West Indies and in northern South America. It is today found in Bermuda and the Bahamas, and both wild and cultivated, from sea-level to an altitude of 3,500 ft (1,150 m) throughout the West Indies and from southern Mexico to Peru and Argentina. It was one of the first fruit trees carried from America to the Old World Tropics where it has become widely distributed from southeastern China to Australia and the warm lowlands of eastern and western Africa. It is common in the markets of Malaya and southeast Asia. Very large, symmetrical fruits have been seen on sale in South Vietnam. It became well established at an early date in the Pacific Islands. The tree has been raised successfully but has never fruited in Israel.

In Florida, the soursop has been grown to a limited extent for possibly 110 years. Sturtevant noted that it was not included by Atwood among Florida fruits in 1867 but was listed by the American Pomological Society in 1879. A tree fruited at the home of John Fogarty of Manatee before the freeze of 1886. In the southeastern part of the state and especially on the Florida Keys, it is often planted in home gardens.

In regions where sweet fruits are preferred, as in South India and Guam, the soursop has not enjoyed great popularity. It is grown only to a limited extent in Madras. However, in the East Indies it has been acclaimed one of the best local fruits. In Honolulu, the fruit is occasionally sold but the demand exceeds the supply. The soursop is one of the most abundant fruits in the Dominican Republic and one of the most popular in Cuba, Puerto Rico, the Bahamas, Colombia and northeastern Brazil.

In 1887, Cuban soursops were selling in Key West, Florida, at 10 to 50 cents apiece. In 1920, Wilson Popenoe wrote that: "In the large cities of tropical America, there is a good demand for the fruits at all times of the year, a demand which is not adequately met at present." The island of Grenada produces particularly large and perfect soursops and regularly delivers them by boat to the market of Port-of Spain because of the shortage in Trinidad. In Colombia, where the soursop is generally large, well-formed and of high quality, this is one of the 14 tropical fruits recommended by the Instituto Latinoamericano de Mercadeo Agricola for large-scale planting and marketing. Soursops produced in small plots, none over 5 acres (2.27 ha), throughout Venezuela supply the processing plants where the frozen concentrate is packed in 6 oz (170 g) cans. In 1968, 2,266 tons (936 MT) of juice were processed in Venezuela. The strained pulp is also preserved commercially in Costa Rica. There are a few commercial soursop plantations near the south coast of Puerto Rico and several processing factories. In 1977, the Puerto Rican crop totaled 219,538 lbs (99,790 kg).

At the First International Congress of Agricultural and Food Industries of the Tropical and Subtropical Zones, held in 1964, scientists from the Research Laboratories of Nestle Products in Vevey, Switzerland, presented an evaluation of lesser-known tropical fruits and cited the soursop, the guava and passionfruit as the 3 most promising for the European market, because of their distinctive aromatic qualities and their suitability for processing in the form of preserved pulp, nectar and jelly.

Varieties

In Puerto Rico, the wide range of forms and types of seedling soursops are roughly divided into 3 general classifications: sweet, subacid, and acid; then subdivided as round, heart-shaped, oblong or angular; and finally classed according to flesh consistency which varies from soft and juicy to firm and comparatively dry. The University of Puerto Rico's Agricultural Experiment Station at one time cataloged 14 different types of soursops in an area between Aibonito and Coamo. In El Salvador, 2 types of soursops are distinguished: *guanaba azucaron* (sweet) eaten raw and used for drinks; and *guanaba acida* (very sour), used only for drinks. In the Dominican Republic, the *guanabana dulce* (sweet soursop) is most sought after. The term "sweet" is used in a relative sense to indicate low acidity. A medium-sized, yellow-green soursop called *guanabana sin fibre* (fiberless) has been vegetatively propagated at the Agricultural Experiment Station at Santiago de las Vegas, Cuba. The foliage of this superior clone is distinctly bluish-green. In 1920, Dr. Wilson Popenoe sent to the United States Department of Agriculture, from Costa Rica, budwood of a soursop he named 'Bennett' in honor of G.S. Bennett, Agricultural Superintendent of the Costa Rican Division of the United Fruit Company. He described the fruit as large and handsome (as shown in the photograph accompanying the introduction record No. 51050) and he declared the tree to be the most productive he had seen.

Climate

The soursop is truly tropical. Young trees in exposed places in southem Florida are killed by only a few degrees of frost. The trees that survive to fruiting age on the mainland are in protected situations, close to the south side of a house and sometimes near a source of heat. Even so, there will be temporary defoliation and interruption of fruiting when the temperature drops to near freezing. In Key West, where the tropical breadfruit thrives, the soursop is perfectly at home. In Puerto Rico, the tree is said to prefer an altitude between 800 and 1,000 ft (244300 m), with moderate humidity, plenty of sun and shelter from strong winds.

Fig. 21: The soursop tree may bear fruits anywhere on its trunk or branches. Multiple-stems of this tree are the result of its having been frozen to the ground more than once.

Soil

Best growth is achieved in deep, rich, well-drained, semi-drysoil, but the soursop tree can be and is commonly grown in acid and sandy soil, and in the porous, oolitic limestone of South Florida and the Bahama Islands.

Propagation

The soursop is usually grown from seeds. They should be sown in flats or containers and kept moist and shaded. Germination takes from 15 to 30 days. Selected types can be reproduced by cuttings or by shield-budding. Soursop seedlings are generally the best stock for propagation, though grafting onto custard apple (*Annona reticulata*), the mountain soursop (*A. montana*), or pond apple (*A. glabra*), is usually successful. The pond apple has a dwarfing effect. Grafts on sugar apple (*A. squamosa*) and cherimoya (*A. cherimola*) do not live for long, despite the fact that the soursop is a satisfactory rootstock for sugar apple in Ceylon and India.

Culture

In ordinary practice, seedlings, when 1 ft (30 cm) or more in height are set out in the field at the beginning of the rainy season and spaced 12 to 15 ft (3.65-4.5 m) apart, though 25 ft (7.5 m) each way has been suggested. A spacing of 20 x 25 ft (6x7.5 m) allows 87 trees per acre (215/ha). Close-spacing, 8 x 8 ft (2.4x2.4 m) is thought aufficient for small gardens in Puerto Rico. The tree grows rapidly and begins to bear in 3 to 5 years. In Queensland, well-watered trees have attained 15 to 18 ft (4.5-5.5 m) in 6 to 7 years. Mulching is recommended to avoid dehydration of the shallow, fibrous root system during dry, hot weather. If in too dry a situation, the tree will cast off all of its old leaves before new ones appear. A fertilizer mixture containing 10% phosphoric acid, 10% potash and 3% nitrogen has been advocated in Cuba and Queensland. But excellent results have been obtained in Hawaii with quarterly applications of 10-10-10 N P K—1\2 lb (.225 kg) per tree the first year, 1 lb (.45 kg)/tree the 2nd year, 3 lbs (1.36 kg)/tree the 3rd year and thereafter.

Season

The soursop tends to flower and fruit more or less continuously, but in every growing area there is a principal season of ripening. In Puerto Rico, this is from March to June or September; in Queensland, it begins in April; in southern India, Mexico and Florida, it extends from June to September; in the Bahamas, it continues through October. In Hawaii, the early crop occurs from January to April; midseason crop, June to August, with peak in July; and there is a late crop in October or November.

Harvesting

The fruit is picked when full grown and still firm but slightly yellow-green. If allowed to soften on the tree, it will fall and crush. It is easily bruised and punctured and must be handled with care. Firm fruits are held a few days at room temperature. When eating ripe, they are soft enough to yield to the slight pressure of one's thumb. Having reached this stage, the fruit can be held 2 or 3 days longer in a refrigerator. The skin will blacken and become unsightly while the flesh is still unspoiled and usable. Studies of the ripening process in Hawaii have determined that the optimum stage for eating is 5 to 6 days after harvest, at the peak of ethylene production. Thereafter, the flavor is less pronounced and a faint offodor develops. In Venezuela, the chief handicap in commercial processing is that the fruits stored on racks in a cool shed must be gone over every day to select those that are ripe and ready for juice extraction.

Yield

The soursop, unfortunately, is a shy-bearer, the usual crop being 12 to 20 or 24 fruits per tree. In Puerto Rico, production of 5,000 to 8,000 lbs per acre (roughly equal kg/ha), is considered a good yield from well-cared-for trees. A study of the first crop of 35 5 year-old trees in Hawaii showed an average of 93.6 lbs (42.5 kg) of fruits per tree. Yield was slightly lower the 2nd year. The 3rd year, the average yield was 172 lbs (78 kg) per tree. At this rate, the annual crop would be 16,000 lbs per acre (roughly equal kg/ha).

Pests & Diseases

Queensland's principal soursop pest is the mealybug which may occur in masses on the fruits. The mealybug is a common pest also in Florida, where the tree is often infessed with scale insects. Sometimes it may be infected by a lace-wing bug.

The fruit is subject to attack by fruit flies—*Anastrepha suspensa, A. striata* and *Ceratitis capitata*. Red spiders are a problem in dry climates.

Dominguez Gil (1978 and 1983), presents an extensive list of pests of the soursop in the State of Zulia, Venezuela. The 5 most damaging are: 1) the wasp, *Bephratelloides* (*Bephrata*) *maculicollis*, the larvae of which live in the seeds and emerge from the fully-grown ripe fruit, leaving it perforated and highly perishable; 2) the moth, *Cerconota* (*Stenoma*) *anonella*, which lays its eggs in the very young fruit causing stunting and malformation; 3) *Corythucha gossipii*; which attacks the leaves; 4) *Cratosomus inaequalis*, which bores into the fruit, branches and trunk; 5) *Laspeyresia* sp., which perforates the flowers. The first 3 are among the 7 major pests of the soursop in Colombia, the other 4 being: *Toxoptera aurantii*; which affects shoots, young leaves, flowers and fruits; present but not important in Venezuela; *Aphis spiraecola*; *Empoasca* sp., attacking the leaves; and *Aconophora concolor*, damaging the flowers and fruits. Important beneficial agents preying on aphids are *A phidius testataceipes, Chrysopa* sp., and *Curinus* sp. Lesser enemies of the soursop in South America include: *Talponia backeri* and *T. batesi* which damage flowers and fruits; *Horiola picta* and *H. lineolata*, feeding on flowers and young branches; *Membracis foliata*, attacking young branches, flower stalks and fruits; *Saissetia nigra*; *Escama ovalada*, on branches, flowers and fruits; *Cratosomus bombina*, a fruit borer; and *Cyclocephala signata*, affecting the flowers.

In Trinidad, the damage done to soursop flowers by *Thecla ortygnus* seriously limits the cultivation of this fruit. The sphinx caterpillar, *Cocytius antueus antueus* may be found feeding on soursop leaves in Puerto Rico. Bagging of soursops is necessary to protect them from *Cerconota anonella*. However, one grower in the Magdalena Valley of Colombia claims that bagged fruits are more acid than others and the flowers have to be handpollinated.

It has been observed in Venezuela and El Salvador that soursop trees in very humid areas often grow well but bear only a few fruits, usually of poor quality, which are apt to rot at the tip. Most of their flowers and young fruits fall because of anthracnose caused by *Collectotrichum gloeosporioides*. It has been said that soursop trees for cultivation near San Juan, Puerto Rico, should be seedlings of trees from similarly humid areas which have greater resistance to anthracnose than seedlings from dry zones. The same fungus causes damping-off of seedlings and die-back of twigs and branches. Occasionally the fungus, *Scolecotrichum* sp. ruins the leaves in Venezuela. In the East Indies, soursop trees are sometimes subject to the root-fungi, *Fomes lamaoensis* and *Diplodia* sp. and by pink disease due to *Corticum salmonicolor*.

Food Uses

Soursops of least acid flavor and least fibrous consistency are cut in sections and the flesh eaten with a spoon. The seeded pulp may be torn or cut into bits and added to fruit cups or salads, or chilled and served as dessert with sugar and a little milk or cream. For years, seeded soursop has been canned in Mexico and served in Mexican restaurants in New York and other northern cities.

Most widespread throughout the tropics is the making of refreshing soursop drinks (called *champola* in Brazil; *carato* in Puerto Rico). For this purpose, the seeded pulp may be pressed in a colander or sieve or squeezed in cheesecloth to extract the rich, creamy juice, which is then beaten with milk or water and sweetened. Or the seeded pulp may be blended with an equal amount of boiling water and then strained and sweetened. If an electric blender is to be used, one must first be careful to remove all the seeds, since they are somewhat toxic and none should be accidentally ground up in the juice.

Fig. 22: Canned soursop concentrate is produced in Venezuela. On the branch at the right is a soursop flower.

In Puerto Rican processing factories, the hand-peeled and cored fruits are passed through a mechanical pulper having nylon brushes that press the pulp through a screen, separating it from the seeds and fiber. A soursop soft drink, containing 12 to 15% pulp, is canned in Puerto Rico and keeps well for a year or more. The juice is prepared as a carbonated bottled beverage in Guatemala, and a fermented, cider-like drink is sometimes made in the West Indies. The vacuum-concentrated juice is canned commercially in the Philippines. There soursop drinks are popular but the normal "milk" color is not. The people usually add pink or green food coloring to make the drinks more attractive. The strained pulp is said to be a delicacy mixed with wine or brandy and seasoned with nutmeg. Soursop juice, thickened with a little gelatin, makes an agreeable dessert.

In the Dominican Republic, a soursop custard is enjoyed and a confection is made by cooking soursop pulp in sugar sirup with cinnamon and lemon peel. Soursop ice cream is commonly frozen in refrigerator ice-cube trays in warm countries.

In the Bahamas, it is simply made by mashing the pulp in water, letting it stand, then straining to remove fibrous material and seeds. The liquid is then blended with sweetened condensed milk, poured into the trays and stirred several times while freezing. A richer product is made by the usual method of preparing an ice cream mix and adding strained soursop pulp just before freezing. Some Key West restaurants have always served soursop ice cream and now the influx of residents from the Caribbean and Latin American countries has created a strong demand for it. The canned pulp is imported from Central America and Puerto Rico and used in making ice cream and sherbet commercially. The pulp is used, too, for making tarts and jelly, sirup and nectar. The sirup has been bottled in Puerto Rico for local use and export. The nectar is canned in Colombia and frozen in Puerto Rico and is prepared fresh and sold in paper cartons in the Netherlands Antilles. The strained, frozen pulp is sold in plastic bags in Philippine supermarkets.

Immature soursops are cooked as vegetables or used in soup in Indonesia. They are roasted or fried in northeastern Brazil. I have boiled the half-grown fruit whole, without peeling. In an hour, the fruit is tender, its flesh off-white and mealy, with the aroma and flavor of roasted ears of green corn (maize).

*Analyses made at the Laboratorio FIM de Nutricion, Havana, Cuba.

Toxicity

The presence of the alkaloids anonaine and anoniine has been reported in this species. The alkaloids muricine, C19H21O4N (possibly des-N-methylisocorydine or des-N methylcorydine) and muricinine, C18H19O4 (possibly des-N-methylcorytuberine), are found in the bark. Muricinine is believed to be identical to reticuline. An unnamed alkaloid occurs in the leaves and seeds. The bark is high in hydrocyanic acid. Only small amounts are found in the leaves and roots and a trace in the fruit. The seeds contain 45% of a yellow non-drying oil which is an irritant poison, causing severe eye inflarnmation.

Other Uses

Fruit: In the Virgin Islands, the fruit is placed as a bait in fish traps.

Seeds: When pulverized, the seeds are effective pesticides against head lice, southern army worms and pea aphids and petroleum ether and chloroform extracts are toxic to black carpet beetle larvae. The seed oil kills head lice.

Leaves: The leaf decoction is lethal to head lice and bedbugs.

Bark: The bark of the tree has been used in tanning. The bark fiber is strong but, since fruiting trees are not expendable, is resorted to only in necessity. Bark, as well as seeds and roots, has been used as fish poison.

Wood: The wood is pale, aromatic, soft, light in weight and not durable. It has been used for ox yokes because it does not cause hair loss on the neck.

In Colombia, it is deemed to be suitable for pipestems and barrelstaves. Analyses in Brazil show cellulose content of 65 to 76%, high enough to be a potential source of paper pulp.

Medicinal Uses: The juice of the ripe fruit is said to be diuretic and a remedy for haematuria and urethritis. Taken when fasting, it is believed to relieve liver ailments and leprosy. Pulverized immature fruits, which are very astringent, are decocted as a dysentery remedy. To draw out chiggers and speed healing, the flesh of an acid soursop is applied as a poultice unchanged for 3 days.

In *Materia Medica* of British Guiana, we are told to break soursop leaves in water, "squeeze a couple of limes therein, get a drunken man and rub his head well with the leaves and water and give him a little of the water to drink and he gets as sober as a judge in no time." This sobering or tranquilizing formula may not have been widely tested, but soursop leaves are regarded throughout the West Indies as having sedative or soporific properties. In the Netherlands Antilles, the leaves are put into one's pillowslip or strewn on the bed to promote a good night's sleep. An infusion of the leaves is commonly taken internally for the same purpose. It is taken as an analgesic and antispasmodic in Esmeraldas Province, Ecuador. In Africa, it is given to children with fever and they are also bathed lightly with it. A decoction of the young shoots or leaves is regarded in the West Indies as a remedy for gall bladder trouble, as well as coughs, catarrh, diarrhea, dysentery and indigestion; is said to "cool the blood," and to be able to stop vomiting and aid delivery in childbirth. The decoction is also employed in wet compresses on inflammations and swollen feet. The chewed leaves, mixed with saliva, are applied to incisions after surgery, causing proudflesh to disappear without leaving a scar. Mashed leaves are used as a poultice to alleviate eczema and other skin afflictions and rheumatism, and the sap of young leaves is put on skin eruptions.

The roots of the tree are employed as a vermifuge and the root bark as an antidote for poisoning. A tincture of the powdered seeds and bay rum is a strong emetic. Soursop flowers are believed to alleviate catarrh.

Morton, J. 1987. Custard Apple. p. 80–83. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Custard Apple

Annona reticulata

Both in tree and in fruit, the custard apple, *Annona reticulata* L., is generally rated as the mediocre or "ugly duckling" species among the prominent members of this genus. Its descriptive English name has been widely misapplied to other species and to the hybrid ATEMOYA, and it is sometimes erroneously termed "sugar apple", "sweetsop" and, by Spanish-speaking people, "*anon*" or "*rinon*", in India, "*ramphal*", all properly applied only to Annona squamosa. It has, itself, acquired relatively few appropriate regional names. Most commonly employed as an alternate name in English-speaking areas is bullock's-heart or bull's-heart; in French, *coeur de boeuf*; Portuguese, *coracao de boi*; in Spanish, often merely *corazon*—all alluding to its form and external blush. The skin color is reflected in the Bolivian name, *chirimoya roia*, the Salvadoran *anona rosada*, and the Guatemalan *anona roja* or *anona colorada*. In the latter country it is also known as *anona de seso*. *Araticum ape* or *araticum do mato* are additional names in Brazil. Some people refer to it as Jamaica apple, or as netted custard apple, which is translated as *anona de redecilla* in Honduras and Nicaragua. *Cachiman, cachiman coeur de boeuf* and *corossol sauvage* may be heard in the French-influenced West Indies.

In the Netherlands Antilles it is *kasjoema*. This name and *boeah nona* are used in Surinam. In Cuba, it is *mamon* or *chirimoya*. Some Central Americans give it the name *anona*, or *anonillo*; Colombians, *anon pelon*. To the Carib Indians the fruit was known as *alacalyoua*; to the Aztecs, *quaultzapotl*, and to the Maya, *tsulimay*, *tsulilpox*, *tsulipox*, *pox*, *oop*, or *op*. It is generally called in the Philippines *sarikaya*; in India *ramphal*, *nona* or *luvuni*, in Malaya, *nona kapri*, or *lonang*; in Thailand, *noi nong*";; in Cambodia, *mo bat* or *mean bat*; in Laos, *khan tua lot*; in South Vietnam, *binh bat*; North Vietnam, *qua na*.

Description

The custard apple tree is not especially attractive. It is erect, with a rounded or spreading crown and trunk 10 to 14 in (25-35 cm) thick. Height ranges from 15 to 35 ft (4.5-10 m). The ill-smelling leaves are deciduous, alternate, oblong or narrow-lanceolate, 4 to 8 in (10-20 cm) long, 3/4 to 2 in (2 5 cm) wide, with conspicuous veins. Flowers, in drooping clusters, are fragrant, slender, with 3 outer fleshy, narrow petals 3/4 to 1 1/4 in (2 3 cm) long; light-green externally and pale-yellow with a dark-red or purple spot on the inside at the base. The flowers never fully open.

Fig. 23: Bahamian custard apples (*Annona reticulata*) show typical variability in form and roughness of surface.

The compound fruit, 3 l/4 to 6 1/2 in (8-16 cm) in diameter, may be symmetrically heart-shaped, lopsided, or irregular; or nearly round, or oblate, with a deep or shallow depression at the base. The skin, thin but tough, may be yellow or brownish when ripe, with a pink, reddish or brownish-red blush, and faintly, moderately, or distinctly reticulated. There is a thick, cream-white layer of custardlike, somewhat granular, flesh beneath the skin surrounding the concolorous moderately juicy segments, in many of which there is a single, hard, dark-brown or black, glossy seed, oblong, smooth, less than 1/2 in (1.25 cm) long. Actual seed counts have been 55, 60 and 76. A pointed, fibrous, central core, attached to the thick stem, extends more than halfway through the fruit. The flavor is sweet and agreeable though without the distinct character of the cherimoya, sugar apple, or atemoya.

Origin and Distribution

The custard apple is believed to be a native of the West Indies but it was carried in early times through Central America to southern Mexico. It has long been cultivated and naturalized as far south as Peru and Brazil. It is commonly grown in the Bahamas and occasionally in Bermuda and southern Florida.

Apparently it was introduced into tropical Africa early in the 17th century and it is grown in South Africa as a dooryard fruit tree. In India the tree is cultivated, especially around Calcutta, and runs wild in many areas. It has become fairly common on the east coast of Malaya, and more or less throughout southeast Asia and the Philippines though nowhere particularly esteemed. Eighty years ago it was reported as thoroughly naturalized in Guam. In Hawaii it is not well known.

Cultivars

No named cultivars are reported but there is considerable variation in the quality of fruit from different trees. The yellow-skinned types seem superior to the brownish, and, when well filled out, have thicker and juicier flesh. Seeds of a purple-skinned, purple-fleshed form, from Mexico, were planted in Florida and the tree has produced fruit of unremarkable quality.

Climate

The custard apple tree needs a tropical climate but with cooler winters than those of the west coast of Malaya. It flourishes in the coastal lowlands of Ecuador; is rare above 5,000 ft (1,500 m). In Guatemala, it is nearly always found below 4,000 ft (1,220 m). In India, it does well from the plains up to an elevation of 4,000 ft (1,220 m); in Ceylon, it cannot be grown above 3,000 ft (915 m). Around Luzon in the Philippines, it is common below 2,600 ft (800 m). It is too tender for California and trees introduced into Palestine succumbed to the cold. In southem Florida the leaves are shed at the first onset of cold weather and the tree is dormant all winter. Fully grown, it has survived temperatures of 27º to 28ºF (-2.78º to 2.22ºC) without serious harm. This species is less drought-tolerant than the sugar apple and prefers a more humid atmosphere.

Soil

The custard apple does best in low-lying, deep, rich soil with ample moisture and good drainage. It grows to full size on oolitic limestone in southern Florida and runs wild in light sand and various other types of soil in the New and Old World tropics but is doubtless less productive in the less desirable sites.

Propagation

Seed is the usual means of propagation. Nevertheless, the tree can be multiplied by inarching, or by budding or grafting onto its own seedlings or onto soursop, sugar apple or pond apple rootstocks. Experiments in Mexico, utilizing cherimoya, llama, soursop, custard apple, *Annona* sp. Af. *lutescens* and *Rollinia jimenezii* Schlecht. as rootstocks showed best results when custard apple scions were side-grafted onto self-rootstock, soursop, or A. sp. Af. *lutescens*. Custard apple seedlings are frequently used as rootstocks for the soursop, sugar apple and atemoya.

Culture

The tree is fast-growing and responds well to mulching, organic fertilizers and to frequent irrigation if there is dry weather during the growing period. The form of the tree may be improved by judicious pruning.

Harvesting and Yield

The custard apple has the advantage of cropping in late winter and spring when the preferred members of the genus are not in season. It is picked when it has lost all green color and ripens without splitting so that it is readily sold in local markets. If picked green, it will not color well and will be of inferior quality. The tree is naturally a fairly heavy bearer. With adequate care, a mature tree will produce 75 to 100 lbs (34-45 kg) of fruits per year. The short twigs are shed after they have borne flowers and fruits.

Pests and Diseases

The custard apple is heavily attacked by the chalcid fly. Many if not all of the fruits on a tree may be mummified before maturity. In India, the ripening fruits must be covered with bags or nets to avoid damage from fruit bats.

A dry charcoal rot was observed on the fruits in Assam in 1947. In 1957 and 1958 it made its appearance at Saharanpur. The causal fungus was identified as *Diplodia annonae*. The infection begins at the stem end of the fruit and gradually spreads until it covers the entire fruit.

Food Uses

In India, the fruit is eaten only by the lower classes, out-of-hand. In Central America, Mexico and the West Indies, the fruit is appreciated by all. When fully ripe it is soft to the touch and the stem and attached core can be easily pulled out. The flesh may be scooped from the skin and eaten as is or served with light cream and a sprinkling of sugar. Often it is pressed through a sieve and added to milk shakes, custards or ice cream. I have made a delicious sauce for cake and puddings by blending the seeded flesh with mashed banana and a little cream.

Food Value Per 100 g of Edible Portion*

Calories	80-101
Moisture	68.3-80.1 g

Ascorbic Acid	15.0-44.4 mg
Nicotinic Acid	0.5 mg

*Minimum and maximum levels of constituents from analyses made in Central America, Philippines and elsewhere.

Toxicity

The seeds are so hard that they may be swallowed whole with no ill effects but the kernels are very toxic. The seeds, leaves and young fruits are insecticidal. The leaf juice kills lice. The bark contains 0.12% anonaine. Injection of an extract from the bark caused paralysis in a rear limb of an experimental toad. Sap from cut branches is acrid and irritant and can severely injure the eyes. The root bark has yielded 3 alkaloids: anonaine, liriodenine and reticuline (muricinine).

Other Uses

The leaves have been employed in tanning and they yield a blue or black dye. A fiber derived from the young twigs is superior to the bark fiber from *Annona squamosa*. Custard apple wood is yellow, rather soft, fibrous but durable, moderately close-grained, with a specific gravity of 0.650. It has been used to make yokes for oxen.

Medicinal Uses: The leaf decoction is given as a vermifuge. Crushed leaves or a paste of the flesh may be poulticed on boils, abscesses and ulcers. The unripe fruit is rich in tannin; is dried, pulverized and employed against diarrhea and dysentery. The bark is very astringent and the decoction is taken as a tonic and also as a remedy for diarrhea and dysentery. In severe cases, the leaves, bark and green fruits are all boiled together for 5 minutes in a liter of water to make an exceedingly potent decoction. Fragments of the root bark are packed around the gums to relieve toothache. The root decoction is taken as a febrifuge.

Morton, J. 1987. Ilama. p. 83–85. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Ilama

Annona diversifolia

This member of the Annonaceae was little known and the subject of much confusion until 1911, when it was investigated and fully described by W.E. Safford, of the United States Department of Agriculture's Bureau of Plant Industry, and given the botanical name of *Annona diversifolia* Safford. In Mexico, it has been called *llama, izlama, illamatzopotl* (translated as *zapote de las viejas*, or "old woman's sapote"), *hilama*, and *papuasa*. In Guatemala, it is called *anona blanca* or *papauce*; in El Salvador, *anona blanca*.

Description

The tree may be spreading or erect, to 25 ft (7.5 m), often branching from the ground. It has aromatic, pale brownish-gray, furrowed bark and glossy, thin, elliptic to obovate or oblanceolate leaves, 2 to 6 in (5-15 cm) long. There are 1 or 2 leaflike, nearly circular, glabrous bracts, 1 to 1 3/8 in (2.5 3.5 cm) long, clasping the base of the flowering branchlets. The new foliage is reddish or coppery. Solitary, long-stalked, maroon flowers, which open to the base, have small rusty hairy sepals, narrow, blunt, minutely hairy outer petals, and stamen-like, pollenbearing inner petals. The fruit is conical, heart-shaped, or ovoid globose, about 6 in (15 cm) long; may weigh as much as 2 Ibs (0.9 kg). Generally, the fruit is studded with more or less pronounced, triangular protuberances, though fruits on the same tree may vary from rough to fairly smooth. The rind, pale-green to deep-pink or purplish, is coated with a dense, velvety gray-white bloom. It is about 1/4 in (6 mm) thick, leathery, fairly soft and granular. In green types, the flesh is white and sweet; in the pink types, it is pink-tinged near the rind and around the seeds, all-pink or even deep-rose, and tart in flavor. It is somewhat fibrous but smooth and custardy near the rind; varies from dryish to fairly juicy, and contains 25 to 80 hard, smooth, brown, cylindrical seeds, 3/4 in (2 cm) long, 3/8 in (1 cm) wide, each enclosed in a close-fitting membrane easily slipped off when split.

Fig. 24: The ilama (*Annona daversifolia*), as grown in southern Florida, has a thick rind and dryish flesh.

Origin and Distribution

The ilama is native and grows wild in foothills from the southwest coast of Mexico to the Pacific coast of Guatemala and El Salvador. The earliest known record of the fruit was made by Francisco Hernandez who was sent by King Philip II of Spain in 1570 to take note of the useful products of Mexico. For many years, it was confused with either the soursop or the custard apple.

The United States Department of Agriculture introduced seeds from El Salvador in 1914 (P.I. No. 35567); from Guatemala in 1917 (P.I. No. 45548); and from Mexico in 1919, 1922 and 1923 (P.I. Nos. 46781, 55709, and 58030). One of the trees planted at the Plant Introduction Garden, Miami, Florida, bore its first fruits in 1923. Several thousand seedlings had been sent to Puerto Rico, St. Croix, various part of tropical America and Asia (including Ceylon), and the Philippines. Apparently few survived. Only in its homeland is the ilama commonly grown in dooryards, occasionally in orchards of 100 trees or more. Dr. Victor Patino took seeds from Mexico to Colombia for planting in the Cauca Valley in 1957. In spite of early enthusiasm for this species, it is seldom mentioned in horticultural literature. In 1942, there were no more than 50 trees in southern Florida, only 3 of bearing age. In 1965, Dr. John Popenoe, Director of Fairchild Tropical Garden, brought seeds from Guatemala and raised a number of seedlings for distribution, but the tree is still quite rare in Florida. It is too tender even for southern California.

Varieties

One named cultivar, 'Imery', introduced into Florida from El Salvador and grown at the Agricultural Research and Education Center, Homestead, is large and pinkfleshed but not as flavorful as some of the white-fleshed acquisitions from Guatemala.

Climate

The ilama is strictly tropical; grows naturally not higher than 2,000 ft (610 m) in Mexico; is cultivated up to 5,000 ft (1,524 m) in El Salvador; up to 5,900 ft (1,800 m) in Guatemala. It seems to do best where there is a long dry season followed by plentiful rainfall. In areas where rainfall is scant, the tree is irrigated.

Soil

Dr. Wilson Popenoe observed that the tree was not particular as to soil but should prosper in rich, loose loam. In Florida, it performs better on deep sand than on oolitic limestone.

Propagation

Ilama seeds, taken from ripe fruits, remain dormant for several weeks or even months and the germination rate thereafter is low. Applications of gibberellic acid at 350 ppm greatly increases germination. Higher concentrations cause malformations in the seedlings. Whip-or cleft-grafting onto custard apple (*A. reticulata*) rootstocks has been successful. Seedlings begin to bear when 3 to 5 years old.

Harvesting

The harvesting season begins in late June in Mexico and lasts only a few weeks. It extends from late July to September in Guatemala; from July to December in Florida. Traditionally, the fruits are not picked until they have begun to crack open, but they can be picked a little earlier and held up to 3 days to soften. They will not ripen if harvested too early.

Yield

The yield is typically low. In Mexico, during the normal fruiting period, some trees will have no fruits, others only 3 to 10; exceptional trees may bear as many as 85 to 100 fruits in a season.

Pests

The Ilama is not as susceptible to the chalcid fly as are its more popular relatives in Florida.

Food Value Per 100 g of Edible Portion*

Moisture	71.5 g

Ascorbic Acid	13.6 mg

*According to analyses made in El Salvador.

Food Uses

The early plant explorers of the United States Department of Agriculture and their contacts in

Mexico and Central America described the ilama as resembling the cherimoya or atemoya in flavor and expected it to be well received in this country and abroad. However, as grown in Florida, it is not as appealing as the sugar apple. There is a slightly unpleasant flavor close to the rind. The flesh is always consumed raw, either in the half shell or, better still, shallowly scooped out, chilled, and served with a little cream and sugar to intensify the flavor, or with a dash of lime or lemon juice.

Morton, J. 1987. Biriba. p. 88–90. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Biriba

Rollinia mucosa

Of the approximately 65 species of the genus *Rollinia* (family Annonaceae), only a few have edible fruit and the best-known is the biriba, *R. mucosa* Baill. (syns. *R. orthopetala* A. DC.; *Annona mucosa* Jacq.; *A. sieberi* A. DC.; and possibly *R. deliciosa* Safford?). The popular Brazilian name has been widely adopted, but in that country it may also be called *biriba de Pernambuco, fruta da condessa, jaca de pobre, araticu, araticum, araticum pitaya*. In Peru, it is *anon*; in Ecuador, *chirimoya*; in Colombia, *mulato*; in Venezuela, *rinon or rinon de monte*; in Mexico, *anona babosa* or *zambo*. In Trinidad it is called wild sugar apple; in Guadeloupe, *cachiman morveux, cachiman cochon* or *cachiman montagne*, in Puerto Rico, *cachiman* or *anon cimarron*, in the Dominican Republic, *candongo* or *anona*.

Description

This fast-growing tree ranges from 13 to 50 ft (4-15 m) in height; has brown, hairy twigs and alternate, deciduous, oblong-elliptic or ovate-oblong leaves, pointed at the apex, rounded at the base, 4 to 10 in (10-25 cm) long, thin but somewhat leathery and hairy on the underside. The flowers, borne 1 to 3 or occasionally more together in the leaf axils, are hermaphroditic, 3/4 to 1 3/8 in (23.5 cm) wide; triangular, with 3 hairy sepals, 3 large, fleshy outer petals with upturned or horizontal wings, and 3 rudimentary inner petals. The fruit is conical to heart-shaped, or oblate; to 6 in (15 cm) in diameter; the rind yellow and composed of more or less hexagonal, conical segments, each tipped with a wart-like protrusion; nearly 1/8 in (3 mm) thick, leathery, tough and indehiscent. The pulp is white, mucilaginous, translucent, juicy, subacid to sweet. There is a slender, opaque-white core and numerous dark-brown, elliptic or obovate seeds 5/8 to 3/4 in (1.6-2 cm) long.

Fig. 26: The biriba (*Rollinia mucosa*) is an attractive light-yellow at first.

Origin and Distribution

This species has an extensive natural range, from Peru and northern Argentina, Paraguay and Brazil and northward to Guyana, Venezuela, Colombia and southern Mexico; Trinidad, the Lesser Antilles including Guadeloupe, Martinique and St. Vincent; and Puerto Rico and Hispaniola. It is much cultivated around Iquitos, Peru, and Rio de Janeiro, Brazil and the fruits are marketed in abundance. It is the favorite fruit in western Amazonia.

Seeds were first introduced into the United States from Para, Brazil, by O.W. Barrett in 1908 (S.P.I. #22512); a second time from Parain 1910 (S.P.I. #27579) and again in 1912 (S.P.I. #27609). The United States Department of Agriculture received seeds from Rio de Janeiro in 1914 (S.P.I. #38171). P.J. Wester may have taken seeds to the Philippines where the species first fruited in 1915. Seedlings were distributed to pioneers in southern Florida but only a very few trees exist here today.

Varieties

The only named selection referred to in the literature is **'Regnard'** reported by P.J. Wester in 1917 as the best variety introduced into the Philippines. A form in the western Amazon region has very pronounced points; weighs up to 8.8 lbs (4 kg).

Pollination

Brazilian scientists have found that 4 species of beetles of the family Chrysomelidae pollinate the flowers, but only 32% of the blooms set fruit. Fruiting begins 55 days after the onset of flowering.

Climate and Soil

The biriba is limited to warm lowlands, from 20º north to 30º south latitudes in tropical America. In Puerto Rico, it occurs at elevations between 500 and 2,000 ft (150-600 m). It has succumbed to temperature drops to 26.5ºF (-3.10ºC) in southern Florida. In Brazil, the tree grows naturally in low areas along the Amazon subject to periodic flooding and it was expected to do well in the Florida Everglades. In the Philippines it is said to flourish where the rainfall is equally distributed throughout the year. Calcareous soils do not seem to be unsuitable in Florida or Puerto Rico as long as they are moist.

Season and Harvesting

In Amazonia, the tree may flower and fruit off and on during the year but the fruits are most abundant from January to June. The fruits ripen in February and March in Rio de Janeiro. In Florida, fruits have matured in November and December. In South America, the fruit is picked when still green and hard in order to transport it intact to urban markets where it gradually turns yellow and soft. When the fruit is fully ripe, handling causes the wart-like protuberances on the rind to turn brown or near-black, rendering it unattractive.

Fig. 27: Handling causes the conical projections on the fruit to turn black.

Pests and Diseases

The most important pests in Brazil are the larvae of *Cerconota anonella* (*Lepidopterae*) which attack fruits in the process of maturing. The borer, *Cratosomus bombina*, penetrates the bark and trunk. A stinging caterpillar, *Sabine* sp., feeds on the leaves. A white fly, *Aleurodicus cocois*, attacks foliage of young and adult plants. *Pseudococcus brevipes* and *Aspidiotus destructor* are found on the leaves and sometimes on the fruits. Black spots on the leaves are caused by the fungus *Cercospora anonae*. *Glomerella cingulata* causes dieback and fruit rot in Florida.

*According to Brazilian analyses.

Food Uses

The fruit is eaten fresh and is fermented to make wine in Brazil.

Other Uses

The wood of the tree is yellow, hard, heavy, strong and is used for ribs for canoes, boat masts, boards and boxes.

Medicinal Uses: The fruit is regarded as refrigerant, analeptic and antiscorbutic. The powdered seeds are said to be a remedy for enterocolitis.

Morton, J. 1987. Avocado. p. 91–102. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Avocado

Persia americana

The avocado, unflatteringly known in the past as alligator pear, midshipman's butter, vegetable butter, or sometimes as butter pear, and called by Spanish-speaking people *aguacate*, *cura*, *cupandra*, or *palta*; in Portuguese, *abacate*; in French, *avocatier*; is the only important edible fruit of the laurel family, Lauraceae. It is botanically classified in three groups: A), *Persea americana* Mill. var. *americana* (P. *gratissima* Gaertn.), West Indian Avocado; B) *P. americana* Mill. var. *drymifolia* Blake (*P. drymifolia* Schlecht. & Cham.), the Mexican Avocado; C) *P. nubigena* var. *guatemalensis* L. Wms., the Guatemalan Avocado.

Description

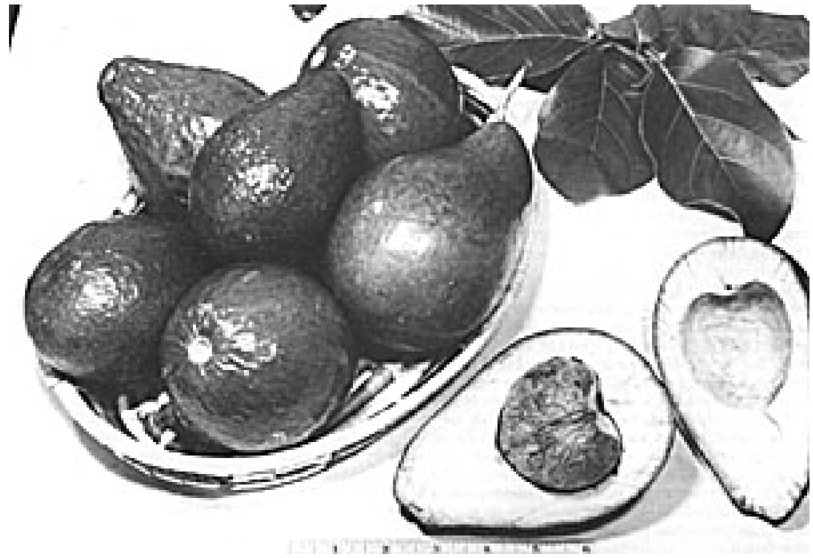

Fig. 28: West Indian avocados (*Persea americana*). The fruit cut open is a 'Hall'.

The avocado tree may be erect, usually to 30 ft (9 m) but sometimes to 60 ft (18 m) or more, with a trunk 12 to 24 in (30-60 cm) in diameter, (greater in very old trees) or it may be short and spreading with branches beginning close to the ground. Almost evergreen, being shed briefly in dry seasons at blooming time, the leaves are alternate, dark-green and glossy on the upper surface, whitish on the underside; variable in shape (lanceolate, elliptic, oval, ovate or obovate), 3 to 16 in (7.5-40 cm) long. Those of the Mexican race are strongly anise-scented. Small, pale-green or yellow-green flowers are borne profusely in racemes near the branch tips. They lack petals but have 2 whorls of 3 perianth lobes, more or less pubescent, and 9 stamens with 2 basal orange nectar glands. The fruit, pear-shaped, often more or less necked, oval, or nearly round, may be 3 to 13 in (7.5-33 cm) long and up to 6 in (15 cm) wide. The skin may be yellow-green, deep-green or very dark-green, reddish-purple, or so dark a purple as to appear almost black, and is sometimes speckled with tiny yellow dots, it may be smooth or pebbled, glossy or dull, thin or leathery and up to 1/4 in (6 mm) thick, pliable or granular and brittle. In some fruits, immediately beneath the skin there is a thin layer of soft, bright-green flesh, but generally the flesh is entirely pale to rich-yellow, buttery and bland or nutlike in flavor. The single seed is oblate, round, conical or ovoid, 2 to 2 1\2 in (5-6.4 cm) long, hard and heavy, ivory in color but enclosed in two brown, thin, papery seedcoats often adhering to the flesh cavity, while the seed slips out readily. Some fruits are seedless because of lack of pollination or other factors.

Origin and Distribution

The avocado may have originated in southern Mexico but was cultivated from the Rio Grande to central Peru long before the arrival of Europeans. Thereafter, it was carried not only to the West Indies (where it was first reported in Jamaica in 1696), but to nearly all parts of the tropical and subtropical world with suitable environmental conditions. It was taken to the Philippines near the end of the 16th Century; to the Dutch East Indies by 1750 and Mauritius in 1780; was first brought to Singapore between 1830 and 1840 but has never become common in Malaya. It reached India in 1892 and is grown especially around Madras and Bangalore but has never become very popular because of the preference for sweet fruits. It was planted in Hawaii in 1825 and was common throughout the islands by 1910; it was introduced into Florida from Mexico by Dr. Henry Perrine in 1833 and into California, also from Mexico, in 1871. Vegetative propagation began in 1890 and stimulated the importation of budwood of various types, primarily to extend the season of fruiting. Some came from Hawaii in 1904 (S. P. I. Nos. 19377-19380).

Now the avocado is grown commercially not only in the United States and throughout tropical America and the larger islands of the Caribbean but in Polynesia, the Philippines, Australia, New Zealand, Madagascar, Mauritius, Madeira, the Canary Islands, Algeria, tropical Africa, South Africa, southern Spain and southern France, Sicily, Crete, Israel and Egypt.

Though the Spaniards took the avocado to Chile, probably early in the 17th Century and it was planted from the Peruvian border southward for over 1000 mi (1,600 km) actual commercial plantings were not established until California cultivars were introduced about 1930 into two areas within 100 mi (160 km) of Santiago where the industry is now centered.

The first trees were planted in Israel in 1908, but named cultivars ('Fuerte' and 'Dickinson') were not introduced until 1924. These aroused interest in the feasibility of the crop for the southern half of the coastal plain and the interior valleys, and development of the industry has steadily gone forward, except for a period in the 1960's when much planting stock was destroyed because of marketing problems. In 1979, Israel produced 33,000 tons (30,000 MT) and exported 28,600 tons (26,000 MT).

In just the last few years, New Zealand has launched a program to expand commercial production, especially in the Bay of Plenty area, with protection from wind and frost, with a view to becoming a major exporter of avocados.

California produced 265 million lbs (12,045 MT) in 1976; 486 million lbs (22,090 MT) in 1981. The Florida avocado potential is estimated at 150 million lbs (6,818 MT). Both states suffer fluctuations because of the impact of periodic freezes, droughts, high winds or other seasonal factors.

Presently, Mexico, with 150,000 acres (62,500 ha) is the leading producer—267,786 tons (243,000 MT); the Dominican Republic is second—144,362 tons (131,000 MT); U.S.A. (California and Florida combined) with 52,000 acres (21,666 ha), third—131,138 tons (119,000 MT); Brazil is fourth—128,934 tons (117,000 MT). Israel, with 16,000 acres (6,666 ha), is fifth; and South Africa sixth. Half of California's plantings are in San Diego County close to Mexico.

As an exporter, Mexico again leads, followed by California, Israel, South Africa and Florida, in that order. Nearly all of Brazil's crop is consumed domestically.

Varieties

WEST INDIAN race: Florida avocados were at first mainly of the summer fruiting West Indian race, but these had to compete commercially with similar fruits imported from Cuba, and growers sought other cultivars maturing at a later season. This led to the development of West Indian X Guatemalan hybrids. The cessation of trade with Cuba in the early 1960's brought about a shift back to summer cultivars in new groves to fill the gap. The majority of the avocados grown in the West Indies, Bahamas and Bermuda and the tropics of the Old World are still of the West Indian race. The skin is leathery, pliable, non-granular, and the flesh low in oil. The leaves are not aromatic. The following are the most prominent of early and more recent West Indian cultivars which have played an important role in the development of the avocado industry in Florida and elsewhere. New selections appear from time to time that may have special adaptability to certain locales or conditions.

'Butler' (a USDA selection in Florida; fruited in 1909, propagated from 1914 to 1918) pear shaped; medium-large; skin smooth; seed of medium size, tight in the cavity. Season: Aug.-Sept. No longer grown in Florida. Cultivated in Puerto Rico.

'Fuchs' ('Fuchsia') (seed of unknown origin planted in Homestead, Florida, in 1910; propagated commercially in 1926); pear shaped to oblong, sometimes with a neck; of medium size; skin smooth; flesh pale greenish-yellow; 4 to 6% oil; seed loose. Season: earlyJune-Aug.; a poor shipper. Tree not very productive in Florida; no longer popular in commercial groves.

'Maoz' (a seedling selected from a plot near Maoz, Israel); pear-shaped; of medium size; skin rough, leathery, violet-purple when ripe; flesh sweetish and very low in oil. Season: medium-late (Oct.). Tree is an alternate bearer but is fairly small, highly salt-tolerant; used in Israel as rootstock on either saline or calcareous soils.

'Pollock' (originated in Miami before 1896; commercially propagated in 1901); oblong to pear shaped; very large, up to 5 lbs (2.27 kg); skin smooth; flesh green near skin, contains 3 to 5% oil; seed large, frequently loose in cavity. Season: early July to Aug. or Oct. Shy-bearing and too large but of superior quality.

'Ruchle' (a seedling of Waldin planted at the Agricultural Research and Education Center, Homestead, in 1923; first propagated in 1946); pear-shaped; of medium size, 10 to 20 oz (280-560 g); flesh low in oil (2-5%). Season begins in July in Florida; Jan. in Queensland. Heavy bearer in Florida.

'Russell' (originated in Islamorada in Florida Keys); pearshaped at apex with long neck giving it a total length up to 13 in (32.5 cm); skin, smooth, glossy, thin, leathery; flesh of excellent quality; seed small. Season: Aug. and Sept. Tree bears well and is recommended for home gardens.

'Simmonds' (possibly from a seed of Pollock, first fruited in Miami in 1913; propagated commercially in 1921); oblongoval to pear-shaped; large; skin smooth, light green; flesh of good flavor, 3 to 6% oil; seed of medium size, usually tight. Season: mid-July to mid-Sept. Tree bears more regularly than Pollock but is less vigorous; sometimes sheds many of its fruits; no longer planted commercially in Florida.

'Trapp' (originated in Miami in 1894; propagated in 1901); round to pear-shaped; medium to large; skin smooth; flesh golden-yellow, green near skin, of excellent quality, 3 to 6% oil; seed large, loose in cavity. Season: medium-late (Sept. to Nov. or Dec.); a good shipper. Was prominent in Florida for 25 years despite tendency to overbloom and bear lightly some years; usually bore regularly and well.

'Waldin' (seed planted in Florida in 1909; propagated commercially in 1917); oblong to oval; medium to large; skin smooth; flesh pale to greenish-yellow, of good flavor, 5 to 10%

oil; seed medium to large, tight. Season: fairly late (mid-Sept. through Oct.). Tree tends to overbear and die back; is hardy. Has been a leading commercial cultivar in central and southern Florida.

There are several Puerto Rican selections—'Alzamora', 'Avila', 'Faria', 'Garcia', 'Hernandez', 'St. Just'—and some cultivars of unknown ancestry: 'Amador', 'Galo', 'Gimenez', 'Torres', and 'Trujillo'.

GUATEMALAN race: (skin varies from thin to very thick and is granular or gritty). Among prominent early Florida and California cultivars were:

'Anaheim' (originated in California); oval to elliptical; large; skin glossy, rough, thick; flesh of fair to good flavor, up to 22% oil, but inferior to'Fuerte', 'Nabal' and 'Benik'; is best in Mar. and Apr. in Israel, July and Aug. in Queensland. Tree slender, erect, tall, cold-sensitive; bears regularly, up to 220 lbs (100 kg) annually in Israel. Considered of poor quality and subject to disease during ripening in Queensland.

'Benik' (introduced from Guatemala to California in 1917 and from California into Israel in 1934); pear-shaped; medium to large; skin rough, purple, medium-thick; flesh of good quality, 15 to 24% oil; seed nearly round, medium. Season: Apr. to Aug. in Calif.; Jan. to Mar. in Israel; July and Aug. in Queensland. The tree begins to bear late and yields only about 116 lbs (53 kg) per year. Color is not popular on the market. Not grown in Florida.

'Dickinson' (a California selection, first propagated in 1912); oval to obovate; small to medium; skin dark-purple with large maroon dots, rough, very thick, granular, brittle; flesh of good quality; seed small to medium, tight. Season: June-Oct. in California; Feb. and Mar. in Florida; Jan. and Feb. in Puerto Rico. Tree is a moderate but regular bearer. In Israel 'Dickinson' is described as round, small to large, very thick-skinned with very large seed; of poor quality, not worth growing. It is no longer grown in Florida or California.

'Edranol' (seedling planted at Vista, California in 1927; propagated in 1932), pear-shaped; of medium size; skin olivegreen, slightly rough, thin leathery; flesh of high quality and nutty flavor, 15 to 18% oil; seed small, tight. Season: Feb. to July at Vista; Apr. to Dec. at Santa Barbara; May and June in Queensland. Disease resistant. Rated as excellent. No longer planted in California but popular in Mexico.

'Hazzard' (seedling of 'Lyon'planted at Vista, California in 1928) pear-shaped; of medium size; skin rough, fairly thin; flesh of good quality, 15 to 34% oil; seed small. Season: Apr. to July in California, July and Aug. in Queensland where it is rated as excellent and free of external and internal diseases and discolorations in storage. The tree grows slowly, reaches only 12 to 15 ft (3.5-4.5 m), begins bearing early and is a dependable producer. Some fruits may crack if left on tree too long. More than 100 trees can be planted per acre (240 per ha).

'Itzamna' (budwood brought from Guatemala to Florida in 1916); oblong pear-shaped; medium large; skin rough; flesh yellow, 11% oil; seed small, tight. Season: very late (Mar. to May). May not bear well; little planted in Florida; a commercial cultivar in California and in Puerto Rico where it is a consistently heavy bearer.

'Linda' (budwood introduced into California from Guatemale in 1914; propagated in

Florida in 1917); elliptical; very large; skin rough, dull-purple when ripe; flesh yellow, 10 to 14% oil; seed small, tight. Season: May to Oct. in California; late (Dec. to Feb.) in Florida. A good shipper but not popular in Florida because of size and color. Of some commercial importance in California. Tree low, spreading, vigorous and bears regularly.

'Lyon' (originated in California; propagated in 1911); broad-pear-shaped; beyond medium to large; skin somewhat rough to rough; bright-green with many small yellowish or red-brown dots; medium-thick, granular and brittle; flesh greenish near skin, of high quality; seed medium-small to medium, tight. Season: Apr. to Aug. in California. Tree comes into bearing early and bears heavily, so much so as to weaken the tree. Grown in Florida only from 1918 to 1922.

'Macarthur' (originated in 1922 at Monrovia, California); pear-shaped; large; skin thin, pliable; flesh has sweet, nutty but watery flavor, contains 13 to 16.7% oil; seed medium to large. Season: Aug. to Nov. in California; Aug. and Sept. in Queensland where it is rated as of poor quality. It is one of the 6 leading commercial cultivars in California, where it is very cold-hardy.

'Nabal'(budwood brought from Guatemala in 1917; propagated in California since 1927, in Florida from 1937; in Israel since 1934); nearly round; medium to large; skin nearly smooth, thick, granular; flesh of high quality, green near skin; 10 to 15 % oil in Florida, 18 to 22 % in Queensland; seed small, tight. Season: June to Sept. in California; Jan. and Feb. in Florida; Oct. and Nov. in Queensland. Tree bears well in central Florida; bears late and poorly in Israel averaging 68 lbs (31 kg) per year in alternate years. In Queensland, bears in alternate years very heavily, but is rated as of medium quality and disease-prone during prolonged ripening.

'Nimlioh' (USDA budwood brought from Guatemala in 1917; propagated commercially in 1921); elliptical; large; skin slightly rough; flesh thick; seed fairly small, tight. Season: late (Jan. and Feb.) in Florida; May to Aug. in California. Tree bears moderate crops on south coast of Puerto Rico. Abandoned in Florida in 1925 because tree found to be weak and not prolific.

'Panchoy' (a USDA introduction into Florida from Guatemala; fruited in 1919); pear-shaped to almost elliptical; medium to large; skin rough, very thick; seed of medium size, tight. Season: very late (Mar. to early Apr.) in Florida; Apr. to Aug. in California. Formerly a heavy bearer in Florida and still is on the south coast of Puerto Rico but subject to die-back. Has been commercially important in California and Hawaii.

'Pinkerton' (seedling, probably of 'Rincon', found on Pinkerton ranch in Ventura Co., California, in 1970; patented); early crop roundish; later, pear shaped with neck; of medium size, 8 to 14 oz (227-397 g); skin medium-leathery, pliable; flesh thick, up to 10% more than in 'Hass' or 'Fuerte'; smooth textured, of good flavor, high in oil, rated as of good quality but inferior to 'Hess' and 'Fuerte'; tends to darken in the latter part of the season; seed small, separates readily from the flesh with the coat adhering to the seed. Season: first crop, Oct. or Nov., 2nd crop, Dec. or Jan. Fruit ships well and has good shelf life, but the neck is a disadvantage on the fresh fruit market; accordingly, the late-season fruits are sent to processing plants. The tree is of low, spreading habit; bears early and heavily; is as cold-sensitive as 'Hass'. About 1200 acres (486 ha) in California in 1984.

'Reed' (originated about 1948 on Reed property in Carlsbad, California, as a seedling, possibly of a 'Anaheim' X 'Nabal' hybrid; patented in 1960; patent now expired); round; medium to large, 8 to 18 oz (227-510 g); skin slightly rough, medium-thick, pliable; flesh cream-colored with rich, faintly nutty flavor; doesn't darken when cut; rated as excellent quality; seed small to medium, tight; coat adheres to seed. Season:July to Oct. in California; late Feb. to Apr. in New Zealand where it is one of the most promising cultivars. Tree erect, can be spaced 15 x 15 ft (4.6x4.6 m); bears early and regularly; about as cold-sensitive as 'Hass'. In 1984, about 1,000 acres (405 ha) in California.

'Schmidt' (budwood introduced into California in 1911; propagated in Florida in 1922); pear-shaped; medium to large; skin rough; flesh pale-yellow, 12 to 16% oil; seed of medium size, tight. Season: very late (Feb. and Mar.). The tree is a poor bearer and cold-sensitive and the fruit of poor keeping quality.

'Sharpless' (originated in California; propagated in 1913); slender-pear-shaped, sometimes with long neck; large to very large; skin slightly rough, greenish-purple to dark-purple with many yellowish dots, thick, granular; flesh of superior quality and flavor; seed small, tight. Very late (Oct. to Feb.) in California.

'Solano' (originated in California; propagated in 1912); obovate to oval; beyond medium to large; skin nearly smooth, bright-green with many yellowish dots, medium-thick, granular; flesh greenish near skin, of fair quality; seed small, tight. Season: Mar. to May in California; Oct. to mid Nov. or Dec. in Florida. A good bearer, but not grown in Florida for many years.

'Spinks' (originated in California; propagated in 1915); broad-obovate; very large; skin rough, dark-purple, thick, granular, brittle; flesh of very good quality and flavor; seed small, tight. Season: Aug. to Apr. in California. Formerly grown in central Florida.

'Taft' (originated in 1899 in California; propagated in 1912); broad pear-shaped; medium to very large; skin faintly rough, more so at base; many yellowish dots, thick, granular but somewhat pliable; flesh of excellent quality and flavor; seed of medium size, tight. Season: May to Dec. in California; Feb. and Mar. in Florida. Poor bearer in California; fair in Florida but cold-sensitive.

'Taylor' (seed of 'Royal' planted in Florida in 1908, propagated commercially in 1914); obovate to pear-shaped, occasionally with neck; small to medium size—12 to 18 oz (340510 g); skin rough, with many small yellow dots; fairly thin; flesh of excellent quality and flavor, 12 to 17% oil; seed of medium size, tight. Season: late (Dec. and Jan. or even to end of Mar.). The tree is cold-hardy but excessively tall and slender.

'Tonnage' (seed of 'Taylor' planted in Florida in 1916; propagated commercially in 1930); pear-shaped, medium large; skin dark green, rough, thick; flesh green near skin, rich in flavor, 8 to 15% oil; seed medium, fairly tight. Season: from mid-Oct. through Nov. in Florida; May to mid-Aug. inArgentine. Tree erect, fairly slender, requiring less distance between trees; is a heavy bearer. Cross pollinated by 'Lula' and 'Collieson' in Argentina.

'Wagner' (seed of 'Royal' planted in California in 1908; propagated in Florida in 1916);

rounded to obovate; small to medium; skin slightly rough; flesh light yellow, 16 to 20% oil; seed large, tight. Season: Late (mid-Jan. to mid-Mar.). Tree lower-growing than 'Taylor', a heavy bearer, but fruit more subject to black spot than 'Taylor'. Not recommended in Florida.

'Wurtz' (originated in 1935 at Encinitas, California; cultivated in Queensland for only the past 12 or 13 years); pearshaped, small to medium; 8 to 12 oz (226-240 g); seed large. Season: May to Sept. in Calif.; late in Queensland. Tree is small and slow growing, bears moderately but regularly. More than 100 trees may be planted per acre (240 per ha).

GUATEMALAN X WEST INDIAN hybrids: Inasmuch as pure Guatemalan avocados proved not well adapted to Florida, Guatemaian X West Indian hybrids have come to be of utmost importance in the Florida avocado industry, representing more than half of the more than 20 major and minor commercial cultivars grown in this state today. Prominent cultivars past and present include:

'Bonita' (seed planted in Florida in 1925); obovate, slightly flattened on one side; of medium size; skin slightly rough; flesh contains 8 to 10% oil; seed of medium size. Season: late (Dec. and Jan.). Hardy in California.

'Booth 1' (seed planted in Florida in 1920); round-obovate; medium-large; skin almost smooth, medium thick, brittle; flesh pale, 8 to 12% oil; seed large and loose; Season: late (Dec. and Jan.). The tree is a heavy bearer but the fruit is of poor quality and the seed is too big.

'Booth 7' (seed planted in Florida in 1920; propagated commercially in 1935); round obovate; of medium size; skin slightly rough, thick, brittle; flesh contains 7 to 14% oil; seed of medium size, tight. Season: late (Dec. to mid-Jan.). The fruit is commercially popular and the tree is a good bearer.

'Booth 8' (seed planted in Florida in 1920); oblong-obovate; medium-large; skin slightly rough, fairly thick, brittle; flesh contains 6 to 12% oil; seed medium large, tight. Season: late (Nov. to mid-Dec.). Popular commercially and the tree is a heavy bearer.

'Chequette' (originated in Miami from seed planted in 1929; propagated in 1939); oval; large; skin glossy, smooth, slightly leathery; flesh of good quality, 13% oil; seed medium, tight. Season: Jan. to Mar. Tree bears heavily in alternate years.

'Collinson' (seed planted in Florida in 1915); broad-obovoid to elliptical; large; skin smooth; flesh of excellent flavor, 10 to 16% oil; seed of medium size, tight. Season: late (Nov. and Dec.). Tree doesn't produce pollen in Florida; is a heavy bearer in Puerto Rico when interplanted with other cultivars. The flesh is apt to blacken around the seed in cold storage Cold-sensitive and unfruitful in Israel.

'Fuchs-20' (a seedling of 'Fuchs' selected in Israel); ellipsoid; medium to large; skin smooth, speckled with yellowish lenticels when ripe; flesh flavor is excellent. Season: medium late (Oct.). Tree is vigorous but a poor bearer; seedlings vary in salt-tolerance but cuttings of resistant selections perform well in saline conditions.

'Grande' (brought to California in 1911 from Atlixco, Mexico); pear-shaped; large; skin rough, green to purplish; seed of medium size, tight. Season: late (Dec. and Jan. in Fla.; Apr. and May in Calif.). Grown in California and Puerto Rico. Tree is a heavy bearer around Mayaguez.

'Hall' (originated in Miami; of unknown parentage; fruited in 1937, propagated in 1938); pear-shaped; large: skin smooth, fairly thick; flesh deep-yellow, 12 to 16% oil; seed medium large, tight. Season: Nov. and Dec. Heavy bearer and coldhardy but subject to scab.

'Herman' (seed planted in Florida in 1935); obovate; skin smooth, fairly thin, flexible; flesh yellow, 10 to 14% oil; seed small. Season: fairly late (mid-Nov. to mid-Jan.). Tree a heavy bearer and hardy.

'Hickson'(seedling, fruited in Florida in 1932; propagated commercially in 1938); obovate; medium to small; skin slightly rough, thick, brittle; flesh of fair to good quality, 8 to 10% oil; seed small, tight. Season: late (Dec. and Jan.). Tree bears heavily every other year; is cold-sensitive.

'Simpson' (a sprout of 'Collinson'; fruited in Florida in 1925); obovate-elliptical; rather large; skin slightly rough and thick but not brittle; flesh pale, 10 to 14% oil; seed medium-large, tight. Season: late (mid Nov. and December). The tree is a good bearer.

'Winslowson' (seed of 'Winslow' planted in Miami in 1911; propagated commercially in 1921); round-oblate; large; skin smooth; flesh pale, 9 to 15% oil; seed of medium size, loose. Season: late (Oct. to Dec. in Fla.; Dec. and Jan. in Puerto Rico). This hybrid is closer to the West Indian race than the Guatemalan and therefore popular in Puerto Rico. Formerly commercial in Florida but abandoned because of loose seed, overblooming, tendency to shed crop, and tree and fruit are susceptible to anthracnose.

In 1963, Puerto Rican horticulturists reported on the performance of 25 selections from 100 studied in the previous 5 years. Four of the selections preceded the establishment of the collection at the Isabela Substation of the University of Puerto Rico. One of the objectives was to identify late maturing varieties with superior quality and yield. Of the leading 10, all are presumed to be Guatemalan X West Indian hybrids except one, 'Kanan No. 1', which is probably Guatemalan, and this and 'Melendez No. 2' are the only ones of alternate bearing habit. 'Gripina' Nos. 2, 5 and 12 were highly rated as, respectively, better than 'Nabal', one of the best commercial cultivars, and most attractive of all. 'Semil' Nos. 23, 31, 34, 42, 43, and 44 seemed equally desirable, with Nos. 34 and 42 noted as wind-resistant.

Puerto Rican breeders have now developed the following Guatemalan X West Indian hybrids: 'Adjuntas', 'Guatemala', 'Melendez 2', 'Gripina 45', and 'Semil 34' and 43, as late-maturing (Nov. to Mar.), having medium oil content, rich-yellow flesh, and tight seed in order to be able to stand handling and shipment.

MEXICAN race: (skin thin and tender, clings to the flesh; flesh of high oil content, up to 30%. The foliage has a pronounced anise-like odor; the tree is more cold resistant than those of the other races or hybrids, thriving near Puebla, Mexico, at 500 ft (1,800 m) above sea-level.

'Duke' (originated in California in 1912); elongated; rather small 5 1\2 to 7 oz (150 200 g); flesh of good quality, 14.5% oil. Season: Sept. to Nov. in Calif.; late July or mid Aug. to mid-Sept. in Israel. Tree is large, symmetrical and wind and cold-resistant, and also highly resistant to root rot, especially when grown from cuttings. It is a poor bearer in some areas of California; has borne 168 lbs (78 kg) annually from the 6th to the 15th year in Israel.

'Ganter' (originated in 1905 in California; introduced into Israel in 1943); small, about 5 1/2 oz (150 g); of good quality, 18% oil; seed small to medium, usually loose. Season: Oct. to Dec. in Calif.; second half of Sept. in Israel. Tree is small, yields no more than 44 lbs (20 kg) per year. Poor shipper.

'Gottfried' (seed of a seedling on Key Largo planted at USDA, Miami, in 1906; distributed in 1918); pear shaped; medium size; skin smooth, purple; flesh of excellent quality, 9 to 13% oil; seed medium. Season: Aug. to Oct. Tree prolific in California; a poor bearer in southern Florida and subject to anthracnose, but hardy and desirable for home gardens on west coast of Florida.

'Mexicola' (originated about 1910 at Pasadena, California; propagated about 1912); very small; skin black; flesh of excellent flavor; seed large. Season: Aug. to Oct. Grown only in home gardens in California. Bears early and regularly; very heat- and cold-resistant; much used as a parent in California breeding programs.

'Northrop' (seedling from C.P. Taft planted about 1900 near Tustin, California; propagated about 1911); small, 3 1/2 to 5 1/2 oz (100-150 g); skin nearly black; flesh of good quality, 26% oil; seed medium. Season: Oct. and Nov. in California; mid July to mid-Sept. in Florida; mid Sept. to mid Oct. in Israel. Fruit does not keep well; flavor disagreeable when overripe. Tree bears regularly but has lower yield than 'Duke'.

'Puebla' (considered pure Mexican but some suggest may be a Mexican X Guatemalan hybrid; was found in 1911 at Atlixco near where 'Fuchs' originated). Of medium size; skin smooth, purple; flesh of good flavor; oil content nearly 20%; seed medium to large. Season: Sept. and Oct. in Florida; early to mid-winter in cool regions of California. Tree does not set fruit regularly in California or Israel and therefore is seldom planted now. Has been recommended for home gardens in Central Florida because of hardiness.

'Zutano' (hybrid, originated in 1926 at Fallbrook, California; registered in 1932); pear shaped; medium-small, skin light green, very thin, leathery; flesh watery, 15 to 22% oil; seed medium. Season: Dec. and Jan. in California; Apr. and May in Queensland where it is considered of poor quality delicate to handle, and prone to disease during ripening. Tree is a good bearer. Ranks among 6 leading commercial cultivars in California, being grown where it is too cold for 'Hass'.

GUATEMALAN X MEXICAN hybrids include:

'Bacon' Quality of flesh slightly better than 'Zutano'. Season: slightly later then 'Zutano'. Tends to be affected with end spot, an external blemish. This cultivar and 'Zutano' are the only 2 reasonably productive of 60 cultivars tried in Los Angeles and Orange Counties in California. In 1957, top working of all the others to these 2 cold hardy cultivars was strongly recommended. 'Bacon' is a good choice for tropical American highlands about 5,200 ft (160 m).

'Fuerte' (a natural hybrid originated at Atlixco, Mexico; introduced into California in 1911); pear shaped; small to medium or a little larger; skin slightly rough to rough, with many small yellow dots, thin, not adherent to flesh; flesh green near skin, 12 to 17% oil; seed small, tight. Season Jan. to Aug. in southern California; Dec. to Feb. in Israel; Apr. and May in Queensland, and New South Wales; mid-Aug. to Oct. in New Zealand. Tree is broad, very productive, but tends to bear biennially. Subject to scab and anthracnose in Florida. Formerly very popular in California (61 % of all avocados shipped); now second to 'Hess' because of a trend to summer instead of winter production and marketing that began in 1972. It is the leading cultivar in Chile where it bears more dependably than in California. It is a very erratic bearer in Israel. Represents 42% of all Australian plantings. Has long been the leading avocado on the European market.

'Hess' (seed planted at La Habra Heights, Calif.; registered in 1932); pear shaped to ovoid; of medium size; has a tendency to be undersized except in New Zealand; skin tough, leathery, dark-purple or nearly black when ripe; pebbled; fairly thin; flesh of good flavor, 18 to 22% oil, generally; up to 35% in Queensland; seed small. Season: begins in mid-Mar. in California; Nov. to Jan. in Queensland; mid-Nov. to Mar. in New Zealand; Aug. and Sept. in New South Wales. Formerly accounted for 20% of California avocados shipped; now is the leading cultivar (70% of the crop in 1984). Tree bears better then 'Nabal' in cool areas of California, but grows tall and requires topping. This is the leading cultivar in New Zealand, representing 50% of all commercial plantings; 25% in Queensland. It is second in importance to 'Fuerte' in Chile.

'Hayes' (a new hybrid in Hawaii, one parent being 'Hass'). Fruit resembles 'Hess' but is larger; skin is glossier, is pebbled, rough, thick and becomes brown-purple. Season: late (mid-Oct. to Dec. in New Zealand). Tree is erect with drooping branches and the fruit is largely sheltered by the foliage.

'Lula' (seed of 'Taft' planted in Miami in 1915); pearshaped, sometimes with neck; medium large; skin almost smooth; flesh pale-to greenish-yellow, 12 to 16% oil; seed large, tight. Season: medium-late (mid-Nov. and Dec.). Tree tall, bears early and heavily; cold resistant, successful in central and southern Florida where it was formerly the leading commercial cultivar. It is the principal cultivar in Martinique for exporting to France; represents 95% of the crop.

'Rincon' (originated at Carpinteria, California); pearshaped; small to medium; skin fairly thin, smooth, leathery; flesh buttery, contains 15 to 26.5% oil; fibers in flesh near base turn black when fruit is cut; seed of medium size. Season: Mar. and Apr. in Queensland, where it is rated as of poor quality. It is one of the 6 leading cultivars in California. Tree has a low spreading habit.

'Ryan' (perhaps seedling of 'amigo' found in 1927 at Whittier, California); pear-shaped; of medium size, 8 to 12 oz (226-340 g); skin medium-rough; flesh of fair quality; seed rather large. Season: May to Sept. in California; July to Oct. in Queensland. Tree large and bears regularly but not as heavily as 'Fuerte' or 'Hess' in Queensland. Important in Chile.

'Sharwil' (originated in Australia); similar to 'Fuerte' in shape but a little more oval; of medium size, skin rather rough, fairly thin; flesh rich in flavor, of high quality, 15 to 26% oil. Season: May and June in New South Wales and Queensland. Tree bears regularly but not heavily. Represents 18 to 20 % of all avocados in New South Wales and Queensland. Disease-free during ripening.

'Susan' (evaluated by California Avocado Society January 2, 1975; patented but patent has now expired); pear-shaped; of medium size, averaging 8 to 10 oz (227-283 g); skin light-green smooth, thin, peels well; flesh pale cream-color, of bland flavor; ripens unevenly with darkening spots; has slight tendency to turn dark when cut; not attractive; of only fair quality; seed large, loose; coat adheres to seed. Season: early fall; short. Tree of medium size; grown commercially only in the San Joaquin Valley because of its cold hardiness.

Many local and introduced cultivars representing all 3 races are being grown and evaluated at the experimental station at Minas Gerais, Brazil. A large collection is also maintained in Bahia. The U.S. Department of Agriculture has an international repository of 170 clones in Miami.

In general, small to medium-sized fruits are best for commercial production and especially for metropolitan markets. Large fruits are suitable for local use especially by large families. Smooth, thin or fairly thin, pliable, green skin is preferred by the consumer. The flesh should be virtually fiberless and of agreeable flavor and, for the dieter, of low oil content. The seed must be small and tight so as not to bruise the flesh during handling and shipping. The seed coats ought to adhere to the seed and not to the cavity. The fruit should ship well and stand cold storage. The tree should be of moderate height, slender enough to permit judiciously close planting without crowding. It should bear at an early age and regularly but not so heavily as to suffer die back, and, of course, should be disease-, insect-, and, in subtropical areas, cold-resistant. Cold-resistant cultivars stand cold-storage better than cold-sensitive cultivars.

Pollination

Many isolated avocado trees fail to fruit from lack of pollination. Commercial growers are careful to match Class A cultivars whose flowers will receive pollen in the morning with Class B cultivars that release pollen in the morning and every grower must be sure to include compatible pollinators in his grove. Bulletin 29 (1971) of the Ministry of Agriculture in Guatemala tabulates the flowering periods (varying from August to April) of 48 introduced and locally selected cultivars, and the hours of the day when each is receptive to or shedding pollen.

Climate

The West Indian race requires a tropical or near tropical (southern Florida) climate and high atmospheric humidity especially during flowering and fruitsetting. The Guatemalan race is somewhat hardier, having arisen in subtropical highlands of tropical America, and it is successful in coastal California. The Mexican race is the hardiest and the source of most of California avocados. It is not suited to southern Florida, Puerto Rico or other areas of similar climate. Temperatures as low as 25ºF (-4ºC) do it little harm. In areas of strong winds, wind-breaks are necessary. Wind reduces humidity, debydrates the flowers and interferes with pollination, and also causes many fruits to fall prematurely.

Soil

The avocado tree is remarkably versatile as to soil adaptability, doing well on such diverse types as red clay, sand, volcanic loam, lateritic soils, or limestone. In Puerto Rico, it has been found healthier on nearly neutral or slightly alkaline soils than on moderately or highly acid soils. The desirable pH level is generally considered to be between 6 and 7, but, in southern Florida, avocados are grown on limestone soils ranging from 7.2 to 8.3. Mexican and Guatemalan cultivars have shown chlorosis on calcareous soils in Israel. The tree's primary requirement is good drainage. It cannot stand excessive soil moisture or even temporary water-logging. Sites with underlying hardpan must be avoided. The water table should be at least 3 ft (.9 m) below the surface. Salinity is prejudicial but certain cultivars (see 'Fuchs-20' and 'Maoz') have shown considerable salt-tolerance in Israel. Avocados grafted onto 'Fuch-20' rootstocks and irrigated with water containing 380 to 400 ppm C1 performed well in a commercial orchard. In the Rio Grande Valley of Texas, cultivars of the Mexican race must be grafted onto salt tolerant West Indian rootstocks.

Propagation

Normally, avocado seeds lose viability within a month. 'Lula' seeds can be stored up to 5 months if placed in non-perforated polyethylene bags and kept at 40ºF (4.4ºC), thus indicating that it may be possible to successfully store seeds of other cultivars ripening at different seasons for later simultaneous planting. Fresh seeds germinate in 4 to 6 weeks, and many people in metropolitan areas grow avocado trees as novelty house plants by piercing the seed partway through with toothpicks on both sides to hold it on the top of a tumbler with water just covering 1/2 in (1.25 cm) of the base. When roots and leaves are well formed (in 2 to 6 weeks), the plant is set in potting soil. Of course, it must be given adequate light and ventilation. In nurseries, seeds that have been in contact with the soil are disinfected with hot water. Experiments with gibberellic acid and cutting of both ends of the seed with a view to achieving more uniform germination have not produced encouraging results. Seedlings will begin to bear in 4 or 5 years and the avocado tree will continue to bear for 50 years or more. Some bearing trees have been judged to be more than 100 years old.

In Australia, seeds planted in early fall germinate in 4 to 6 weeks; if planted later, they may remain dormant all winter and germinate in early spring. Seedlings should be kept in partial shade and not overwatered. While many important selections have originated from seeds, vegetative propagation is essential to early fruiting and the perpetuation of desirable cultivars. However, seedlings are grown for rootstocks.

For many years, shield budding was commonly practiced in Florida, but this method requires considerable skill and experience and is not successful with all cultivars. Therefore, it was largely replaced by whip, side-, or cleft-grafting, all of which make a stronger union than budding.

In the past, seedlings were grafted when 18 to 36 in (45-90 cm) high. It is now considered far better to graft when 6 to 9 in (15-23 cm) high, making the graft 1 to 3 in (2.5-7.5 cm) above ground level. West Indian rootstocks are desirable for overcoming chlorosis in avocados in Israel.

Avocado cuttings are generally difficult to root. Cuttings of West Indian cultivars will generally root only if they are taken from the tops or side shoots of young seed rings. But etiolated cuttings (new shoots) from gibberellin treated hardwood and semi hardwood cuttings of 'Pollock' as well as 'Lula' have been rooted with 50-60% success and, when treated with IBA, 66-83% success under mist in Trinidad. Cuttings of 'Fuchs-20' have rooted under mist with 40 to 50 or even 70% in Israel. Cuttings of 'Maoz' have rooted at the rate of 60% by a special technique developed in California. An Israeli selection, 'G.A. 13' has given 70 to 90% success in rooting cuttings under mist for the purpose of utilizing them as rootstocks in saline and high lime situations. Air-layering is sometimes done to obtain uniform material uninfluenced by rootstock, for research on specific problems. Degree of success depends on the cultivar (those of the Mexican race rooting most quickly), and air-layering is best done in spring and early summer.

At times, mature avocado groves are top worked to change from an unsatisfactory cultivar, or one declining in popularity, to a more profitable one, or an assortment of cultivars for different markets. In 1957, 2,700 ";obsolete"; avocado trees in Ventura, California, were being grafted (top-worked) to mainly 'Hass', some to 'Bacon' and 'Rincon'. This procedure may involve thousands of trees in a given region. It is done in December and January in Florida.

Inasmuch as avocado roots are sensitive to transplanting, it is now considered advisable to raise planting material in plastic bags which can be slit and set in the field without disturbing the root system.

Spacing

Spacing is determined by the habit of the cultivar and the character of the soil. In light soil, 25 x 25 ft (7.5x7.5 m) may be sufficient. In deep, rich soil, the tree makes its maximum growth and a spacing of 30 or 35 ft (9.1 or 10.7 m) may be necessary. If trees are planted so close that they will ultimately touch each other, the branches will die back. Some growers plant 10 to 15 ft (3-4.5 m) apart initially and remove every other tree at 7 to 8 years of age. If the surplus trees are not bulldozed but just cut down leaving a stump, application of herbicide may be needed to prevent regrowth. Ammonium sulfamate has been proven effective. In modernized plantings, space between rows is necessary for mechanical operations.

Holes at least 2 ft (0. 6 m) deep and wide are prepared well in advance with enriched soil formed into a mound. After the young plant is put in place a mulch is beneficial, weeds should be controlled, and watering is necessary until the roots are well established. Generally small amounts of fertilizer are given every 2 months with the amount gradually increasing until fruiting begins. Bearing trees need, on the average, 3 to 4 lbs (1 1/2-2 kg) 3 times a year, beginning when the tree is making vegetative growth. No fertilizer should be given at blooming time; one must wait until the fruits are firmly set. Nitrogen has the greatest influence on tree growth, its resistance to cold temperatures, and on fruit size and yield. Fertilizer mixes vary greatly with the type of soil. Mineral deficiencies determined by leaf analysis, are usually remedied by foliar spraying. Magnesium deficiency was formerly a serious handicap to avocado growers in Florida and Kenya. In California, zinc deficiency has been corrected by applying zinc chelates or zinc sulfate to the soil instead of spraying the foliage.

Keeping the upper soil moist has been greatly facilitated by drip irrigation, which also may carry 80% of the fertilizer requirement.

Because some cultivars tend to grow too tall for practical purposes, commercial growers cut trees back to 16 or 18 ft (4.8-5.4 m), let them grow back to 30 ft (9.1 m) and top them again. But decapitation is not a perfect remedy because the tendency of the avocado tree is to grow a new top very quickly. Recently it has been found that the growth-inhibiting chemical, TIBA (triiodobenzoic acid) slows down terminal growth and encourages lateral shoots. A system of pruning to encourage lower branching is being tried on 'Lula' in Martinique.

Avocado branches frequently need propping to avoid breaking with the weight of the developing fruits.

Some growers find it profitable to interplant bananas until the avocado trees reach bearing age.

Maturity and Harvesting

Avocados will not ripen while they are still attached to the tree, apparently because of an inhibitor in the fruit stem. Homeowners usually consider the entire crop pickable when a few mature (full grown) fruits have fallen. This is not a dependable guide because the prolonged flowering of the avocado results in fruits in varying stages of development on the tree at the same time. The largest fruits, of course, should be picked first but the problem is to determine when the largest are full grown (perfectly mature for later perfect ripening). If picked when full grown and firm, avocados will ripen in 1 to 2 weeks at room temperature. If allowed to remain too long on the tree, the fruits may be blown down by wind and they will be bruised or broken by the fall.

Florida maturity standards for marketing have been determined by weight and time of year for each commercial cultivar so that immature fruits will not reach the market. Immature fruits do not ripen but become rubbery, shriveled and discolored. Most West Indian cultivars will ripen properly if picked when the specific gravity becomes 0. 96 or lower, but 'Waldin' is fully mature when the specific gravity is still above 0.98. Guatemalan and Guatemalan X West Indian cultivars generally are harvest-mature when the specific gravity is 0.98 or lower. In California, physiological maturity of 'Bacon', 'Fuerte,' 'Hess' and 'Zutano' has been determined by measurement of length, diameter and volume, but dry weight, correlating with oil content, is considered a better maturity index. California law has, since 1925, required a minimum of 8 % oil, but oil content varies greatly among cultivars and also the climatic region where the fruit is grown. Some people complain that the 8% standard is too low for some cultivars. Maximum flavor of 'Fuerte' develops when the fruit is harvested at an oil content of 16%. Therefore, a minimum dry weight standard of 21 % has been recommended.

Formerly, avocados were detached by means of a forked stick and allowed to fall, but this causes much damage and loss. Nowadays harvesters usually use clippers for lowhanging fruits and for those higher up a long handled picking pole with a sharp ";V"; on the metal rim to cut the stem and a strong cloth bag to catch the fruit. Gloves are worn to avoid fingernail scratches on the fruit. In California, studies have been made of the effects of hand clipping (leaving stem on), hand snapping (which removes the stem), tree-shaking, and limb shaking (which removes the stem from some of the fruits). All methods are acceptable if the stem scar is waxed on stemless fruits to avoid weight loss before ripening at which time the stem detaches naturally. In Australia, some growers are using hydraulic lifts to facilitate hand-picking. A tractor fitted with a triple-decked picking platform has been adopted by some large growers in Chile. Efforts to develop dwarf avocado trees by means of sandwich interstocks from low growing types have been going on in California since 1964.

Avocados must be handled with care and are packed and padded in single or double-layer boxes or cartons for shipment. A special ";Bruce box";, holding 32 lbs (14.5 kg) is used for large fruit. The fruits may be held in position in molded trays.

Yield

It will be seen that the yield varies greatly with the cultivar, age of tree, the locale, weather and other conditions. The small tree, 'Ganter', has yielded 44 lbs (20 kg) annually; 'Nabal', 68 lbs (31 kg); 'Benik', 116 lbs (53 kg); 'Duke', 168 lbs (76 kg), and 'Anaheim', 220 lbs (100 kg). Close-planting in southern Florida provides yields averaging 11,000 lbs per acre (11,000 kg per ha) in young groves and nearly twice this amount is anticipated after the time has come to thin the planting by half.

Girdling has been tested in Florida, Australia and Israel as a means of increasing the yield of shy bearing but popular cultivars. It must be repeated every year to be fully effective. It may decrease the yield of normally fruitful cultivars.

Marketing

Inasmuch as the avocado, outside of Latin America, has been widely regarded as a luxury fruit, large scale marketing has been dependent on consumer education and advertising. Calavo Growers of California is an enterprising association of 2,600 avocado growers. The Mayflower Fruit Association, of which Blue Anchor is a member, packs over 60% of the avocados grown in the San Joaquin Valley. The California Avocado Commission spends millions of dollars in newspaper, magazine, television, radio and other publicity financed by grower assessments. The Florida Lime and Avocado Administrative Committees, together with the Florida Division of Marketing's Bureau of Market Expansion and Promotion, spend about 1/4 million dollars annually for advertising and publicity through the Press and by means of special marketing displays and distribution of recipes. The trademarks, ";Calavo"; and ";Flavocado"; (Florida Avocado Growers Exchange), are recognized nationally and internationally.

The 8% oil standard established in California kept Florida avocados out of the California market until a court decision in 1972 outlawed the discrimination against Florida fruits which average about half the oil content of California cultivars and are advocated by growers as having better flavor and fewer calories. Calavo Growers Cooperative of

California now handles 57% of the local avocado crop and 33% of the Florida crop, selling directly to the retail markets. Combined Florida and California efforts have raised the rate of regular avocado consumption in the United States from 6% in the late 1960's to over 15% today. In California, the Avocado Marketing Research Information Center was created in 1983 to gather and report information on production, foreign and domestic shipments and other activities.

Israel makes substantial investments in developing European markets for avocados and has attained the position of principal exporter to Europe. France and the United Kingdom are the chief consumers.

Storage

Ripening of avocados may be hastened by exposure to an atmosphere of at least 10 ppm ethylene 25 to 49 hours after harvest. The avocado does not respond to earlier treatment. Changes in pectinesterase activity and pectin content are being studied to measure ripening of avocados in storage. Dipping in latex has retarded decay in avocados stored at room temperature.

Avocados ship well and are sent to overseas markets under refrigeration in surface vessels. The fruits are subject to chilling injury (dark-brown or gray discoloration of the mesocarp) in refrigerated storage and degree of susceptibility varies with the cultivar and stage at harvesting and length of time in storage. Most commercial cultivars can be held safely at temperatures between 40º and 55ºF (4.5º-12.8ºC) for at least two weeks. The best ripening temperature after removal from storage is 60ºF (15.5ºC).

Removal of ethylene from controlled atmospheric storage (2% oxygen, 10% carbon dioxide) prolongs the marketable life of avocados. Reducing atmospheric pressure to subatmospheric 60 mm Hg in the refrigerated storage unit at 42.8ºF (6ºC) retards ripening of avocados by reducing respiration and ethylene production. Removed after 70 days, fruits have ripened normally at atmospheric pressure and 57.2ºF (14ºC). Experimental calcium treatments have delayed ripening and reduced internal chilling injury in storage but make the fruit externally less attractive and are, therefore, considered commercially undesirable.

'Hess' fruits dipped in fungicide 24 hours after harvest and sealed in polyethylene bags containing an ethylene absorbent (potassium permanganate on vermiculite or on aluminum silicate), have been successfully stored for 40 or 50 days at 50ºF (10ºC). Waxed 'Fuerte' avocados stored for 2 weeks at 41ºF (5ºC) and ripened at 68ºF (20ºC) ripened only 1 day later than non-waxed; however, waxing does reduce weight loss.

In 1965, to overcome the problem of oversupply during the harvesting season and undersupply during the offseason, California adopted liquid-nitrogen freezing of peeled or unpeeled avocado halves, which can be thawed and served as the equivalent of fresh fruits in restaurants, on airplanes and in institutions.

Pests and Diseases

Avocados have no major insect enemies in Florida but migrating cedar waxwings feed on leaves, flowers and very young fruits and the fruits are commonly attacked by squirrels, rats and mice. The avocado red mite, *Oligonychus yothersi*; is the most common predator on the leaves in some groves and not in others. Red-banded thrips, *Selenothrips rubrocinctus*, the greenhouse thrips, *Heliothrips haemorrhoidalis*, and red-spider, *Tetranychus mytilaspidis*, may feed on avocado leaves and blemish the fruits from time to time. There are several scales also which may feed on foliage, especially the Florida wax scale, *Ceroplastes floridensis*, the pyriform, or soft white, scale, *Protopulvinaria pyriformis*, Dictyospermum scale, *Chrysomphalus dictyospermi*; and the black scale, *Saissetia oleae*. Among two dozen other minor pests in Florida are the citrus mealybug, *Pseudococcus citri* and avocado mealybug, *P. nipae*. Stinkbugs may prick the fruits leaving little dents in the skin coupled with gritty areas at the same locations inside.

In California, 2 lepidopterous pests, *Amorbia cuneana* and the omnivorous looper, *Sabulodes aegrotata*, when present in large numbers, cause severe defoliation and fruit-scarring. Biological control is being achieved by release of the egg parasite, *Trichogramma platneri*; which is now commercially available to growers. Since 1949, the orange tortrix (a leaf roller), *Argyrotaenia citrana*, has been increasing as a menace to the avocado in California, the larvae feeding on twigs, terminal buds and foliage, flowers, and fruits. Since the pest requires shaded areas, it is best controlled by thinning out a close-planted grove or top-working to less susceptible cultivars.

The fruit-spotting bug, *Amblypelta nitida*, and banana spotting bug, *A. Iutescens*, are important pests requiring control in Queensland. The Mediterranean fruit fly is a major hazard in Israel, but very thick-skinned fruits such as 'Anaheim' are not attacked. The Queensland fruit fly, *Dacus tryoni*; seriously damages only Mexican cultivars or Guatemalan X Mexican hybrids in Australia. In 1971, a nematode survey in Bahia, Brazil, revealed 9 genera of known or suspected parasitic nematodes associated with avocado tree decline. Israeli avocado growers are seeking and testing means of biological control of the more serious of the 3 dozen insects and mites preying on the crop in that country. In Mexico, the avocado weevil, *Heilipus lauri*; tunnels into the seeds.

The major disease of avocados in South and Central America and some islands of the West Indies, in California, Hawaii, and various other areas, is root-rot caused by the fungus, *Phytophthora cinnamomi*, which is being combatted by the use of strict sanitary procedures and resistant rootstocks, especially 'Duke'. At the University of California, Riverside, over 750 seedlings and cuttings were being tested for root-rot resistance in 1976 and 1977 and the most promising tried out for grafting compatibility with commercial cultivars. Also, soil fumigation experiments with methyl bromide and newly developed chemicals were being carried forward. The disease has been so devastating in the high rainfall areas of New South Wales and Queensland that plantings have expanded into the semi-arid Murray Valley in the hope of avoiding it. In New Zealand, it is not a problem on deep, volcanic soils, but occurs on shallow, heavier soils. It was allegedly introduced into Chile with balled trees from California and vigorous measures are being taken to control it.

Mushroom root-rot from *Clitocybe tabescens* may occasionally occur. Cercospora spot (brown spots on the leaves and fruits), caused by the fungus, *Cercospora purpurea*, may cause cracks in affected areas of the skin and thus allow entrance of the anthracnose fungus, *Colletotrichum gloeosporioides*, which invades and spoils the flesh. *Glomerella cingulata* is an important source of anthracnose in Queensland. Some cultivars are subject to scab which is readily controlled by copper sprays.

More than 30 other pathogens are variously responsible for wood rot, collar rot, dieback, leafspot, stem-and rot of fruit, branch canker, and powdery mildew. Sunblotch viroid cripples young trees and damages fruits in California and Israel. So far, it is unknown in New Zealand. Stems of young trees may be affected by sunburm, and hot, dry winds cause tipburm of leaves. The avocado tree may show copper or zinc deficiency or tipburm from an excess of mineral salts.

Food Uses

Indians in tropical America break avocados in half, add salt and eat with tortillas and a cup of coffee—as a complete meal. In North America, avocados are primarily served as salad vegetables, merely halved and garnished with seasonings, lime juice, lemon juice, vinegar, mayonnaise or other dressings. Often the halves are stuffed with shrimp, crab or other seafood. Avocado flesh may be sliced or diced and combined with tomatoes, cocumbers or other vegetables and served as a salad. The seasoned flesh is sometimes used as a sandwich filling. Avocado, cream cheese and pineapple juice may be blended as a creamy dressing for fruit salads.

Mexican guacamole, a blend of the pureed flesh with lemon or lime juice, onion juice or powder, minced garlic, chili powder or Tabasco sauce, and salt and pepper has become a widely popular ";dip"; for crackers, potato chips or other snacks. The ingredients of guacamole may vary and some people add mayonnaise.

Because of its tannin content, the flesh becomes bitter if cooked. Diced avocado can be added to lemon-flavored gelatin after cooling and before it is set, and chunks of avocado may be added to hot foods such as soup, stew, chili or omelettes just before serving. In Guatemalan restaurants, a ripe avocado is placed on the table when a hot dish is served and the diner scoops out the flesh and adds it just before eating. For a ";gourmet"; breakfast, avocado halves are warmed in an oven at low heat, then topped with scrambled eggs and anchovies.

In Brazil, the avocado is regarded more as a true fruit than as a vegetable and is used mostly mashed in sherbet, ice cream, or milk shakes. Avocado flesh is added to heated ice cream mixes (such as boiled custard) only after they have cooled. If mashed by hand, the fork must be a silver one to avoid discoloring the avocado. A New Zealand recipe for avocado ice cream is a blend of avocado, lemon juice, orange juice, grated orange rind, milk, cream, sugar and salt, frozen, beaten until creamy, and frozen again.

Some Oriental people in Hawaii also prefer the avocado sweetened with sugar and they combine it with fruits such as pineapple, orange, grapefruit, dates, or banana.

In Java, avocado flesh is thoroughly mixed with strong black coffee, sweetened and eaten as a dessert.

Avocado slices have been pickled and marketed in glass jars. California began marketing frozen guacamole in 1951, and a frozen avocado whip, developed at the University of

Miami, was launched in 1955. To help prevent enzymatic browning of these products, it is recommended that sodium bisulfite and/or ascorbic acid be mixed in before freezing.

Avocado Oil

Oil expressed from the flesh is rich in vitamins A, B, G and E. It has a digestibility coefficient of 93.8% but has remained too costly to be utilized extensively as salad oil. The amino acid content has been reported as: palmitic, 7.0; stearic, 1.0; oleic, 79.0; linoleic, 13.0.

The oil has excellent keeping quality. Samples kept in a laboratory in Los Angeles at 40ºF (4.4ºC) showed only slight rancidity after 12 years. There is much interest in the oil in Italy and France. The Institut Francais de Recherches Fruitieres Outre Mer has studied the yield of oil in 25 cultivars. Joint Italian/Venezuelan studies of 5 prominent cultivars indicated that the fatty acid composition and tryglyceride structure was not influenced by variety. The oil is used as hair-dressing and is employed in making facial creams, hand lotions and fine soap. It is said to filter out the tanning rays of the sun, is non-allergenic and is similar to lanolin in its penetrating and skinsoftening action. In Brazil, 30% of the avocado crop is processed for oil, 2\3 of which is utilized in soap, 1/3 in cosmetics. The pulp residue after oil extraction is usable as stockfeed.

Food Value Per 100 g of Edible Portion (Flesh)*

Moisture	65.7-87.7 g
Ether Extract	5.13-19.80 g
Fiber	1.0-2.1 g
Nitrogen	0.130-.382 g
Ash	0.46-1 68 g
Calcium	3.6-20.4 mg
Phosphorus	20.7-64.1 mg
Iron	0.38-1.28 mg
Carotene	0.025-.0475 mg
Thiamine	0.033-0.117 mg
Riboflavin	0.065-0.176 mg
Niacin	0.999-2.220 mg
Ascorbic Acid	4.5-21.3 mg

*Analyses of West Indian, Guatemalen and Mexican avocados marketed in Central America.

Browning of the flesh of freshly cut avocado fruits is caused by polyphenol oxidase isoenzymes. Avocado halves average only 136 to 150 calories.

The avocado has a high lipid content-from 5 to 25% depending on the cultivar. Among the saturated fatty acids, myristic level may be .1%, palmitic, 7.2, 14.1 or 22.1%; stearic, 0.2, 0.6 or 1.7%. Of the unsaturated fatty acids, palmitoleic may range from 5.5 to 11.0%; oleic may be 51.9, 70.7 or 80.97%, linoleic, 9.3, 11.2 or 14.3%. Non saponifiable represents 1.6 to 2.4%. Iodine number is 94.4. In feeding experiments which excluded animal fat, 16 patients were given 1/2 to 1 l/2 avocados per day. Total serum cholesterol and phospholipid values in the blood began to fall in one week. Body weight did not increase. Cholesterol values did not rise and 8 patients showed decreases in total serum cholesterol and phospholipids.

Amino acids of the pulp (N = 16 p. 100) are recorded as: arginine, 3.4; cystine, 0: histidine, 1.8; isoleucine, 3.4; leucine, 5.5; lysine, 4.3;methionine, 2.1; phenylalanine, 3.5; threonine, 2.9; tryptophan, 0; tyrosine, 2.3; valine, 4.6; aspartic acid, 22.6; glutamic acid, 12.3; alanine, 6.0; glycine, 4.0; proline, 3.9; serine, 4.1.

Toxicity

Unripe avocados are said to be toxic. Two resins derived from the skin of the fruit are toxic to guinea pigs by subcutaneous and peritoneal injection. Dopamine has been found in the leaves. The leaf oil contains methyl chavicol. Not all varieties are equally toxic. Rabbits fed on leaves of 'Fuerte' and 'Nabal' died within 24 hours. Those fed on leaves of 'Mexicola' showed no adverse reactions. Ingestion of avocado leaves and/or bark has caused mastitis in cattle, horses, rabbits and goats. Large doses have been fatal to goats. Craigmill *et al*. at Davis, California, have confirmed deleterious effects on lactating goats which were allowed to graze on leaves of 'Anaheim' avocado an hour each day for 2 days. Milk was curdled and not milkable, the animals ground their teeth, necks were swollen and they coughed, but the animals would still accept the leaves on the 4th day of the experiment. By the 10th day, all but one goat were on the road to recovery. All abnormal signs had disappeared 20 days later. In another test, leaves of a Guatemalan variety were stored for 2 weeks in plastic bags and then given to 2 Nubian goats in addition to regular feed over a period of 2 days. Both suffered mastitis for 48 hours. Avocado leaves in a pool have killed the fish. Canaries have died from eating the ripe fruit. The seeds, ground and mixed with cheese or cornmeal, have been used to poison rodents. However, tests in Hawaii did not show any ill effect on a mouse even at the rate of 1/4 oz (7 g) per each 2.2 lbs (1 kg) of body weight, though the mouse refused to eat the dried, grated seed material until it was blended with cornmeal. Avocado seed extracts injected into guinea pigs have caused only a few days of hyperexcitability and anorexia. At Davis, mice given 10 to 14 g of half-and-half normal ration and either fresh or dried avocado seed died in 2 or 3 days, though one mouse given 4 times the dose of the others survived for 2 weeks.

The seed contains 13.6% tannin, 13.25% starch. Amino acids in the seed oil are reported as: capric acid, 0.6; myristic, 1.7; X, 13.5; palmitic, 23.4; X, 10.4; stearic, 8.7; oleic, 15.1; linoleic, 24.1; linolenic, 2.5%. The dried seed contains 1.33% of a yellow wax containing sterol and organic acid. The seed and the roots contain an antibiotic which prevents bacterial spoilage of food. It is the subject of two United States patents.

The bark contains 3.5% of an essential oil which has an anise odor and is made up largely of methyl chavicol with a little anethole.

Other Uses

The seed yields a milky fluid with the odor and taste of almond. Because of its tannin content, it turns red on exposure, providing an indelible red-brown or blackish ink which was used to write many documents in the days of the Spanish Conquest. These are now preserved in the archives of Popayan. The ink has also been used to mark cotton and linen textiles.

In Guatemala, the bark is boiled with dyes to set the color.

Much avocado wood is available when groves are thinned out or tall trees are topped. The sapwood is cream-colored or beige; the heartwood is pale red-brown, mottled, and dotted with small drops of gummy red sap; fine-grained; light—40 lbs per cu ft—(560-640 kg/cu m); moderately soft but brittle; not durable; susceptible to drywood termites and fungi. The wood has been utilized for construction, boards and turnery. An Australian woodworker has reported that it is suitable for carving, resembles White Beech (*Eucalyptus kirtonii*); is easy to work, and dresses and polishes beautifully. He has made it into fancy jewel boxes. It probably requires careful seasoning. A Florida experimenter made bowls of it but they cracked.

Honeybees gather a moderate amount of pollen from avocado flowers. The nectar is abundant when the weather is favorable. When unmixed by that from other sources it produces a dark, thick honey favored by those who like buckwheat honey or sugarcane sirup.

Medicinal Uses: The fruit skin is antibiotic; is employed as a vermifuge and remedy for dysentery. The leaves are chewed as a remedy for pyorrhea. Leaf poultices are applied on wounds. Heated leaves are applied on the forehead to relieve neuralgia. The leaf juice has antibiotic activity. The aqueous extract of the leaves has a prolonged hypertensive effect. The leaf decoction is taken as a remedy for diarrhea, sore throat and hemorrhage; it allegedly stimulates and regulates menstruation. It is also drunk as a stomachic. In Cuba, a decoction of the new shoots is a cough remedy. If leaves, or shoots of the purple-skinned type, are boiled, the decoction serves as an abortifacient. Sometimes a piece of the seed is boiled with the leaves to make the decoction.

The seed is cut in pieces, roasted and pulverized and given to overcome diarrhea and dysentery. The powdered seed is believed to cure dandruff. A piece of the seed, or a bit of the decoction, put into a tooth cavity may relieve toothache. An ointment made of the pulverized seed is rubbed on the face as a rubefacient—to redden the cheeks. An oil extracted from the seed has been applied on skin eruptions.

Related Species

Persea schiedeana Nees, called *coyo, coyocte, chalte, chinini; chucte, chupte, cotyo, aguacate de monte, aguacaton*, wild pear, and *yas*, grows wild in mountain forests from southern Mexico to Panama at altitudes between 4,600 and 6,200 ft (1,400-1,900 m). The tree is usually from 50 to 65 ft (15-20 m) tall, occasionally to 165 ft (50 m). Young branches are densely brown-hairy. The leaves are deciduous, obovate to oval, often cordate at the base; 5 to 12 in (12.5-30 cm) long, 2 3/4 to 6 in (7-15 cm) wide, white-hairy on the underside. Downy flowers, borne in densely grayish-hairy panicles, are light greenish-yellow, the perianth and stamens turning red with age. The fruit, resembling that of the avocado and equally variable, is generally pear-shaped, weighing 8 to 14 oz (227-397 g), with thick, leathery, flexible skin. Variously described as brownish-white, light-brown, pale-green, greenish-brown or dark-brown, the flesh is oily with a milky juice, few to many coarse fibers, but a very appealing, avocado-coconut flavor. The seed is very large. The cotyledons, unlike those of the avocado, are pink internally.

The tree is left standing when forests are cleared and is cultivated in Veracruz and on some farms in Guatemala. The fruits from the best of the wild and cultivated trees are marketed locally. The timber is used in construction and carpentry. This species was introduced into the USA from Guatemala and Honduras in 1948 as a wilt-resistant rootstock for the avocado. It is very sensitive to frost. In 1974 it was reported to be a poor bearer in Puerto Rico.

A more distant relative is *Beilschmiedia anay* Kosterm. (*Huielandia anay* Blake), called *anay, payta, escalalan* or *excalan*, which is native to moist, relatively low altitudes, 985 to 2,300 ft (300 to 700 m) in southern Mexico, Guatemala, Costa Rica and Colombia. Seeds were collected by Dr. Wilson Popenoe in 1917 and seedlings were set out in the Plant Introduction Garden of the U.S. Department of Agriculture, Miami.

The tree attains a height of 66 ft (20 m); the young branches are brown-hairy. Leathery leaves, broad-elliptic or broad-ovate, are 4 3/4 to 12 in (12-30 cm) long and 3 to 7 1/2 in (7.5-19 cm) wide, white-hairy only on the veins. The flowers (in December and January) are fragrant, greenish, in slender panicles to 5 in (13 cm) long. The fruit is ellipsoid-pyriform, 2 3/4 to 6 in (7-15 cm) long, with very thin, glossy, purplish-black skin and sparse green, oily flesh similar to that of the avocado in texture and flavor. The seed is obovoid, up to 2 3\4 in long, with thick, purplish-yellow, red spotted coat, and strong almond odor. In Guatemala, the fruit matures in August and September, falls while hard, and ripens in 2 or 3 days. Analyses in Guatemala show (per 100 g/flesh): moisture, 73.86 g; protein, 1.62-1.80 g; carbohydrates, 3.32-3.90 g; fat, 12.98-17.44 g; cellulose, 2.12 g; ash, 1.38 g.

Food Value Per 100 g of Edible Portion (*flesh*)*

Moisture	76.5-77.6 g
Ether Extract	5.55-7.59 g
Fiber	1.0-1.8 g
Nitrogen	0.191-0.204 g
Ash	0.72-0.91 g
Calcium	11.4-12.5mg
Phosphorus	35.5-36.2 mg
Iron	0.31-0.35 mg
Carotene	0.003-0.033 mg
Thiamine	0.048-0.070 mg
Riboflavin	0.067-0.089 mg

Niacin	0.598-0.718 mg
Ascorbic Acid	5.7-16.4mg

Loquat

Eriobotrya japonica

A fruit of wide appeal, the loquat, *Eriobotrya japonica* Lindl., (syn. *Mespilus japonicus* Thunb.), of the rose family, Rosaceae, has been called Japan, or Japanese, plum and Japanese medlar. To the Italians, it is *nespola giapponese;* to French-speaking people, it is n*éflier du Japon*, or *bibassier*. In the German language, it is *japanische mispel,* or *wollmispel;* in Spanish, *nispero, nispero japonés*, or *nispero del Japón;* in Portuguese, *ameixa amarella,* or *ameixa do Japao.*

Description

A tree of moderate size, the loquat may reach 20 to 30 ft (6-9 in), has a rounded crown, short trunk, and woolly new twigs. The evergreen leaves, mostly whorled at the branch tips, are elliptical-lanceolate to obovate lanceolate, 5 to 12 in (12.5-30 cm) long and 3 to 4 in (7.5-10 cm) wide; dark-green and glossy on the upper surface, whitish-or rusty-hairy beneath, thick, stiff, with conspicuous parallel, oblique veins, each usually terminating at the margin in a short, prickly point. Sweetly fragrant flowers, borne in rusty-hairy, terminal panicles of 30 to 100 blooms, are white, 5-petalled, 1/2 to 3/4 in (1.25-2 cm) wide. The fruits, in clusters of 4 to 30, are oval, rounded or pear-shaped, 1 to 2 in (2.5-5 cm) long, with smooth or downy, yellow to orange, sometimes red-blushed, skin, and white, yellow or orange, succulent pulp, of sweet to subacid or acid flavor. There may be 1 to 10 seeds, though, ordinarily, only 3 to 5, dark-brown or light-brown, angular -ellipsoid, about 5/8 in (1.5 cm) long and 5/16 in (8 mm) thick.

Plate XI: LOQUAT, *Eriobotrya japonica*

Origin and Distribution

The loquat is indigenous to southeastern China and possibly southern Japan, though it may have been introduced into Japan in very early times. It is said to have been cultivated in Japan for over 1, 000 years. The western world first learned of it from the botanist Kaempfer in 1690. Thunberg, who saw it in Japan in 1712, provided a more elaborate description. It was planted in the National Gardens, Paris, in 1784 and plants were taken from Canton, China, to the Royal Botanical Gardens at Kew, England, in 1787. Soon, the tree was grown on the Riviera and in Malta and French North Africa (Algeria) and the Near East and fruits were appearing on local markets. In 1818, excellent fruits were being produced in hothouses in England. The tree can be grown outdoors in the warmest locations of southern England.

Cultivation spread to India and southeast Asia, the medium altitudes of the East Indies, and Australia, New Zealand and South Africa. Chinese immigrants are assumed to have carried the loquat to Hawaii.

In the New World, it is cultivated from northern South America, Central America and Mexico to California: also, since 1867, in southern Florida and northward to the Carolinas, though it does not fruit north of Jacksonville. It was quite common as a small-fruited ornamental in California gardens in the late 1870's. The horticulturist, C.P. Taft, began seedling selection and distributed several superior types before the turn of the century, but further development was slow. Dwarfing on quince root-stocks has encouraged expansion of loquat cultivation in Israel since 1960. In the northern United States and Europe, the tree is grown in greenhouses as an ornamental, especially var. *variegata* with white and pale-green splashes on the leaves.

In India and many other areas, the tree has become naturalized, as it volunteers readily from seed.

Japan is the leading producer of loquats, the annual crop amounting to 17,000 tons. Brazil has 150,000 loquat trees in the State of Sao Paulo.

Varieties

The loquat has been the subject of much horticultural improvement, increasing the size and quality of the fruit. There are said to be over 800 varieties in the Orient. T. Ikeda catalogued 46 as more or less important in Japan; over 15 have originated in Algeria through the work of L. Trabut; C.P. Taft selected and introduced at least 8 into cultivation in California; 5 or 6 have been selected in Italy; only 1 in Florida. A number of widely planted, named cultivars have been classed as either "Chinese" or "Japanese". In the Chinese group, the trees have slender leaves, the fruit is pear-shaped or nearly round with thick, orange skin and dark-orange flesh, not very juicy, subacid, but of distinct flavor. The seeds are small and numerous. The harvesting period is midseason to late and the fruits are of good keeping quality.

In the Japanese group, the tree has broad leaves, the fruit is pear-shaped or long-oval, the skin is usually pale-yellow, the flesh whitish, very juicy, acid but otherwise not very distinct in flavor. The seeds are large and there may be just a few or only one. The harvesting period is early to midseason. Keeping quality is fair to poor.

In Egypt, most loquats are of Lebanese origin. Egyptian horticulturists have selected from seedlings of 'Premier' 2 superior clones, 'Golden Ziad' and 'Maamora Golden Yellow' and have vegetatively propagated them on quince rootstocks for commercial distribution.

Some of the oldtime selections, 'Advance', 'Champagne', 'Premier', 'Success' and 'Tanaka' are no longer popular in California but are performing well in other areas. In Florida, 'Oliver' has always been the most common cultivar, though a number of others–'Advance', 'Champagne', 'Early Red', 'Pineapple', 'Premier', 'Tanaka' and 'Thales' have been more or less successful.

In the State of Sao Paulo, Brazil, 2 cultivars are raised on a commercial scale–'Precoce de Itaquera' and 'Mizuho'. In the southernmost state of the U.S.S.R., Georgia, several loquat cultivars are grown, including 'Champagne', 'Comune', 'Grossa de Sicilia', 'Premier', 'Tanaka', and 'Thales'.

The following are the cultivars most commonly described:

'Advance' (Japanese group)–A seedling selected by C. P. Taft in California in 1897. Fruit is borne in large clusters; pear-shaped to elliptic-round; of medium to large size; skin downy, yellow, thick and tough; flesh thick, cream-colored, juicy, subacid, of excellent flavor. Seeds of medium size, may be as many as 4 or 5; average is 3.20 per fruit. A late cultivar though it ripens earlier than 'Champagne' which it other-wise closely resembles. Tree is a natural dwarf, to a little over 5 ft (1.58 m); is highly resistant to pear blight. Self-infertile; a good pollinator for other cultivars. It is interplanted with 'Golden Yellow' and 'Pale Yellow' in India.

'Ahdar' (Lebanese; grown in India)–oval, of medium size; greenish-yellow with white flesh; bears moderately; late-ripening; of poor keeping quality.

'Ahmar' (Lebanese; grown in India)–pear-shaped, large, with reddish-orange skin; yellow flesh, firm, juicy; early ripening; of good keeping quality. A leading cultivar in Lebanon. Very precocious. Self-infertile.

'Akko 1' or 'Acco 1' (of Japanese origin)–long-oval to pear-shaped, 20 to 25 g in weight; skin orange with a little russeting, thick; flesh yellow, juicy, of average flavor, and there are 3 or 4 seeds. Ripens in midseason, beginning in mid-April in Israel where it constitutes 10 to 20% of commercial plantings. Precocious and a good bearer; sets 20 to 30 fruits per cluster and requires drastic thinning, leaving about 6 fruits. Fruit is subject to sunburn. Stands harvesting and shipping well, keeps in good condition less than 2 weeks under refrigeration. This cultivar is self-fertile.

'Akko 13' or 'Acco 13' (of Japanese origin)–pear-shaped, 20 to 25 g in weight; dark-orange, with no russeting; flesh yellow, juicy, with acid, agreeable flavor; 2 or 3 seeds. Bears from end of March through April in Israel, regularly and abundantly; constitutes 50 to 70% of commercial plantings in Israel; of good handling and keeping quality; stands transportation for 2 weeks at 32ºF (O.OºC). Fruit is subject to sunburn. Needs cross-pollination.

'Asfar' (Lebanese, grown in India)–oval, smaller than 'Ahmar', with yellow skin and flesh, very juicy, of superior flavor, but very perishable.

'Blush' ('Red Blush') -Resembles 'Advance' but is very large. Was selected by C.P. Taft as being immune to blight, but was abandoned after 'Advance' proved to be highly blight-resistant.

'Champagne' (Japanese), often misidentified as 'Early Red'. Selected and introduced into cultivation in California by C. P. Taft around 1908. Elongated pear-shaped, often oblique; small to large (depending on where it is grown); skin pale-golden to deep-yellow, thick, tough, astringent; flesh white or yellow, soft, juicy, mild and subacid to sweet; of excellent flavor. There are 3 to 5 seeds. Midseason to late. Prolific; fruits borne in large clusters. Perishable; good for preserving. Tree has long, narrow, pointed leaves; is self -infertile.

'Early Red' (Japanese); originated by Taft in 1909. Obliquely pear-shaped; medium-large; skin orange-red with white dots, thick, tough, acid; flesh orange, very juicy, sweet, of fair to excellent flavor; has 2 or 3 seeds. Earliest in season, often appearing on California markets at the end of January or in the beginning of February. Borne in compact clusters.

'Eulalia' (a seedling of 'Advance' selected by M. Payan in California in 1905)–pear-shaped to obovate -pear-shaped; skin faintly downy, orange-yellow with red blush and pale gray dots, thick, tough; flesh pinkish or orange, melting, soft, very juicy; subacid in flavor. Seeds medium in size, numerous. Early in season.

'Fire Ball' (popular in India)–ovate to ovate-elliptic; small, with yellow, thick skin; flesh white to straw-colored, thick, crisp, smooth, of mild, subacid flavor. Seeds are large: average 2.90 per fruit. Midseason. Tree is a natural dwarf to 9.5 ft (2.84 in).

'Glenorie Superb' (grown in Western Australia)–round, large, dark-orange with yellow flesh which is juicy and sweet. Somewhat late in season. Inclined to bruise during harvesting.

'Golden Red' (grown in California)–flesh pale-orange, medium-thick, smooth, melting, of subacid, agreeable taste; few seeded. Midseason.

'Golden Yellow' (grown in India)–ovate-elliptic; of medium size; skin orange-yellow; flesh pale-orange, medium-thick, soft, smooth, with subacid, mild flavor. Seeds of medium size; average 4.83 per fruit.

'Golden Ziad' (#2-6) (grown in Egypt)–dark-yellow to light-orange; up to 1 1/2 in (3.96 cm) long; average number of seeds, 2.93-3.83 per fruit. Early. High-Yielding; 50 lbs (23.5 kg) per tree.

'Herd's Mammoth' (grown in Western Australia)–long and slightly tapering at the stem end; large; yellow to orange with white to cream-colored flesh. Ripens earlier than 'Victory'. Subject to black spot; not often planted.

'Improved Golden Yellow' (grown in India)–ovate-elliptic; skin orange-yellow; flesh orange-yellow, thick, crisp, smooth, with subacid to sweet, mild flavor. Seeds large; average 3.06 per fruit. Tree to 15 ft (4.49 in). Early.

'Improved Pale Yellow' (grown in India)–flesh pale-orange or cream-colored, firm or soft, smooth, of subacid, pleasant flavor, with medium number of seeds. Midseason.

'Kusunoki' (grown in Japan)–small; early.

'Large Agra' (grown in India)–ovate-round; of medium size; skin deep-yellow; flesh yellow or pale-orange, medium thick, smooth, firm, of pleasant flavor, fairly sweet. Seeds small; average 5.10 per fruit. Midseason. Tree a medium-dwarf–to 9 1/2 ft (2.83 in).

'Large Round' (grown in India)–ovate-round; of medium size; yellow of skin with cream-colored flesh, firm, coarse, subacid to sweet, mild. Seeds of medium size; average 4.80 per fruit. Midseason. Tree fairly tall–13 ft. (3.92 in).

'Maamora Golden Yellow' (#7-9) (grown in Egypt)–dark-yellow to light-orange; to 1 1/2 in (3.91 cm long); seeds average 2.40 to 4.03 per fruit; late in season. High-yielding–44 lbs (20 kg) per tree.

'Mammoth' (grown in Australia; mentioned in California in 1889)–flesh orange, medium thick, granular, coarse, of subacid, agreeable flavor. Midseason.

'Matchless' (grown in India) pear shaped; flesh medium-thick, pale-orange, smooth, soft, of mild, subacid flavor; medium number of seeds. Midseason.

'Mizuho' (grown in Japan)–rounded-oval; extra large (70-120 g); juicy, with agreeable, slightly acid though also sweet flavor, and with 5 or more seeds. Subject to fruit spots and sunburn.

'Mogi' (grown in Japan)–elliptical, light-yellow; small (40-50 g); Ripens in early spring. Tree is cold sensitive. Self-fertile. Constitutes 60% of the Japanese crop of loquats.

'Obusa' (a hybrid of 'Tanaka' and 'Kusonoki', developed and grown in Japan)–deep yellow, very large (80-100 g); of medium flavor; good keeping and shipping quality. Ripens earlier than Tanaka. Tree bears regularly and is resistant to insects and diseases, but fruit is subject to sunburn (purple stains on skin).

'Oliver' ('Olivier' X 'Tanaka'). In the past was considered the best loquat for southern Florida.

'Pale Yellow' (grown in India)–oblique -elliptic to round; light yellow, large; flesh white or cream-colored, thin, smooth, melting, of subacid to sweet flavor; seeds large; average 4.8 per fruit. Early. Tree is fairly tall–to 13 ft (4 in).

'Pineapple' (developed and introduced into cultivation in California by Taft in 1899)–round or sometimes pear-shaped; light-yellow with white flesh. Of good quality but inferior to 'Champagne'. Abandoned in California because of the weakness of the tree.

'Precoce de Itaquera' (erroneously called 'Tanaka'; grown in Brazil; believed to be a local selection of 'Mogi')–oval-pear-shaped; deep-orange; very small (25.3-29.1 g). Flesh is firm and acid-sweet. Very productive: 1,500 to 2,000 fruits per tree annually. Subject to sunburn (purple stains on skin) but less so than 'Mizuho'. Was for a long time the leading cultivar in the State of Sao Paulo but has lost ground to 'Mizuho' even though a pear-shaped fruit is preferred by consumers, because it does not keep or ship as well as the 'Mizuho', which now makes up 65% of the plantings and 'Precoce de Itaquera' 35%.

'Premier' (originated by Taft in California in 1899)–oval to oblong-pear-shaped; large; skin downy, orange-yellow to salmon-orange with large white dots; medium-thick, tough; flesh whitish, melting, juicy, subacid, of agreeable flavor; seeds average 4 or 5 per fruit. Late. Good for dooryards. Does not ship well, nor keep well.

'Safeda' (grown in India)–flesh is cream-colored, thick, smooth and melting, of subacid, excellent flavor; contains medium number of seeds. Early to midseason.

'Saint Michel' (unclassified; grown in Israel)–round but has the thin skin and white flesh of the Japanese group. Ripens late. Self-infertile.

'Swell's Enormity' (grown in Western Australia)–pear-shaped, very large; deep apricot-colored externally with flesh of the same color. Acid if harvested too early. Very late in season. Subject to sunburn in hot weather.

'Tanaka' (Chinese group; a seedling originated in Japan; young trees introduced by the United States Department of Agriculture in 1902; widely grown)–ovoid or round; large (70-80 g) in Japan; in some other areas small (30 g); skin orange or orange-yellow; flesh brownish-orange, medium thick, coarse, firm, juicy, sweet or subacid, of excellent taste. There may be 2 to 4 seeds; average 2.70 per fruit. Ripens late–beginning the first of May, which is too late for California because of susceptibility to sunburn. The tree is of medium size-nearly 10 ft (2.98 m); precocious; bears regularly; is self-fertile to a degree. Constitutes 10% of commercial crop in Israel; 35% of the crop in Japan. Highly cold-tolerant.

'Thales', also known as 'Gold Nugget' and 'Placentia', (Chinese group; very similar to 'Tanaka' and possibly a clone. Introduced from Japan and planted at Placentia, California, between 1880 and 1900)–oblong-obovate to round, large, skin orange-yellow with numerous white dots, tough; flesh, orange, thick, firm, juicy, of sweet, apricot-like flavor. There are 2 to 4 seeds. Late in season. Fruits borne only a few to a cluster; keep and ship well. Self-fertile.

'Thames Pride' (grown in India)–ovate-elliptic, of medium size or sometimes large; pale-orange or deep-yellow with cream colored or pale-orange, juicy, coarse, somewhat granular flesh of subacid flavor; moderately seedy; average 3.20 seeds per fruit. Early in season. Tree tall, to 13 1/2 ft (4.19 m). Bears heavily. This cultivar is grown and canned commercially.

'Tsrifin 8' (grown in Israel)–rounded pear-shaped; 25 to 30 g in weight; yellow-orange with some russeting. Of excellent quality with good acid and sugar content. Stands handling. shipping and storage well. Late–mid-April to mid-May. Precocious, bears regularly and abundantly but is subject to sunburn. Constitutes 10% of Israeli plantings.

'Victor' (originated by C.P. Taft in 1899)–oblong-pear-shaped; large; skin deep-yellow, medium-thick, tough. Flesh whitish, translucent, melting, very juicy, of sweet, mild flavor. There may be 3 to 5 seeds. Very late; too late for California. Good for canning.

'Victory' (the most popular cultivar in West Australia)–oval, large, yellow to orange, becoming amber on the sunny side. Flesh is white to cream-colored, juicy, sweet. Midseason to occasionally early.

'Wolfe', (S.E.S. #4) (a seedling of 'Advance' selected and named at the Agricultural Research and Education Center of the University of Florida in Homestead, and released in 1966)–obovoid to slightly pear-shaped; 1 3/4 to 2 in (4.5-5 cm) long and 1 to 1 1/4 in (2.5-3.2 cm) wide; yellow with fairly thick skin and pale-yellow, thick, firm, juicy flesh of excellent flavor, acid but also sweet when tree-ripe; has 1 to 5 seeds (usually 1 to 3). Tree reaches 25 ft (7.5 in) and bears well nearly every year,

Pollination

The loquat is normally pollinated by bees. Some cultivars such as 'Golden Yellow' are not self-fertile. 'Pale Yellow', 'Advance', and 'Tanaka' are partially self-fertile. In India, it has been observed that cross-pollination generally results in 10-17 % increased production over self-pollination. 'Tanaka' pollinated by 'Pale Yellow' has a lower yield than when self-pollinated, indicating a degree of cross-incompatibility. Whereas, when pollinated by 'Advance', the normal yield of 'Tanaka' is nearly doubled.

When cross-pollinating for the purpose of hybridizing, only flowers of the second flush should be used, as early and late flushes have abnormal stamens, very little viable pollen, and result in poor setting and undersized fruits.

Climate

The loquat is adapted to a subtropical to mild-temperate climate. In China it grows naturally at altitudes between 3,000 and 7,000 ft (914-2,100 m). In India, it grows at all levels up to 5, 000 ft (1,500 m). In Guatemala, the tree thrives and fruits well at elevations between 3,000 and 6,900 ft (900-1,200 m), but bears little or not at all at lower levels.

Well-established trees can tolerate a drop in temperature to 12º F (-11.11º C). In Japan, the killing temperature for the flower bud is 19.4º F (7º C); for the mature flower, 26.6º F (-3º C). At 25º F (-3.89º C), the seed is killed, causing the fruit to fall.

Loquats are grown on hillsides in Japan to have the benefit of good air flow. Extreme summer heat is detrimental to the crop, and dry, hot winds cause leaf scorch. Where the climate is too cool or excessively warm and moist, the tree is grown as an ornamental but will not bear fruit.

Soil

The tree grows well on a variety of soils of moderate fertility, from light sandy loam to heavy clay and even oolitic limestone, but needs good drainage.

Propagation

Generally, seeds are used for propagation only when the tree is grown for ornamental purposes or for use as rootstock. Loquat seedlings are preferred over apple, pear, quince or pyracantha rootstocks under most conditions. Quince and pyracantha may cause extreme dwarfing-to less than 8 ft (2.5 in). Quince rootstock tolerates heavier and wetter soils than loquat but is apt to put out numerous suckers. Loquat seeds remain viable for 6 months if stored in partly sealed glass jars under high humidity at room temperature, but the best temperature for storage is 40º F (5º C). They are washed and planted in flats or pots soon after removal from the fruit and the seedlings are transplanted when 6 to 7 in (15-17.5 cm) high to nursery rows. When the stem is 1/2 in (1.25 cm) thick at the base, the seedlings are ready to be top-worked. In India, inarching is commonly practiced but budding and grafting are more popular in most other areas. Shield-budding, using 3-month-old scions, is successful. Cleft-grafting has been a common practice in Florida. Veneer-grafting in April has proved to be a superior method in Pakistan. Cuttings are not easy to root. Air-layering may be only 20% successful, though 80 to 100% of the layers root in 6 weeks if treated with 3% NAA (2-naphthoxyacetic acid).

Trees that are vegetatively propagated will begin to bear fruit in 5 years or less, as compared to 8 to 10 years in seedling trees. Old seedling trees can be converted by cutting back severely and inserting budwood of a preferred cultivar.

Culture

The rainy season is best for planting loquats. When planted on rich soil, normal size trees should be set 25 to 30 ft (7.5-9 m) apart, allowing about 83 trees per acre (200 per ha). In Brazil, a spacing of 23 x 23 ft (7x7 m) is recommended on flat land, 26 x 20 ft (8x6 m) or 26 x 16.5 ft (8x5 m) on slopes. Dwarf trees are spaced at 13 x 6.5 ft (4x2 m) in Japan and this may allow 208 per acre (500 per ha). The tree is a heavy feeder. For good fruit production the trees require ample fertilization and irrigation. In the tropics, animal manure is often used. A good formula for applications of chemical fertilizer is: 1 lb (.45 kg) 6-6-6 NPK three times a year during the period of active growth for each tree 8 to 10 ft in height. The trees should be watered at the swelling of blossoms and 2 to 3 waterings should be given during harvest-time. Thinning of flowers and young fruits in the cluster, or the clipping off of the tip of the cluster, or of entire clusters of flowers and fruits, is sometimes done to enhance fruit size. This is carefully done by hand in Japan. With the 'Tanaka' cultivar, the Japanese leave only one fruit per cluster; with the 'Mogi', two. In Taiwan, thinning is done by spraying with NAA when the flowers are fully open.

In Taiwan, because of the hazard of strong typhoons, the loquat is grown as a mini-dwarf no more than 3 ft (0.9 m) high and wide, and branch tips may be tied to the ground because branches kept at a 451 angle flower heavily. Spraying with gibberellic acid (60 ppm) at full bloom enhances fruit set and increases fruit size and weight, total reducing sugars and ascorbic acid content, reduces fruit drop, number of seeds, and acidity. Spraying the same at 300 ppm results in small, seedless fruits. There should be judicious pruning after harvest, otherwise terminal shoots become too numerous and cause a decline in vigor which may result in biennial bearing. In Brazil, the clusters are bagged to eliminate sunburn (purple staining of the skin) to which both of the leading cultivars are susceptible.

Because of the shallow root system of the loquat, great care must be taken in mechanical cultivation not to damage the roots. The growing of dwarf trees greatly reduces the labor of flower-and fruit-thinning, bagging, and, later, harvesting and pruning.

Season

Generally, the loquat tree blooms in the fall and fruits in early spring. However, in tropical climates, the tree may flower 2 or 3 times a year beginning in July and set fruit mainly from the second flowering. In Florida, ripening begins in February; in California, usually in April; in Israel, the crop ripens from March to May. In Brazil, the harvesting extends from May to October.

Harvesting

Loquats reach maturity in 90 days from full flower opening. Determination of ripeness is not easy, but it is important because unripe fruits are excessively acid. Full development of color for each cultivar is the best guide.

The fruits are difficult to harvest because of the thick, tough stalk on each fruit which does not separate readily from the cluster, and the fruits must be picked with stalk attached to avoid tearing the skin. Clusters are cut from the branch with a sharp knife or with clippers. Whole clusters are not particularly attractive on the market, therefore the individual fruits are clipped from the cluster, the stalk is detached from each fruit and the fruits are graded for size and color to provide uniform packs. Great care is taken to avoid blemishes.

Major Japanese growers have monorail systems for conveying the picked fruits and equipment from their hillside plantations.

Yield

Dwarf loquats in Israel have produced 7 tons/ha at 3 years of age, 25 tons/ha at 7 years. Normal size trees in Brazil are expected to bear 110 lbs (50 kg) per tree, 4.17 tons per acre (10 tons/ha) when planted at a rate of 83 trees per acre (200 trees/ha). The 'Wolfe' cultivar in southern Florida has borne 100 lbs (45 kg) per tree at 5 years of age; 300 lbs (136 kg) when 15 to 20 years old.

Keeping Quality

Loquats generally will keep for 10 days at ordinary temperatures, and for 60 days in cool storage. After removal from storage, the shelf-life may be only 3 days. Treatment with the fungicide, benomyl, makes it possible to maintain loquats for one month at 60º F (15.56º C) with a minimum of decay. Other fungicides tried have proved much less effective. Cold storage of loquats in polyethylene bags alters the flavor of the fruit, promotes internal browning and the development of fungi.

Pests and Diseases

In Japan, scale insects, aphids, fruit flies and birds damage the fruits and may necessitate covering the clusters with cloth or paper bags. Laborers can attach 1,000 to 1,500 bags per day. An acre may require 62,500 bags (150,000/ha). A pole with a hook at the tip is employed to bring each branch within reach. The process is labor intensive. In Israel, wire netting is placed over trees to protect the crop from birds.

The Caribbean fruit fly *(Anastrepha suspensa)* has ruined the dooryard loquat crop for the past several years in Florida. The fruit flies, *A. striata* and *A. serpentina,* require control in Venezuela, the Mediterranean fruit fly, *Ceratitis capitata,* in Tunisia. Another fruit fly, *Dacus dorsalis, is* the major pest in India, forces the harvesting of mature fruits while they are still too hard to be penetrated, and the complete removal of all immature fruits at the same time so that they will not remain as hosts. The soil around the base of the tree must be plowed up and treated to kill the pupae. The second most important predator is the bark-eating caterpillar*, Indarbela quadrinotata.*

Minor pests include leaf-eating chafer beetles, *A doretus duvauceli, A. lasiopygus, A. horticola* and *A. versutus;* gray weevils, *Myllocerus lactivirens* and *M. discolor* which attack the margins of the leaves. The scale insects, *Coccus viridis, Eulecanium coryli, Parlatoria oleae, P. pseudopyri, Pulvinaria Psidii* and *Saissetia hemisphaerica* suck the sap from loquat leaves and branches. Carpenter bees, *Megochile anthracina,* cut holes in the leaves and take the tissue to line their mud nests. Aphids *(Aphis malvae)* suck sap from twigs and shoots and sooty mold develops on the honeydew which they excrete. Flowers are attacked by thrips *(Heliothrips sp.).* The caterpillars of the anar butterfly, *Virachola isocrates,* bore into the fruits and lay eggs on the fruits, flowers and leaves. In New Zealand, a leaf-roller caterpillar eats into the buds and flowers. In California, the main pests of loquat are the codlin moth *(Cydia pomonella),* the green apple aphis *(Aphis pomi)* and scales.

The roots of loquat trees in India are preyed on by nematodes–C*riconemoides xenophax, Helicotylenchus spp., Hemicriconemoides communis, Haplolaimus spp.* and *Xiphinema insigne.*

Diseases

Pear blight *(Bacillus amylovorus)* is the major enemy of the loquat in California and has killed many trees. *Phytophthora* is responsible for crown rot and *Pseudomonas eriobotryae* causes cankers in California. Scab may occur on the bark of the trunk and larger branches. A serious disease is collar rot and root rot caused by *Diplodia natalensis. D. eriobotrya* sometimes affects the leaves. The parasitic fungus, *Monochaetia indica,* induces leaf spot in India. Leaf spot is also caused by the soil-inhabiting fungus *Schlerotium rolfsii. Spilocaeae eriobotryae* causes black spot on fruits and leaves in Italy and South Western Australia. Fleck, caused by the fungus *Fabraea maculata is* recognized by red-brown spots with whitish centers on leaves, shoots and fruit. In Florida, leaf spot may result from infection by *Pestalotia sp.* The foliage of young plants in Brazilian nurseries is damaged by the fungus *Entomosporium maculatum.* Other fungus problems of the loquat include stem-brown disease caused by *Batryosphaeria dothidee;* die-back from *Macrophoma* sp., withertip from *Collectotrichum gloeosporioides,* and twig blight and canker from *Cytospora chrysospernw.* Post-harvest fruit rot is the result of infection by *Diplodia natalensis, Pestalotia sp.* or *Aspergillus niger.*

Sunburn, "purple spot", is responsible for much fruit loss in hot regions with long summers. Chemical sprays have been employed to hasten fruit maturity to avoid sunburn. Various types of bags have been tried in Brazil to protect the fruit from this blemish. The best are 2- and 3-ply newspaper bags.

Food Uses

The skin of the loquat is easily removed. Peeled and seeded fruits are eaten fresh, sometimes combined with sliced banana, orange sections and grated coconut. They are delicious simply stewed with a little sugar added. The fruits are also used in gelatin desserts or as pie-filling, or are chopped and cooked as a sauce. Loquats canned in sirup are exported from Taiwan. Some people prepare spiced loquats (with cloves, cinnamon, lemon and vinegar) in glass jars. The fruit is also made into jam and, when slightly underripe, has enough pectin to make jelly. The jelly was formerly manufactured commercially in California on a small scale.

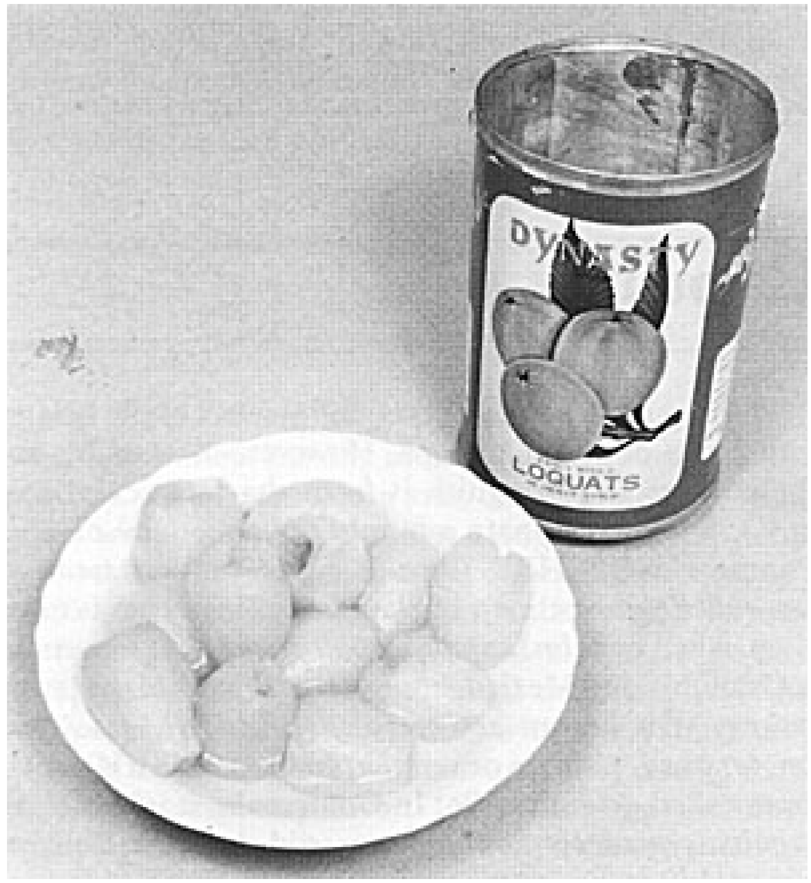

Fig. 29: Peeled, seeded loquats *(Eriobotrya japonica)* canned in sirup in Taiwan.

Food Value Per 100 g of Edible Portion*	
Calories	168
Protein	1.4 g
Fat	0.7 g
Carbohydrates	43.3 g
Calcium	70 mg
Phosphorus	126 mg
Iron	1.4 mg

Vitamin A	2,340 I.U.
Ascorbic Acid	3 mg

*Analyses reported by the Agricultural Research Service of the United States Department of Agriculture.

The fruit contains laevulose, sucrose and malic acid and lesser amounts of citric, tartaric and succinic acid. The pulp contains the carotenoids *B*-carotene (33%); *y*-carotene (6%); cryptoxanthin (22%), lutein, violaxanthin, neoxanthin (3-4% each). The peel is 5 times richer than the pulp in carotenoids which are similar to those in apricots.

Toxicity

A 5-year-old girl in Florida ate 4 unripe loquats, fell asleep and was difficult to awaken and seemed dazed. After about 2 hours, she was back to normal. There have been instances of poisoning in poultry from ingestion of loquat seeds. The seeds contain amygdalin (which is converted into HCN); also the lipids, sterol, β-sitosterol, triglyceride, sterolester, diglyceride and compound lipids; and fatty acids, mainly linoleic, palmitic, linolenic and oleic. There is amygdalin also in the fruit peel. The leaves possess a mixture of triterpenes, also tannin, vitamin B and ascorbic acid; in addition, there are traces of arsenic. Young leaves contain saponin. Some individuals suffer headache when too close to a loquat tree in bloom, The emanation from the flowers is sweet and penetrating.

Other Uses

Wood: The wood is pink, hard, close-grained, medium-heavy. It has been used instead of pear wood in making rulers and other drawing instruments.

Animal feed: The young branches have been lopped for fodder.

Perfume: In the 1950's, the flowers attracted the interest of the perfume industry in France and Spain and some experimental work was done in extraction of the essential oil from the flowers or leaves. The product was appealing but the yield was very small.

Medicinal Uses: The fruit is said to act as a sedative and is eaten to halt vomiting and thirst.

The flowers are regarded as having expectorant properties. An infusion of the leaves, or the dried, powdered leaves, may be taken to relieve diarrhea and depression and to counteract intoxication from consumption of alcoholic beverages. Leaf poultices are applied on swellings.

Morton, J. 1987. Capulin. p. 108–109. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Capulin

Prunus salicifolia

The capulin is a true cherry and doesn't really belong with fruits of warm regions. However, it must be included here to distinguish it from the Jamaica cherry (q.v.), for the two share a number of colloquial names. *Prunus salicifolia* HBK. (syns. P. *capuli* Cav.; P. *serotina* var. *salicifolia* Koehne), of the family Rosaceae, is most often called *capulin, capuli, capoli* or *capolin*, especially in Colombia and Mexico, but in certain parts of the latter country it is known as *cerezo, detsé, detzé, taunday, jonote, puan, palman or xengua.* In Colombia it is sometimes called *cerezo criollo.* In Guatemala, it is known as *capulin, cereza, cereza común*, or wild cherry; in Bolivia, it *is capuli;* in Eucador, *capuli* or black cherry.

Description

The tree is erect, reaching 40 to 50 ft (12-15 m) in height, with a short, stout trunk to 3 ft (0.9 m) in diameter. The deciduous, alternate, aromatic leaves are lanceolate to ovate-lanceolate, 2 3/8 to 7 in (6-18 cm) long, dark-green and glossy above, pale beneath; thin, finely toothed. New leaves are often rosy. Flowers, borne in slender, pendent racemes with 1 or more leaves at the base, are about 3/4 in (2 cm) wide with white petals and a conspicuous tuft of yellow stamens. The aromatic fruit is round, 3/8 to 3/4 in (1-2 cm) wide, with red or nearly black, rarely white or yellowish, smooth, thin, tender skin and pale-green, juicy pulp of sweet or acid, agreeable, but slightly astringent flavor. There is a single stone with a bitter kernel.

Origin and Distribution

The capulin is native and common throughout the Valley of Mexico from Sonora to Chiapas and Veracruz, and possibly also indigenous to western Guatemala. It has been cultivated since early times in these areas and other parts of Central America and in Colombia, Ecuador, Peru and

Bolivia, and is extensively and abundantly naturalized. The fruit is an important food, not only of the Indians, but of all the inhabitants, and it was at times a mainstay of the invading Spaniards. Great quantities appear in the native markets, especially of El Salvador, Guatemala and Ecuador. In Guatemala, seedlings of the capulin are utilized as rootstock on which commercial cultivars of the northern cherry are grafted. The capulin is little-known in eastern South America and elsewhere in the world. It was introduced into the cool medium elevations of the Philippines in 1924.

Climate

The tree requires a subtropical to subtemperate climate. It grows naturally at elevations between 4,000 and 11,000 ft (1,200-3,400 m).

Season

In Mexico, the tree blooms from January to March and the fruits ripen in July and August. In Guatemala, flowers appear from January to May and fruits from May to September. The fruiting season in El Salvador extends from December through April.

Food Uses

The ripe fruits are eaten raw or stewed; also are preserved whole or made into jam. In Mexico they are used as filling for special tamales. With skin and seeds removed, they are mixed with milk and served with vanilla and cinnamon as dessert. Sometimes the fruits are fermented to make an alcoholic beverage.

Food Value Per 100 g of Edible Portion*	
Moisture	76.8-80.8 g
Protein	0.105-0.185 g
Fat	0.26-0.37 g
Fiber	0.1-0.7 g
Ash	0.56-0.82 g
Calcium	17.2-25.1 mg
Phosphorus	16.9-24.4 mg
Iron	0.65-0.84 mg
Carotene	0.005-0.162 mg
Thiamine	0.016-0.031 mg
Riboflavin	0.018-0.028 mg
Niacin	0.640-1.14 mg
Ascorbic Acid	22.2 32.8 mg

*According to analyses made in Guatemala and Ecuador.

Other Uses

Seeds: The seeds contain 30-38% of a yellow, semidrying oil suitable for use in soap and paints.

Flowers: The flowers are much visited by honeybees.

Wood: The sapwood is yellow with touches of red. The heartwood is reddish-brown, fine-grained, very hard, strong, durable. It is used for furniture, interior paneling, cabinets, turnery and general carpentry. Old roots are valued for carving tobacco pipes, figurines, et cetera.

Medicinal Uses: A sirup made of the fruits is taken to alleviate respiratory troubles. The leaf decoction is given as a febrifuge and to halt diarrhea and dysentery; also applied in poultices to relieve inflammation. A leaf infusion is prescribed in Yucatan as a sedative in colic and neuralgia and as an antispasmodic. The pounded bark is employed in an eyewash.

The leaves contain essential oil, fat, resin, tannin, amygdalin, glucose, a brown pigment and mineral salts. The bark contains starch, brown pigment, amygdalin, gallic acid, fat, calcium, potassium and iron. All of these parts must be utilized cautiously because the bark, leaves or seeds in contact with water can release HCN.

Morton, J. 1987. Mysore Raspberry. p. 109–110. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Mysore Raspberry

Rubus neveus

Many species of *Rubus* (family Rosaceae), especially from the warm regions of the world, have been tried in southern Florida. Only one has been truly successful here, the Mysore raspberry, *R. niveus* Thunb., (syns. *R. lasiocarpus* Hook. f. in part; *R. albescens* Roxb.; *R. mysorensis* Heyne), also called Ceylon, hill or Mahabaleshwar, raspberry in India and *pilai* in the Philippines.

Description

The plant is a large scrambling shrub growing 10 to 15 ft (3-4.5 m) high, with cylindrical, flexible stems downy when young, later purple, coated with a white bloom. It is thoroughly set with sharp, hooked thorns. The leaves, 4 to 8 in (10-20 cm) long, are composed of 5 to 9 elliptic-ovate leaflets 1 to 2 1/2 in (2.5-6.25 cm) long, coarsely toothed, dark-green above and, on the underside, white-hairy with small, sharp spines along the rachis, petiole and midrib. Pink or red-purple, 5-petalled flowers, 1/2 in (1.25 cm) across, occur in lax axillary and terminal clusters. The fruit is rounded-conical, flat at the base; compound, made up of individual drupelets; red when unripe, purple-black when ripe, with a very fine bloom; 1/2 to 3/4 in (1.25-2 cm) in diameter, juicy and of sweet, rich black-raspberry flavor. The clusters may contain as many as 2 dozen or even more. The seeds are small and not objectionable.

Origin and Distribution

Plate XII: MYSORE RASPBERRY, *Rubus niveus*

The species is native to Burma and India, particularly the lower Himalayas, from Punjab to Assam, the Deccan peninsula, and the Western Ghats; and is common in the evergreen forests of Mahabaleshwar. The more hairy var. *horsfieldii* Focke extends south through Malaya to Indonesia and Bontoc and Benguet in the Philippines. From India, the Mysore raspberry was introduced into Kenya, East Africa, and has been grown in the mountains there for many years. Seeds from Kenya were obtained by F. B. Harrington of Natal, South Africa, in 1947. In 1948, he supplied seeds to the University of Florida's Agricultural Research and Education Center, Homestead. The resulting seedlings were planted out in 1949 and fruited so well the following winter that plants were distributed to many experimenters throughout south and central Florida. By 1952, many nurseries were offering the plants for sale and had difficulty filling the demand. By 1955, a major supermarket in Lake Worth was selling the fruits by the pint. In 1955, the University of Puerto Rico received planting material from Florida and established plantings in the central-western mountains of that island.

In Florida, some interest was still alive in 1965, but early enthusiasm waned as homeowners neglected their raspberry bushes, growth became too rampant, picking more and more difficult among the tangle of thorny canes, and birds competed eagerly for the crop. Many plantings were destroyed, and few remain.

Climate

This raspberry has a remarkable climatic range in Asia, from the relatively warm altitude of 1,500 ft (450 m) to the temperate environment at 10,000 ft (3,000 m). In Florida, brief drops in temperature to 35º F (1.67º C) have done the plants no harm but 20º F (-1.67º C) has killed young, tender growth, and prolonged freezing weather has killed the plants to the ground or outright.

Soil

In Florida, the plant flourishes on limestone or acid sand. In Puerto Rico it is grown on lateritic Alonso clay with a pH of 5.0. Good drainage is essential.

Propagation

The Mysore raspberry is often grown from seed but germination is slow and irregular (from 3 weeks to several months), and the seedlings are subject to damping-off. Germination can be expedited by pre-treatment with concentrated sulphuric acid. Stem cuttings root well, but the preferred method of propagation is by tip-layering. They develop plentiful roots in 3 to 4 weeks.

Culture

Florida gardeners place the plants 2 1/2 to 4 ft (0.75-1.2 m)apart in rows 6 to 8 ft (1.8-2.4 m) apart supported by 2 or 3 strands of wire attached to end-posts. In Puerto Rico, the plants are set out in hills spaced 6 to 8 ft (1.8-2.4 m) apart each way. If taller than 18 in (45 cm), they are cut back, surrounded by 2 or 3 stakes 6 ft (1.8 m) high linked by crosswires. As the canes grow, they are loosely tied to the stakes and wires. A mulch is desirable to retain Moisture and control weeds.

During the first year, in Puerto Rico, the plants are given 1 to 2 oz (28-56 g) each of ammonium sulfate quarterly. Thereafter, a 9-10-5 fertilizer formula is applied quarterly, 4 to 6 oz (113-170 g) per plant.

On Florida limestone, the recommended fertilizer consisting of 4-8-4 or 4-7-5 NPK with 3 to 4% magnesium and 30 to 40% organic nitrogen is applied every 2 to 3 weeks. And it is considered highly desirable that a mixture of zinc, copper and manganese be sprayed on the underside of the leaves 3 to 4 times per year.

Irrigation is necessary in dry seasons. Old canes should be cut to the ground at the end of the fruiting period and there should be severe pruning and thinning out in the late fall to force new growth for a winter-spring crop.

Season

The Mysore raspberry tends to bloom and fruit throughout the year but summer fruits are of poor size and quality. Therefore, the seasonal pruning has the additional purpose of preventing spring and summer flowering and allowing the first blooms to appear in December. Thus managed, the fruits are borne continuously from about February to May or June.

Harvesting

The fruits should be harvested only when they are not wet from dew or rain and when they are fully ripe and separate easily from the receptacle which remains on the plant. Gathering should be done at least 2 or 3 times a week to avoid losses by falling and spoilage. The fruits are highly perishable and should be consumed or processed as soon as possible.

Yield

In full sun, the crop is light. Where the plants receive some light shade in the afternoon, the yield is heavy. A single plant may yield 2,400 to 3,000 fruits over a 4-month period. A plot of 8 test plants in Florida produced 50 lbs (22.5 kg) in one season.

Pests and Diseases

The 2-spotted mite, *Tetranychus bimaculatus,* congregates on the underside of the leaves of shade-grown seedlings, turning them yellow. Occasionally, flower buds and fruits are attacked by the green stink bug, *Nezara viridula, also* called pumpkin or squash bug.

Anthracnose *(Elsinoe veneta)* causes spotting and scabbing of the canes toward the end of the fruiting season. Affected canes should be cut off and destroyed to prevent further infection.

Damping-off of seedlings can be avoided by planting seeds in a mixture of peat moss and vermiculite, or in sphagnum moss.

Food Uses

The fruits are enjoyed fresh, alone or served with sugar and cream or ice cream. They are excellent for making pie, tarts, jam and jelly. The fresh fruits can be quick-frozen for future use.

Morton, J. 1987. Red Ceylon Peach. p. 111–112. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Red Ceylon Peach

Prunus persica

The peach, *Prunus Persica* Batsch, is not ordinarily included among tropical or subtropical fruits. It is grown mainly in temperate regions of the world, including North America from the mild-temperate areas of Nova Scotia and the Ontario peninsula close to the Great Lakes, to north-central Florida, and across the Gulf States to California.

The earliest settlers in the South grew peaches, especially the highly-esteemed 'Spanish Blood'. Commercial culture began in the southern states with the introduction of other types and, by 1900, peach culture was receiving serious attention in many parts of the country. There are 5 races of the peach differing widely in their characteristics. The United States Department of Agriculture introduced many cultivars of the South China race, typified by the 'Peen-to', a flat type well adapted to moderately warm climates. The peach tree has a chilling requirement of a certain number of hours at 45° F (7.22° C) from the time of leaf-fall to the emerging of new buds. This period varies with the race and cultivar from 30 to 1,000 hours. Late in the 1880's, the 'Red Ceylon', which requires no more than 50 hours of chilling, became well-established in southern Florida. In 1904, this cultivar was planted at the agricultural experiment station at Santiago de Las Vegas, Cuba, and was soon being grown all around the Havana area because it was the only peach found suitable to that tropical climate and the local soils.

Description

The tree is dwarf, slender and willowy, with deciduous, alternate, slender, pointed leaves; bears pink, 5-petalled flowers on bare branches in January and February, sometimes March, and fruits heavily in April and May. The fruit is oval with a protruding knob at the apex, 2 3/4 in (7 cm) long and 2 3/8 in (6 cm) wide; velvety, green with deep-red blush when ripe. The flesh is mainly white but a rich strawberry-red in the center; tender, juicy, and of excellent, sweet-acid flavor having a slight suggestion of bitter-almond. The stone is free, corrugated and very hard; small in proportion to the size of the fruit. Despite its unattractiveness externally and small dimensions, the 'Red

Ceylon' is much-appreciated on close acquaintance. It is peeled, sliced and enjoyed fresh or stewed and can be used for various culinary purposes. The sliced fruit can be frozen in sirup and relished out-of-season as topping on cake or ice cream. In fact, one becomes so partial to this peach that the ordinary commercial peaches, though far more beautiful, seem somewhat rubbery and much less flavorful by comparison.

Fig. 30: The supple branches of the 'Red Ceylon Peach' (Prunus persica) bend to the ground when laden with fruit.

Other Cultivars

Two other subtropical cultivars have been successfully grown in southern Florida:

'Saharanpur'–a selection from seedlings received in 1969 from the Horticultural Research Institute, Saharanpur, India. The fruit is very similar to that of 'Red Ceylon' except that it lacks the fine red coloration in the center. The seedlings received from India were probably of the selection **'Shabati'** reported by Dr. L. B. Singh as having been released in 1950 and widely distributed all over India where winter chilling requirement of 30 to 40 hours could be guaranteed.

'Okinawa'–a fruit of superior form but of inferior quality. This cultivar has been valued mainly as a rootstock because of its greater nematode-resistance.

Culture

The 'Red Ceylon' peach has been commonly propagated by seed or by grafting. The seeds may take several months to germinate unless cracked which will induce sprouting in 10 to 90 days. The tree grows rapidly and bears in 2 years from seed. It is relatively nematode-resistant and requires little care, but should receive plenty of water for good production.

Status

In the 1940's and 1950's the 'Red Ceylon' peach was being deservedly promoted as a useful fruit for home gardens. It is impractical for marketing because of the protruding tip which bruises and then spoils readily. Seedlings and grafted plants were being sold by nurseries. Unfortunately, with the advent of the Caribbean fruit fly in 1965, and its rapid spread in southern Florida, interest in peach-growing dwindled, for the peach is a major host of this pest. Marie Neal wrote that, in Hawaii, a type of peach with small fruits having whitish flesh was formerly grown from the lowlands to an altitude of 3,000 ft (900 m), but its cultivation was discouraged because of the prevalence of the Mediterranean fruit fly.

The 'Red Ceylon' and the 'Okinawa' have been used as rootstocks for peaches in central Florida, though such tender rootstocks may make the grafted tree inclined to cold-sensitivity. In 1957, a hybrid between the 'Red Ceylon' and the 'Southland' peach was developed at the University of Florida's Agricultural Experiment Station in Gainesville.

Plate XIII: RED CEYLON PEACH, *Prunus persica*

In the past 2 decades there have been continuous efforts to develop low-chilling cultivars for central Florida and also hardier types as a crop replacement for the orange in the northern part of the "Citrus Belt" where severe damage to orange trees occurred in the winter of 1962-1963 and 200,000 bearing trees were killed by freezes in December 1983 and January 1985.

Dr. Ralph Sharpe has been a leader in peach-breeding in this state for many years. Through his research and that of his colleagues, Florida now has a substantial peach industry. The low-chilling, semi -cling-stone **'Floridaprince',** requiring only 150 hours below 45º F (7.22º C), was released to nurseries in late 1985.

Morton, J. 1987. Sansapote. p. 113–114. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Sansapote

Licania platypus

A fruit held in rather low esteem, the sansapote, *Licania platypus* Fritsch (syn. *Moquilea platypus* Hemsl.), of the family Chrysobalanaceae, is often called *sonzapote*, *sunzapote*, *sungano*, *zapote cabelludo, sapote* or *sangre* in Costa Rica and El Salvador; *sonzapote* in Nicaragua; *zapote amarillo, zapote borracho, zapote cabello, zapote de mico, zapote de mono, mesonsapote, mezonzapote*, *cabeza de mico*, or *caca de niño* in Mexico; *sonza, sunza, zunza, chaute jolobob in* Guatemala; *urraco* in Honduras; *chupa* in Colombia; monkey apple in Belize.

Description

The handsome tree is erect, stately, reaching 100 to 160 ft (30-50 m) in height; has a rounded crown of thick branches, heavily foliaged, and dark purplish or brown bark dotted with tiny white or reddish-white lenticels. It is sometimes slightly buttressed. The deciduous leaves are alternate, occasionally spiraled, elliptic- to narrow-lanceolate, pointed at both ends; 4 to 12 in (10-30 cm) long, 1 1/4 to 3 1/2 in (3-9 cm) wide, with thick midrib, indented above and prominent beneath. New foliage is bronze or red-purple and very showy. The abundant, fragrant flowers, in broad terminal, branched panicles 4 to 14 in (10-35 cm) long, are small and densely hairy with recurved petals and numerous protruding stamens. Only 1 to 3 fruits develop from each particle. The obovoid or pyriform. fruit, 5 to 8 in (13-20 cm) long, 4 to 5 1/2 in (10-14 cm) wide, has a thin, dark-brown or reddish, warty rind covered with white lenticels. The flesh, somewhat pumpkin-scented, is yellow or orange-yellow, soft, fibrous, dry or juicy and of subacid or sweet flavor. Usually there is a single rounded or ovate-oblong, flattened seed, 2 3/8 to 4 in (6-10 cm) long.

Fig 31: The sansapote, photographed by the U.S. Department of Agriculture plant explorers, Cook, Collins and Doyle, at Nicoya, Costa Rica, in 1903. Published in Henry Pittier's *New or Noteworthy Plants from Colombia and Central America #3* (Contribution of the U.S. National Herbarium Vol. 13, Part 12), the Smithsonian Institution; 1912.

Origin and Distribution

The sansapote grows wild in dense forests from southern Mexico to Panama, on both coasts, and also in northern Colombia. It is much planted as an ornamental and shade tree throughout Central America. It was introduced into the Philippines in the early 1900's and into Hawaii only about 25 years ago. In the spring of 1913, the United States Department of Agriculture received seeds from the Department of Agriculture in San José, Costa Rica (S.P.I. #34915). In November of the same year, seeds of a small-fruited type from the Pacific Coast and a large-fruited type from the Atlantic slope were received from the same source (S.P.I. #36590). Another introduction was made from Colombia in 1916 (S.P.I. #42991).

Few of the trees planted in southern Florida have survived. Several young specimens have died at the Fairchild Tropical Garden. One at the Subtropical Horticulture Research Station, Miami, has bloomed several times after rains but has not fruited. William Whitman obtained seeds from the Ministry of Agriculture, El Salvador, in 1957. One tree grew well, suffered severe hurricane damage in 1964, recovered, bloomed in late 1969 and, in the summer of 1970, produced a dozen fruits; over 100 in 1971. The fruits are not highly regarded in Central America but are sold in native markets. Tapirs and peccaries feast on those that are left on the ground.

Climate

This is a tropical species limited to low elevations–not more than 2,000 ft (600 m) above sea-level.

Season

According to Pennington, the tree blooms from July to September in Mexico and the fruits ripen from August to December. Perhaps he means of the following year. In Costa Rica and Honduras the fruit is said to take a year to develop to maturity. In Florida, one tree bloomed in November and the first fruits ripened 9 months later and the season extended from summer to fall.

Food Uses

The fruit is eaten raw when better fruits are not available. According to Standley, it has the reputation of being unwholesome, causing fever and other illnesses.

Food Value Per 100 g of Edible Portion*

Moisture	64.6-67.4 g
Protein	0.230-0.291 g
Fat	0.26-0.49 g
Fiber	0.9-2.5 g
Ash	0.96-1.61 mg
Calcium	10.5-33.2 mg
Phosphorus	24.5-29.1 mg
Iron	0.52-1.70 mg
Carotene	0.157-0.273 mg
Thiamine	0.005-0.16 mg
Riboflavin	0.013-0.027 mg
Niacin	1.466-1.530 mg
Ascorbic Acid	11.0-35.6 mg

*According to analyses made in Costa Rica and El Salvador.

Other Uses

The sapwood is pale-yellow or light yellowish-brown; the heartwood is purplish-brown or reddish, fine-grained, very heavy and strong, suitable for fine furniture and cabinetwork, but it is not durable in contact with the ground. It is little-known inasmuch as the trees are valued and seldom felled. Related species provide timber for construction and charcoal. The seeds of *L. rigida* Benth. yield oiticica oil, much like tung oil.

Morton, J. 1987. Tamarind. p. 115–121. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Tamarind

Tamarindus indica

Of all the fruit trees of the tropics, none is more widely distributed nor more appreciated as an ornamental than the tamarind, *Tamarindus indica* L. (syns. *T. occidentalis* Gaertn.; *T. officinalis* Hook.), of the family Leguminosae. Most of its colloquial names are variations on the common English term. In Spanish and Portuguese, it is *tamarindo;* in French, *tamarin*, *tamarinier*, *tamarinier des Indes*, or *tamarindier;* in Dutch and German, *tamarinde;* in Italian, *tamarandizio;* in Papiamiento of the Lesser Antilles, *tamarijn*. In the Virgin Islands, it is sometimes called *taman;* in the Philippines, *sampalok* or various other dialectal names; in Malaya, *asam jawa;* in India, it is tamarind or *ambli*, *imli*, *chinch*, etc.; in Cambodia, it is *ampil* or *khoua me;* in Laos, *mak kham;* in Thailand, *ma-kharm;* in Vietnam, *me*. The name "tamarind" with a qualifying adjective is often applied to other members of the family Leguminosae having somewhat similar foliage.

Description

Plate XIV: TAMARIND, *Tamarindus indica*

The tamarind, a slow-growing, long-lived, massive tree reaches, under favorable conditions, a height of 80 or even 100 ft (24-30 m), and may attain a spread of 40 ft (12 m) and a trunk circumference of 25 ft (7.5 m). It is highly wind-resistant, with strong, supple branches, gracefully drooping at the ends, and has dark-gray, rough, fissured bark. The mass of bright-green, fine, feathery foliage is composed of pinnate leaves, 3 to 6 in (7.5-15 cm) in length, each having 10 to 20 pairs of oblong leaflets 1/2 to 1 in (1.25-2.5 cm) long and 1/5 to 1/4 in (5-6 mm) wide, which fold at night. The leaves are normally evergreen but may be shed briefly in very dry areas during the hot season. Inconspicuous, inch-wide flowers, borne in small racemes, are 5-petalled (2 reduced to bristles), yellow with orange or red streaks. The flowerbuds are distinctly pink due to the outer color of the 4 sepals which are shed when the flower opens.

The fruits, flattish, beanlike, irregularly curved and bulged pods, are borne in great abundance along the new branches and usually vary from 2 to 7 in long and from 3/4 to 1 1/4 in (2-3.2 cm) in diameter. Exceptionally large tamarinds have been found on individual trees. The pods may be cinnamon-brown or grayish-brown externally and, at first, are tender-skinned with green, highly acid flesh and soft, whitish, under-developed seeds. As they mature, the pods fill out somewhat and the juicy, acidulous pulp turns brown or reddish-brown. Thereafter, the skin becomes a brittle, easily-cracked shell and the pulp dehydrates naturally to a sticky paste enclosed by a few coarse strands of fiber extending lengthwise from the stalk. The 1 to 12 fully formed seeds are hard, glossy-brown, squarish in form, 1/8 to 1/2 in (1.1-1.25 cm) in diameter, and each is enclosed in a parchmentlike membrane.

Origin and Distribution

Native to tropical Africa, the tree grows wild throughout the Sudan and was so long ago introduced into and adopted in India that it has often been reported as indigenous there also, and it was apparently from this Asiatic country that it reached the Persians and the Arabs who called it *"tamar hindi"* (Indian date, from the date-like appearance of the dried pulp), giving rise to both its common and generic names. Unfortunately, the specific name, *"indica"*, also perpetuates the illusion of Indian origin. The fruit was well known to the ancient Egyptians and to the Greeks in the 4th Century B.C.

The tree has long been naturalized in the East Indies and the islands of the Pacific. One of the first tamarind trees in Hawaii was planted in 1797. The tamarind was certainly introduced into tropical America, Bermuda, the Bahamas, and the West Indies much earlier. In all tropical and near-tropical areas, including South Florida, it is grown as a shade and fruit tree, along roadsides and in dooryards and parks. Mexico has over 10,000 acres (4,440 ha) of tamarinds, mostly in the states of Chiapas, Colima, Guerrero, Jalisco, Oaxaca and Veracruz. In the lower Motagua Valley of Guatemala, there are so many large tamarind trees in one area that it is called "El Tamarindal". There are commercial plantings in Belize and other Central American countries and in northern Brazil. In India there are extensive tamarind orchards producing 275,500 tons (250,000 MT) annually. The pulp is marketed in northern Malaya and to some extent wherever the tree is found even if there are no plantations.

Varieties

In some regions the type with reddish flesh is distinguished from the ordinary brown-fleshed type and regarded as superior in quality. There are types of tamarinds that are sweeter than most. One in Thailand is known as **'Makham waan'.** One distributed by the United States Department of Agriculture's Subtropical Horticulture Research Unit, Miami, is known as **'Manila Sweet'.**

Climate

Very young trees should be protected from cold but older trees are surprisingly hardy. Wilson Popenoe wrote that a large tree was killed on the west coast of Florida (about 7.5º lat. N) by a freeze in 1884. However, no cold damage was noted in South Florida following the low temperatures of the winter of 1957-1958 which had severe effects on many mango, avocado, lychee and lime trees. Dr. Henry Nehrling reported that a tamarind tree in his garden at Gotha, Florida, though damaged by freezes, always sprouted out again from the roots. In northwestern India, the tree grows well but the fruits do not ripen. Dry weather is important during the period of fruit development. In South Malaya, where there are frequent rains at this time, the tamarind does not bear.

Soil

The tree tolerates a great diversity of soil types, from deep alluvial soil to rocky land and porous, oolitic limestone. It withstands salt spray and can be planted fairly close to the seashore.

Propagation

Tamarind seeds remain viable for months, will germinate in a week after planting. In the past, propagation has been customarily by seed sown in position, with thorny branches protecting the young seedlings. However, today, young trees are usually grown in nurseries. And there is intensified interest in vegetative propagation of selected varieties because of the commercial potential of tamarind products. The tree can be grown easily from cuttings, or by shield-budding, side-veneer grafting, or air-layering.

Culture

Nursery-grown trees are usually transplanted during the early rainy season. If kept until the second rainy season, the plants must be cut back and the taproot trimmed. Spacing may be 33 to 65 ft (10-20 m) between trees each way, depending on the fertility of the soil. With sufficient water and regular weeding, the seedlings will reach 2 ft (60 cm) the first year and 4 ft (120 cm) by the second year.

In Madagascar, seedlings have begun to bear in the 4th year; in Mexico, usually in the 5th year; but in India, there may be a delay of 10 to 14 years before fruiting. The tree bears abundantly up to an age of 50-60 years or sometimes longer, then productivity declines, though it may live another 150 years.

Season

Mexican studies reveal that the fruits begin to dehydrate 203 days after fruit-set, losing approximately 1/2 moisture up to the stage of full ripeness, about 245 days from fruit-set. In Florida, Central America, and the West Indies, the flowers appear in summer, the green fruits are found in December and January and ripening takes place from April through June. In Hawaii the fruits ripen in late summer and fall.

Harvesting

Tamarinds may be left on the tree for as long as 6 months after maturity so that the moisture content will be reduced to 20% or lower. Fruits for immediate processing are often harvested by pulling the pod away from the stalk which is left with the long, longitudinal fibers attached. In India, harvesters may merely shake the branches to cause mature fruits to fall and they leave the remainder to fall naturally when ripe. Pickers are not allowed to knock the fruits off with poles as this would damage developing leaves and flowers. To keep the fruit intact for marketing fresh, the stalks must be clipped from the branches so as not to damage the shell,

Yield

A mature tree may annually produce 330 to 500 lbs (150-225 kg) of fruits, of which the pulp may constitute 30 to 55%, the shells and fiber, 11 to 30 %, and the seeds, 33 to 40%.

Keeping Quality

To preserve tamarinds for future use, they may be merely shelled, layered with sugar in boxes or pressed into tight balls and covered with cloth and kept in a cool, dry place. For shipment to processors, tamarinds may be shelled, layered with sugar in barrels and covered with boiling sirup. East Indians shell the fruits and sprinkle them lightly with salt as a preservative. In Java, the salted pulp is rolled into balls, steamed and sun-dried, then exposed to dew for a week before being packed in stone jars. In India, the pulp, with or without seeds and fibers may be mixed with salt (10%), pounded into blocks, wrapped in palmleaf matting, and packed in burlap sacks for marketing. To store for long periods, the blocks of pulp may be first steamed or sun-dried for several days.

Pests and Diseases

One of the major pests of the tamarind tree in India is the Oriental yellow scale, *Aonidiella orientalis.* Tamarind scale, *A. tamarindi*, and black, or olive, scale, *Saissetia oleae*, are also partial to tamarind but of less importance. Butani (1970) lists 8 other scale species that may be found on the tree, the young and adults sucking the sap of buds and flowers and accordingly reducing the crop.

The mealybug, *Planococcus lilacinus, is* a leading pest of tamarind in India, causing leaf-fall and sometimes shedding of young fruits. Another mealybug, *Nipaecoccus viridis, is* less of a menace except in South India where it is common on many fruit trees and ornamental plants. *Chionaspis acuminata-atricolor* and *Aspidiotus* spp., suck the sap of twigs and branches and the latter also feeds on young fruits. White grubs of *Holotrichia insularis* may feed on the roots of young seedlings. The nematodes, *Xiphinema citri* and *Longidorus elongatus* may affect the roots of older trees. Other predators attacking the leaves or flowers include the caterpillars, *Thosea aperiens, Thalarsodes quadraria, Stauropus alternus,* and *Laspeyresia palamedes;* the black citrus aphid, *Toxoptera aurantii,* the whitefly, *Acaudaleyrodes rachispora;* thrips, *Ramaswamia hiella subnudula, Scirtothrips dorsalis,* and *Haplothrips ceylonicus;* and cow bugs, *Oxyrhachis tarandus, Otinotus onerotus,* and *Laptoentrus obliquis.*

Fruit borers include larvae of the cigarette beetle, *Lasioderma serricorne,* also of *Virachola isocrates, Dichocrocis punctiferalis, Tribolium castaneum, Phycita orthoclina, Cryptophlebia (Argyroploca) illepide, Oecadarchis sp., Holocera pulverea, Assara albicostalis, Araecerus suturalis, Aephitobius laevigiatus,* and *Aphomia gularis.* The latter infests ripening pods on the tree and persists in the stored fruits, as do the tamarind beetle, *Pachymerus (Coryoborus) gonogra,* and tamarind seed borer, *Calandra (Sitophilus) linearis.* The rice weevil, *Sitophilus oryzae,* the rice moth, *Corcyra cepholonica,* and the fig moth, *Ephestia cautella,* infest the fruits in storage. The lesser grain borer, *Rhyzopertha dominica* bores into stored seeds.

In India, a bacterial leaf-spot may occur. Sooty mold is caused by *Meliola tamarindi.* Rots attacking the tree include saprot, *Xylaria euglossa,* brownish saprot, *Polyporus calcuttensis,* and white rot, *Trametes floccosa.* The separated pulp has good keeping quality but is subject to various molds in refrigerated storage.

Food Uses

The food uses of the tamarind are many. The tender, immature, very sour pods are cooked as seasoning with rice, fish and meats in India. The fully-grown, but still unripe fruits, called "swells" in the Bahamas, are roasted in coals until they burst and the skin is then peeled back and the sizzling pulp dipped in wood ashes and eaten. The fully ripe, fresh fruit is relished out-of-hand by children and adults, alike. The dehydrated fruits are easily recognized when picking by their comparatively light weight, hollow sound when tapped and the cracking of the shell under gentle pressure. The shell lifts readily from the pulp and the lengthwise fibers are removed by holding the stem with one hand and slipping the pulp downward with the other. The pulp is made into a variety of products. It is an

Fig 32: Acid-sweet pulp of the tamarind *(Tamarindus indica) is* blended with sugar as a confection, or preserved as jam or nectar. It enhances chutney and some well-known sauces.

important ingredient in chutneys, curries and sauces, including some brands of Worcestershire and barbecue sauce, and in a special Indian seafood pickle called "tamarind fish". Sugared tamarind pulp is often prepared as a confection. For this purpose, it is desirable to separate the pulp from the seeds without using water. If ripe, fresh, undehydrated tamarinds are available, this may be done by pressing the shelled and defibered fruits through a colander while adding powdered sugar to the point where the pulp no longer sticks to the fingers. The seeded pulp is then shaped into balls and coated with powdered sugar. If the tamarinds are dehydrated, it is less laborious to layer the shelled fruits with granulated sugar in a stone crock and bake in a moderately warm oven for about 4 hours until the sugar is melted, then the mass is rubbed through a sieve, mixed with sugar to a stiff paste, and formed into patties. This sweetmeat is commonly found on the market in Jamaica, Cuba and the Dominican Republic. In Panama, the pulp may be sold in corn husks, palmleaf fiber baskets, or in plastic bags.

Fig. 33: Bahamian children hold mature but still green tamarinds in hot ashes until they sizzle, then dip the tip in the ashes and eat them. The high calcium content contributes to good teeth.

Tamarind ade has long been a popular drink in the Tropics and it is now bottled in carbonated form in Guatemala, Mexico, Puerto Rico and elsewhere. Formulas for the commercial production of spiced tamarind beverages have been developed by technologists in India. The simplest home method of preparing the ade is to shell the fruits, place 3 or 4 in a bottle of water, let stand for a short time, add a tablespoonful of sugar and shake vigorously. For a richer beverage, a quantity of shelled tamarinds may be covered with a hot sugar sirup and allowed to stand several days (with or without the addition of seasonings such as cloves, cinnamon, allspice, ginger, pepper or lime slices) and finally diluted as desired with ice water and strained.

In Brazil, a quantity of shelled fruits may be covered with cold water and allowed to stand 10 to 12 hours, the seeds are strained out, and a cup of sugar is added for every 2 cups of pulp; the mixture is boiled for 15 to 20 minutes and then put up in glass jars topped with paraffin. In another method, shelled tamarinds with an equal quantity of sugar may be covered with water and boiled for a few minutes until stirring shows that the pulp has loosened from the seeds, then pressed through a sieve. The strained pulp, much like apple butter in appearance, can be stored under refrigeration for use in cold drinks or as a sauce for meats and poultry, plain cakes or puddings. A foamy "tamarind shake" is made by stirring this sauce into an equal amount of dark-brown sugar and then adding a tablespoonful of the mixture to 8 ounces of a plain carbonated beverage and whipping it in an electric blender.

If twice as much water as tamarinds is used in cooking, the strained product will be a sirup rather than a sauce. Sometimes a little soda is added. Tamarind sirup is bottled for domestic use and export in Puerto Rico. In Mayaguez, street vendors sell cones of shaved ice saturated with tamarind sirup. Tamarind pulp can be made into a tart jelly, and tamarind jam is canned commercially in Costa Rica. Tamarind sherbet and ice cream are popular and refreshing. In making fruit preserves, tamarind is sometimes combined with guava, papaya or banana. Sometimes the fruit is made into wine.

Inasmuch as shelling by hand is laborious and requires 8 man-hours to produce 100 lbs (45 kg) of shelled fruits, food technologists at the University of Puerto Rico have developed a method of pulp extraction for industrial use. They found that shelling by mechanical means alone is impossible because of the high pectin and low moisture content of the pulp. Therefore, inspected and washed pods are passed through a shell-breaking grater, then fed into stainless steel tanks equipped with agitators. Water is added at the ratio of 1:1 1/2 or 1:2 pulp/water, and the fruits are agitated for 5 to 7 minutes. The resulting mash is then passed through a screen while nylon brushes separate the shells and seeds. Next the pulp is paddled through a finer screen, pasteurized, and canned.

Young leaves and very young seedlings and flowers are cooked and eaten as greens and in curries in India. In Zimbabwe, the leaves are added to soup and the flowers are an ingredient in salads.

Tamarind seeds have been used in a limited way as emergency food. They are roasted, soaked to remove the seedcoat, then boiled or fried, or ground to a flour or starch. Roasted seeds are ground and used as a substitute for, or adulterant of, coffee. In Thailand they are sold for this purpose. In the past, the great bulk of seeds available as a by-product of processing tamarinds, has gone to waste. In 1942, two Indian scientists, T. P. Ghose and S. Krishna, announced that the decorticated kernels contained 46 to 48% of a gel-forming substance. Dr. G. R. Savur of the Pectin Manufacturing Company, Bombay, patented a process for the production of a purified product, called "Jellose", "polyose", or "pectin", which has been found superior to fruit pectin in the manufacture of jellies, jams, and marmalades. It can be used in fruit preserving with or without acids and gelatinizes with sugar concentrates even in cold water or milk. It is recommended as a stabilizer in ice cream, mayonnaise and cheese and as an ingredient or agent in a number of pharmaceutical products.

Food Value Per 100 g of Edible Portion

Oxalic Acid		196 mg	
Tartaric Acid	8-23.8 mg		
Oxalic Acid	trace only		

*The pulp is considered a promising source of tartaric acid, alcohol (12% yield) and pectin (2 1/2% yield). The red pulp of some types contains the pigment, chrysanthemin.

Seeds contain approximately 63% starch, 14-18% albuminoids, and 4.5-6.5% of a semi-drying oil.

Food Value

Analyses of the pulp are many and varied. Roughly, they show the pulp to be rich in calcium, phosphorus, iron, thiamine and riboflavin and a good source of niacin. Ascorbic acid content is low except in the peel of young green fruits.

Other Uses

Fruit pulp: in West Africa, an infusion of the whole pods is added to the dye when coloring goat hides. The fruit pulp may be used as a fixative with turmeric or annatto in dyeing and has served to coagulate rubber latex. The pulp, mixed with sea water, cleans silver, copper and brass.

Leaves: The leaves are eaten by cattle and goats, and furnish fodder for silkworms–*Anaphe sp.* in India, *Hypsoides vuilletii* in West Africa. The fine silk is considered superior for embroidery.

Tamarind leaves and flowers are useful as mordants in dyeing. A yellow dye derived from the leaves colors wool red and turns indigo-dyed silk to green. Tamarind leaves in boiling water are employed to bleach the leaves of the buri palm *(Corypha elata* Roxb.) to prepare them for hat-making. The foliage is a common mulch for tobacco plantings.

Flowers: The flowers are rated as a good source of nectar for honeybees in South India. The honey is golden-yellow and slightly acid in flavor.

Seeds: The powder made from tamarind kernels has been adopted by the Indian textile industry as 300% more efficient and more economical than cornstarch for sizing and finishing cotton, jute and spun viscose, as well as having other technical advantages. It is commonly used for dressing homemade blankets. Other industrial uses include employment in color printing of textiles, paper sizing, leather treating, the manufacture of a structural plastic, a glue for wood, a stabilizer in bricks, a binder in sawdust briquettes, and a thickener in some explosives. It is exported to Japan, the United States, Canada and the United Kingdom.

Tamarind seeds yield an amber oil useful as an illuminant and as a varnish especially preferred for painting dolls and idols. The oil is said to be palatable and of culinary quality. The tannin-rich seedcoat (testa) is under investigation as having some utility as an adhesive for plywoods and in dyeing and tanning, though it is of inferior quality and gives a red hue to leather.

Wood: The sapwood of the tamarind tree is pale-yellow. The heartwood is rather small, dark purplish-brown, very hard, heavy, strong, durable and insect-resistant. It bends well and takes a good polish and, while hard to work, it is highly prized for furniture, panelling, wheels, axles, gears for mills, ploughs, planking for sides of boats, wells, mallets, knife and tool handles, rice pounders, mortars and pestles. It has at times been sold as "Madeira mahogany". Wide boards are rare, despite the trunk dimensions of old trees, since they tend to become hollow-centered. The wood is valued for fuel, especially for brick kilns, for it gives off an intense heat, and it also yields a charcoal for the manufacture of gun-powder. In Malaysia, even though the trees are seldom felled, they are frequently topped to obtain firewood. The wood ashes are employed in tanning and in de-hairing goatskins. Young stems and also slender roots of the tamarind tree are fashioned into walking-sticks.

Twigs and barks: Tamarind twigs are sometimes used as "chewsticks" and the bark of the tree as a masticatory, alone or in place of lime with betelnut. The bark contains up to 7% tannin and is often employed in tanning hides and in dyeing, and is burned to make an ink. Bark from young trees yields a low-quality fiber used for twine and string. Galls on the young branches are used in tanning.

Lac: The tamarind tree is a host for the lac insect, *Kerria lacca*, that deposits a resin on the twigs. The lac may be harvested and sold as stick-lac for the production of lacquers and varnish. If it is not seen as a useful byproduct, tamarind growers trim off the resinous twigs and discard them.

Medicinal Uses: Medicinal uses of the tamarind are uncountable. The pulp has been official in the British and American and most other pharmacopoeias and some 200,000 lbs (90,000 kg) of the shelled fruits have been annually imported into the United States for the drug trade, primarily from the Lesser Antilles and Mexico. The European supply has come largely from Calcutta, Egypt and the Greater Antilles. Tamarind preparations are universally recognized as refrigerants in fevers and as laxatives and carminatives. Alone, or in combination with lime juice, honey, milk, dates, spices or camphor, the pulp is considered effective as a digestive, even for elephants, and as a remedy for biliousness and bile disorders, and as an antiscorbutic. In native practice, the pulp is applied on inflammations, is used in a gargle for sore throat and, mixed with salt, as a liniment for rheumatism. It is, further, administered to alleviate sunstroke, *Datura* poisoning, and alcoholic intoxication. In Southeast Asia, the fruit is prescribed to counteract the ill effects of overdoses of false chaulmoogra, *Hydnocarpus anthelmintica* Pierre, given in leprosy. The pulp is said to aid the restoration of sensation in cases of paralysis. In Colombia, an ointment made of tamarind pulp, butter, and other ingredients is used to rid domestic animals of vermin.

Tamarind leaves and flowers, dried or boiled, are used as poultices for swollen joints, sprains and boils. Lotions and extracts made from them are used in treating conjunctivitis, as antiseptics, as vermifuges, treatments for dysentery, jaundice, erysipelas and hemorrhoids and various other ailments. The fruit shells are burned and reduced to an alkaline ash which enters into medicinal formulas. The bark of the tree is regarded as an effective astringent, tonic and febrifuge. Fried with salt and pulverized to an ash, it is given as a remedy for indigestion and colic. A decoction is used in cases of gingivitis and asthma and eye inflammations; and lotions and poultices made from the bark are applied on open sores and caterpillar rashes. The powdered seeds are made into a paste for drawing boils and, with or without cumin seeds and palm sugar, are prescribed for chronic diarrhea and dysentery. The seedcoat, too, is astringent, and it, also, is specified for the latter disorders. An infusion of the roots is believed to have curative value in chest complaints and is an ingredient in prescriptions for leprosy.

The leaves and roots contain the glycosides: vitexin, isovitexin, orientin and isoorientin. The bark yields the alkaloid, hordenine.

Superstitions

Few plants will survive beneath a tamarind tree and there is a superstition that it is harmful to sleep or to tie a horse beneath one, probably because of the corrosive effect that fallen leaves have on fabrics in damp weather. Some African tribes venerate the tamarind tree as sacred. To certain Burmese, the tree represents the dwelling-place of the rain god and some hold the belief that the tree raises the temperature in its immediate vicinity. Hindus may marry a tamarind tree to a mango tree before eating the fruits of the latter. In Nyasaland, tamarind bark soaked with corn is given to domestic fowl in the belief that, if they stray or are stolen, it will cause them to return home. In Malaya, a little tamarind and coconut milk is placed in the mouth of an infant at birth, and the bark and fruit are given to elephants to make them wise.

Morton, J. 1987. Carob. p. 65–69. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Carob

Ceratonia siliqua

Non-fleshy and bean-like, the carob would not be generally regarded as a fruit, in the food-use sense, except for its sweetness. To many people it is familiar only by name as "St. John's Bread", in allusion to the "locusts" which, according to the Bible, sustained St. John the Baptist in the desert, and the "husks" which tempted the hungry Prodigal Son, though "no man gave unto him." The word "locust" was originally applied to the carob tree; later to migratory and other grasshoppers; and the name is attached to a number of other leguminous trees with pinnate leaves and oblong pods *(Gleditsia, Hymenaea, Parkia, Robinia)*. The carob tree is called *carrubo* in *Sicily, carrubio* in Italy, *algarrobo* in Guatemala, *alfarrobeira* in Brazil.

Description

The tree reaches 50 to 55 ft (15-17 m) in height and at an age of 18 years may have a trunk 33 in (85 cm) in circumference. The evergreen leaves are pinnate with 6 to 10 opposite leaflets, oval, rounded at the apex, dark-green, leathery, 1 to 2 1/2 in (2.5-6.25 cm) long. The tiny red flowers are in short, slender racernes borne in clusters along the branches–male, female or hermaphrodite on

Fig. 34: A rarity in southern Florida, this carob tree on the campus of the University of Miami was 15 years old when photographed in 1954. It is still bearing small fruits every year without cross-pollination.

separate trees. The pod is light- to dark-brown, oblong, flattened, straight or slightly curved, with a thickened margin; 4 to 12 in (10-30 cm) long, 3/4 to 1 in (1-2.5 cm) wide, glossy, tough and fibrous. It is filled with soft, semi-translucent, pale-brown pulp, scant or plentiful, and 10 to 13 flattened, very hard seeds which are loose in their cells and rattle when the pod is fully ripe and dry. The unripe pod is green, moist and very astringent; the ripe pod sweet when chewed (avoiding the seeds) but the odor of the broken pod is faintly like Limburger cheese because of its 1.3% isobutyric acid content.

Origin and Distribution

Alphonse de Candolle said that the carob "grew wild in the Levant, probably on the southern coast of Anatolia and in Syria, perhaps also in Cyrenaica. Its cultivation began within historic time. The Greeks diffused it in Greece and Italy, but it was afterwards more highly esteemed by the Arabs, who propagated it as far as Morocco and Spain. In all these countries the tree has become naturalized here and there in a less productive form . . . ".

In Spain and Portugal it survives only on their Atlantic coasts. Throughout the Mediterranean region, it is grown only in the warmest areas near the coast, and the neighboring islands–Cyprus, Crete, Sicily, Sardinia and Majorca. Producers in the Bari region of Italy on the Adriatic coast have long exported the pods to Russia and central Europe. Prince Belmonte in the Province of Salerno, Italy, was a leading influence in the 19th century in the use of the carob as an ornamental and avenue tree and in the planting of thousands for reforestation of the slopes of the Appenines.

Spanish missionaries introduced the carob into Mexico and southern California. In 1856, 8,000 seedlings, from seed brought in from Spain by the United States Patent Office, were distributed in the southern states. More seeds came from Israel in 1859. Many carobs were planted in Texas, Arizona, California and a few in Florida as ornamental and street trees. Seeds privately imported from Dalmatia were planted in California in 1873.

In the Mediterranean region, peasants have virtually lived on the pods in times of famine, but the tree is valued mostly as providing great amounts of pods as feed for livestock, as it is also in the State of Campinas, Brazil. Imported pods used to be regularly sold by street vendors in the Italian section of lower New York City for chewing. In the early 1920's, there was much promotion of carob culture in California, especially allied with the development of arid lands, and there was a flurry of activity in producing "health food" products from imported pods. Some of these products are still sold today, especially as substitutes for chocolate. Dr. J. Eliot Coit, of Vista, California, led in the study of the carob and wrote extensively on its potential improvement as a crop and its utilization.

In 1949, Dr. Walter Rittenhouse provided funds for the establishment of a 30-year test plot in northern San Diego County, where 400 local nursery seedlings and many trees grafted with Mediterranean budwood were planted and evaluated. Fruits from several thousand ornamental carob trees in California and Arizona were collected in an effort to identify superior types for human food use. Budwood of the most promising clones was supplied to horticulturists in Tunisia, Israel, Australia, South Africa, Hawaii, Mexico, Brazil and Chile.

Varieties

From more than 80 clones, 7 selections made by Coit were set out at the Citrus Research Center of the University of California for preservation. The 7 are, briefly:

'Amele'-an old commercial variety from Italy; S.P.I. #19437. Female. Pods light-brown, straight or slightly curved, 5 1/2 to 6 1/4 in (14-16 cm) long, 3/4 to 1 in (2-2.5 cm) wide; 53.8% sugar content under irrigation near Indio. Flavor good. Season: September at Indio; October at Vista.

'Casuda'-a very old cultivar from Spain. Female. Pod brown, mostly straight; 4 3/4 in (12 cm) long; 3/5 in (1.5 cm) wide; 51.7 % sugar at Vista; 56.7 % under irrigation at Indio. Flavor fair. Season: September at Indio; October at Vista.

'Clifford'-seedling street tree in Riverside. Hermaphrodite. Pod light-brown, slightly curved, 5 1/8 in (13 cm) long, 3/4 in (2 cm) wide; 52.9% sugar content. Flavor fair. Season: early October; bears regularly and heavily.

'Sfax'-from Menzel bou Zelfa, Tunisia; S.P.I. #187063. Female. Pod red-brown, straight or slightly curved; 6 in (15 cm) long, 3/4 in (2 cm) wide; 56.6% sugar at Vista, 45.6% at Indio. Excellent flavor. Season: August at Indio, September at Vista. A regular, medium-heavy bearer.

'Santa Fe'-seedling from Santa Fe Springs, California. Hermaphrodite; self-fertile. Pod light-brown, slightly curved, often twisted; 7 to 7 7/8 in (18-20 cm) long, 3/4 in (2 cm) wide; 47.5% sugar at Vista. Excellent flavor. Season: October. Bears regular, good crops. Good for coastal foothills. Not suited to irrigated culture at Indio.

'Tantillo'-from Sicily; S.P.I. #233580. Hermaphrodite. Pod dark-brown, mostly straight; 5 1/8 to 6 in (13-15 cm) long, 3/4 in (2 cm) wide. Of fair flavor. Season: mid-September to mid-October. Bears heavily and regularly.

'Tylliria'-from Cyprus; their chief export variety; S.P.I. # 189008. Female. Pod dark mahogany-brown, slightly curved, 6 in (15 cm) long, 3/4 to 1 in (2-2.5 cm) wide; 47.4% sugar at Vista; 50.9% at Indio; 48.8% in Cyprus. Good flavor. Season: mid-August to mid-September at Indio; October at Vista. Adapted to coastal foothills. (As reported from Cyprus, seed content is 7.6 to 10.6%; pod contains 51 % sugar and the seeds 49% gum).

These 7 superseded some older cultivars, including 'Bolser', 'Conejo', 'Gabriel', 'Horne', and 'Molino'; all hermaphroditic.

Other common cultivars in Cyprus are:

'Koundourka'-a tree with weeping branches; mature pods generally less than 6 1/2 in (17 cm) long; they split readily; have 14.7% seeds with a high (58%) gum content.

'Koumbota'-a large-growing tree with "knotty" pods with low seed content. Pods contain 53% sugar; seeds, 53% gum.

Grafted types are classed as 'Imera'. The name 'Apostolika' is a general term for seedlings of fair quality. Wild types as a group are called 'Agria'.

Pollination

In a planting of female trees, one male should be included for every 25 or 30 females. In southern Europe, branches from male trees are grafted onto some of the females in an orchard instead of interplanting male trees.

Climate

The carob is slightly hardier than the sweet orange. Young trees suffer frost damage. Mature tees can endure a temperature drop to 20º F (-6.67º C). Frost during the blooming period will reduce or prevent fruit-set. The tree does best in a Mediterranean-type climate with cool, not cold, winters, mild to warm springs, and warm to hot summers with little or no rain. Temperatures in carob-growing regions of Israel may reach 104º to 122º F (40º-50º C) in summer. Ideal annual precipitation is 30 in (75 cm), but widely spaced trees will thrive with only 6 to 15 in (15-37.5 cm) without irrigation in mild climates. The pods should not be exposed to rain or heavy dew after they have turned brown and developed a high sugar content. Wet pods ferment quickly.

Soil

The tree flourishes in widely divergent soils, from rocky hillsides to deep sand or heavy loam, but must have good drainage. In Nicosia, Cyprus, a large plantation was developed by dynamiting planting holes in caprock underlaid with limestone (pH 9). The carob is not tolerant of acid or wet soils; it is extremely drought-tolerant.

Propagation

Fresh seeds germinate quickly and may be sown directly in the field. Dried, hard seeds need to be scarified or chipped and then soaked in water or dilute sulfuric or hydrochloric acid solutions until they swell. In Cyprus, seeds are planted in sand and kept wet for 6 weeks or more, periodically sifting out those that have swollen to 3 times normal size. Germination rate may be only 25%. The swollen seeds are traditionally planted in flats and when they produce the second set of leaves they are transferred to small pots. When 12 in (30 cm) tall, they are transplanted to large containers or nursery rows. A recently developed technique is to plant the seeds in 2 halves of clay drainpipes bound together or in plastic tubes packed in deep wooden boxes to accommodate the long taproot. In perhaps a year, the tubes are split and the seedlings are planted in the field in holes made with a post-hole digger. Budding is done when the stem is at least 3/8 in (1 cm) thick.

The shield-budding system is employed, or sometimes a blend of budding and grafting, in February and March in Cyprus, in April, May and June in California and Mexico. Male trees or those that bear poorly are top-worked to productive cultivars.

Culture

The carob grows slowly during the first year. Stem-elongation in young plants has been expedited by application of gibberellin (50 mg/liter monthly, or 25 mg/liter semi-monthly) for 5 months. It is necessary to cut back the taproot 6 months before transferring to the field if the plant is not grown by the tube/post-hole method. Large trees cannot be successfully transplanted.

A good spacing is 30 ft (9 in) apart each way. Most carob growers consider fertilizing unnecessary but the government of Cyprus subsidizes fertilization–so much per tree. Irrigation must be provided in very dry seasons if the tree is grown for its fruits. Budded trees begin to bear in the 6th year from planting. A carob tree may remain productive for 80 to 100 years.

Harvesting

The pods must be harvested before winter rains. They are shaken down by means of a long pole with a terminal hook to grasp the branches. Those that don't fall readily are knocked off with the pole. The pods are caught on canvas sheets laid on the ground. Then they are sun-dried for 1 or 2 days until the moisture content is reduced to 8% or below and then go through a kibbling process–crushing and grading into 4 categories: cubed, medium-kibbled, meal, and seed kernels.

Yield

At 6 years of age, a budded tree in California should yield about 5 lbs (2.25 kg). At 12 years, the crop should be 100 lbs (45 kg). Productivity increases steadily up to 25 or 30 years when the yield may average 200 lbs (90 kg). In Israel individual trees have produced 450 to 550 lbs (204-227 kg) 18 years after grafting. Some ancient trees in the Mediterranean area are reported to have borne 3,000 lbs (1,360 kg) in a season.

Pests and Diseases

In the Mediterranean area, the major pest is the carob moth, *Myelois ceratoniae*. It lays eggs on the flowers or newly-formed pods and the larvae bore into the pods and ruin them. The larvae of a midge, *Asphondylia gennadii,* cause stunting of the pods. Some of the best cultivars are resistant to these pests.

In Cyprus, the tree is subject to several scale insects: *Aspidiotus ceratoniae, Lecanium sp., Lepidosaphes sp.* and the red scale, *Aonidiella aurantii.* A beetle, *Cerambyx velutinus,* may bore holes in the trunk. Rats climb the trees, hide among the branches, gnaw the bark until the branches die. Such branches are pruned out twice a year. The only pests reported as attacking carob trees in California are scale insects, including the red scale. Ground squirrels feed on plants under 2 years of age. Pocket gophers are very fond of carob roots, and rabbits and deer graze on the young trees.

Diseases are few. In Cyprus, deformation of young pods may be caused by the fungus *Oidium ceratoniae. Cercospora ceratoniae* occasionally induces leaf-spotting.

Food Uses

Apart from being chewed as a sweetmeat, carob pods are processed to a cocoa -like flour which is added to cold or heated milk for drinking. It has been combined with wheat flour in making bread or pancakes. A flour made by beating the seeded pods is high in fiber and has been utilized in breakfast foods. The finer flour is also made into confections, especially candy bars. The pods, coarsely ground and boiled in water yield a thick, honey-like sirup, or molasses.

Plate XV: CAROB, *Ceratonia siliqua*

The seeds constitute 10 to 20% of the pod. They yield a tragacanth-like gum (manogalactan), called in the trade "Tragasol", which is an important commercial stabilizer and thickener in bakery goods, ice cream, salad dressings, sauces, cheese, salami, bologna, canned meats and fish, jelly, mustard, and other food products. The seed residue after gum extraction can be made into a starch- and sugar-free flour of 60% protein content for diabetics.

In Germany, the roasted seeds have served as a substitute for coffee. In Spain, they have been mixed with coffee.

It has been demonstrated that the extracted sugars of the pod (sucrose, glucose, fructose and maltose in the ratio 5:1:1:0:7) can be utilized to produce fungal protein. Infusions of the pulp are fermented into alcoholic beverages.

Food Value Per 100 g of Carob Flour

Calories	180
Moisture	11.2 g
Protein	4.5 g
Fat	1.4 g
Carbohydrates*	80.7 g
Fiber	7.7 g
Ash	2.2 g
Calcium	352 mg
Phosphorus	81 mg

*Sugar content may be as high as 72%.

The pods contain up to 1.5% tannins which interfere with the body's utilization of protein.

Other Uses

Pods: The pods are relished by horses, cattle, pigs, goats and rabbits. Whole pods are broken up in a hammermill in order to crush the seeds as well. Because of the tannin content, carob pods should constitute no more than 10% of total feed, other-wise they will depress growth rate. They cannot be fed to chickens. The flour is often utilized in dog biscuits. Great quantities of pods have been imported into the United States for flavoring uncured tobacco.

Seeds: The seed gum is much employed in the manufacture of cosmetics, pharmaceutical products, detergents, paint, ink, shoe polish, adhesives, sizing for textiles, photographic paper, insecticides and match heads. It is also utilized in tanning. Where rubber latex is produced, the gum is added to cause the solids to rise to the surface. It is also used for bonding paper pulp and thickening silkscreen pastes, and some derivatives are added to drilling mud. It has many other actual or potential applications. A flour made from the seeds serves as cattle feed.

Wood: The heartwood is hard and close-grained. It is prized for turnery and cabinetwork. As a fuel it burns slowly and makes excellent charcoal. It yields algarrobin, which gives textiles a light-brown hue.

Morton, J. 1987. Carambola. p. 125–128. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Carambola

Averrhoa carambola

A curious, attractive fruit of the Oxalidaceae, the carambola, *Averrhoa carambola* L., has traveled sufficiently to have acquired a number of regional names in addition to the popular Spanish appelation which belies its Far Eastern origin. In the Orient, it is usually called *balimbing, belimbing,* or *belimbing manis* ("sweet belimbing"), to distinguish it from the bilimbi or *belimbing asam, A. bilimbi* L. In Ceylon and India, the carambola has the alternate names of *kamaranga, kamruk,* or other variants of the native *kamrakh.* In Vietnam, it is called *khe, khe ta,* or similar terms; in Kampuchea, *spu*; in Laos, *nak fuang,* or the French name, *carambolier;* in Thailand, *ma fueang*. Malayans may refer to it as *belimbing batu, belimbing besi, belimbing pessegi, belimbing sayur, belimbing saji, kambola, caramba,* or as "star fruit". Australians use the descriptive term, five corner; in Guam, it is *bilimbines;* to the Chinese, it is *yang-táo.* Early English travelers called it Chinese, or Coromandel gooseberry, or cucumber tree. In Guyana, it is five fingers; in the Dominican Republic, it is *vinagrillo;* in Haiti, *zibline;* in some of the French Antilles, *cornichon;* in El Salvador, *pepino de la India;* in Surinam, *blimbing legi* or *fransman-birambi;* Costa Rica, *tiriguro;* in Brazil, *camerunga* or *caramboleiro,* or *limas de Cayena;* in Mexico, *carambolera* or *caramboler* or *árbol de pepino;* in Trinidad, it may be called coolie tamarind. Venezuelans call it *tamarindo chino* or *tamarindo dulce.*

Description

Plate XVI: CARAMBOLA, *Averrhoa carambola*

The carambola tree is slow-growing, short-trunked with a much-branched, bushy, broad, rounded crown and reaches 20 to 30 ft (6-9 m) in height. Its deciduous leaves, spirally arranged, are alternate, imparipinnate, 6 to 10 in(15-20 cm) long, with 5 to 11 nearly opposite leaflets, ovate or ovate-oblong, 1 1/2 to 3 1/2 in (3.8-9 cm) long; soft, medium-green, and smooth on the upper surface, finely hairy and whitish on the underside. The leaflets are sensitive to light and more or less inclined to fold together at night or when the tree is shaken or abruptly shocked. Small clusters of red-stalked, lilac, purple-streaked, downy flowers, about 1/4 in (6 mm) wide, are borne on the twigs in the axils of the leaves. The showy, oblong, longitudinally 5- to 6-angled fruits, 2 1/2 to 6 in (6.35-15 cm) long and up to 3 1/2 (9 cm) wide, have thin, waxy, orange-yellow skin and juicy, crisp, yellow flesh when fully ripe. Slices cut in cross-section have the form of a star. The fruit has a more or less pronounced oxalic acid odor and the flavor ranges from very sour to mildly sweetish. The so-called "sweet" types rarely contain more than 4% sugar. There may be up to 12 flat, thin, brown seeds 1/4 to 1/2 in (6-12.5 mm) long or none at all.

Origin and Distribution

The carambola is believed to have originated in Ceylon and the Moluccas but it has been cultivated in southeast Asia and Malaysia for many centuries. It is commonly grown in the provinces of Fukien, Kuangtung and Kuangsi in southern China, in Taiwan and India. It is rather popular in the Philippines and Queensland, Australia, and moderately so in some of the South Pacific islands, particularly Tahiti, New Caledonia and Netherlands New Guinea, and in Guam and Hawaii.

There are some specimens of the tree in special collections in the Caribbean islands, Central America, tropical South America, and also in West Tropical Africa and Zanzibar. Several trees have been growing since 1935 at the Rehovoth Research Station in Israel. In many areas, it is grown more as an ornamental than for its fruits.

It was introduced into southern Florida before 1887 and was viewed mainly as a curiosity until recent years when some small groves have been established and the fruits have been used as "conversation pieces" to decorate gift shipments of citrus fruits, and also, in clear-plastic-wrapped trays, have been appearing in the produce sections of some supermarkets. One fruit-grower and shipper now has 50 acres (20 ha) planted but suggests that other prospective growers be cautious as the market may remain limited. Shipments go mainly to Vancouver, Quebec, Cleveland, and Disneyworld. Small amounts are sold locally.

Varieties

There are 2 distinct classes of carambola–the smaller, very sour type, richly flavored, with more oxalic acid; the larger, so-called "sweet" type, mild-flavored, rather bland, with less oxalic acid.

In 1935, seeds from Hawaii were planted at the University of Florida's Agricultural Research and Education Center in Homestead. A selection from the resulting seedlings was vegetatively propagated during the 1940's and 1950's and, in late 1965, was officially released under the name **'Golden Star'** and distributed to growers. The fruit is large, deeply winged, decorative, and mildly subacid to sweet. Furthermore, this cultivar shows the least minor-element deficiency in alkaline soil, and even isolated trees bear well and regularly without cross-pollination.

Several cultivars from Taiwan are being grown at the United States Department of Agriculture's Subtropical Horticulture Research Unit in Miami, including 'Mih Tao' (P. I. No. 272065) introduced in 1963, also 'Dah Pon' and 'Tean Ma' and others identified only by numbers, and Fwang Tung' brought from Thailand by Dr. R J. Knight in 1973. There are certain "lines" of carambola, such as 'Newcomb', 'Thayer' and 'Arkin' being grown commercially in southern Florida. Some cultivars and seedlings bear flowers with short styles, others only flowers with long styles, a factor which affects self- and cross-pollination.

Climate

The carambola should be classed as tropical and sub-tropical because mature trees can tolerate freezing temperatures for short periods and sustain little damage at 27º F (-2.78º C). In Florida, the tree survives in sheltered sites as far north as St. Petersburg on the west coast and Daytona Beach on the east. It thrives up to an elevation of 4,000 ft (1,200 m) in India. In an interior valley of Israel, all trees succumbed to the prevailing hot, dry winds. The carambola needs moisture for best performance and ideally rainfall should be fairly evenly distributed all year. In Australia, it is claimed that fruit quality and flavor are best where annual rainfall is 70 in (180 cm) or somewhat more.

Soil

Not too particular as to soil, the carambola does well on sand, heavy clay or limestone, but will grow faster and bear more heavily in rich loam. It is often chlorotic on limestone. It needs good drainage; cannot stand flooding.

Propagation

The carambola is widely grown from seed though viability lasts only a few days. Only plump, fully developed seeds should be planted. In damp peat moss, they will germinate in one week in summer, require 14 to 18 days in winter. The seedlings are transplanted to containers of light sandy loam and held until time to set out. They are very tender and need good care. Seedlings are highly variable. Air-layering has been practiced and advocated. However, root formation is slow and later performance is not wholly satisfactory. Inarching is successful in India, shield-budding in the Philippines and the Forkert method in Java. Trees can be top-worked by bark-grafting, a popular technique in Java. For mass production, side-veneer grafting of mature, purplish wood, onto carambola seedlings gives best results for most workers. The rootstocks should be at least 1 year old and 3/8 to 5/7 in (1-1.5 cm) thick. One Florida farmer prefers cleft-grafting of green budwood and has 90% success. Grafted trees will fruit in 10 months from the time of planting out. Mature trees can be top-worked by bark-grafting.

Culture

The tree needs full sun. A spacing of 20 ft (6 m) has been advocated but if the trees are on good soil no less than 30 ft (9 m) should be considered. At the Research Center in Homestead, trees 8 to 10 ft (2.4-3 m) high respond well to 1 lb (0.5 kg) applications of N, P, K, Mg in the ratio of 6-6-6-3 given 3 to 4 times per year. If chlorosis occurs, it can be corrected by added iron, zinc and manganese. Some advisers recommend minor-element spraying 4 times during the year if the trees are on limestone soils. Moderate irrigation is highly desirable during dry seasons. Heavy rains during blooming season interfere with pollination and fruit production. Interplanting of different strains is usually necessary to provide cross-pollination and obtain the highest yields.

Harvesting and Yield

In India, carambolas are available in September and October and again in December and January. In Malaya, they are produced all the year. In Florida, scattered fruits are found through the year but the main crop usually matures from late summer to early winter. Some trees have fruited heavily in November and December, and again in March and April. There may even be three crops. Weather conditions account for much of the seasonal variability.

The fruits naturally fall to the ground when fully ripe. For marketing and shipping they should be hand-picked while pale-green with just a touch of yellow.

Trees that receive adequate horticultural attention have yielded 100 to 250 or even 300 lbs (45-113-136 kg) of fruit.

Keeping Quality

Carambolas have been shipped successfully without refrigeration from Florida to northern cities in avocado lugs lined and topped with excelsior. The fruits are packed solidly, stem-end down, at a 45º angle, the flanges of one fruit fitting into the "V" grooves of another. Of course, they cannot endure rough handling.

In storage trials at Winter Haven, Florida, carambolas picked when showing the first signs of yellowing kept in good condition for 4 weeks at 50º F (10º C); 3 weeks at 60º F (15.56º C); 2 weeks at 70º F (21.1º C). Waxing extends storage life and preserves the vitamin value.

Pests and Diseases

The carambola is relatively pest-free except for fruit flies. In Malaya, fruit flies (especially *Dacus dorsalis*) are so troublesome on carambolas that growers have to wrap the fruits on the tree with paper. Experimental trapping, with methyl eugenol as an attractant, has reduced fruit damage by 20%. In Florida, a small stinkbug causes superficial blemishes and a black beetle attacks overripe fruits. Reniform nematodes may cause tree decline.

Anthracnose caused by *Colletotrichum gloeosporioides* may be a problem in Florida, and leaf spot may arise from attack by *Phomopsis* sp., *Phyllosticta* sp. or *Cercospora averrhoae. Cercospora* leaf spot is reported also from Malaya, Ceylon, China and may occur in the Philippines as well. A substance resembling sooty mold makes many fruits unmarketable in summer.

Food Uses

Ripe carambolas are eaten out-of-hand, sliced and served in salads, or used as garnish on avocado or seafood. They are also cooked in puddings, tarts, stews and curries. In Malaya, they are often stewed with sugar and cloves, alone or combined with apples. The Chinese cook carambolas with fish. Thais boil the sliced green fruit with shrimp. Slightly underripe fruits are salted, pickled or made into jam or other preserves. In mainland China and in Taiwan, carambolas are sliced lengthwise and canned in sirup for export. In Queensland, the sweeter type is cooked green as a vegetable. Cross-sections may be covered with honey, allowed to stand overnight, and then cooked briefly and, put into sterilized jars. Some cooks add raisins to give the product more character. A relish may be made of chopped unripe fruits combined with horseradish, celery, vinegar, seasonings and spices. Indian experimenters boiled horizontal slices with 3/4 of their weight in sugar until very thick, with a Brix of 68º. They found that the skin became very tough, the flavor was not distinctive, and the jam was rated as only fair. Sour fruits, pricked to permit absorption of sugar and cooked in sirup, at first 33º Brix, later 72º, made an acceptable candied product though the skin was still tough. The ripe fruits are sometimes dried in Jamaica.

Carambola juice is served as a cooling beverage. In Hawaii, the juice of sour fruits is mixed with gelatin, sugar, lemon juice and boiling water to make sherbet. Filipinos often use the juice as a seasoning. The juice is bottled in India, either with added citric acid (1% by weight) and 0.05 % potassium metabisulphite, or merely sterilizing the filled bottles for 1/2 hr in boiling water.

To make jelly, it is necessary to use unripe "sweet" types or ripe sour types and to add commercial pectin or some other fruit rich in pectin such as green papaya, together with lemon or lime juice.

The flowers are acid and are added to salads in Java; also, they are made into preserves in India. The leaves have been eaten as a substitute for sorrel.

Food Value

Ripening and storage studies were conducted at the Florida Citrus Experiment Station at Lake Alfred in 1966. They found quite a difference in the acid make-up of mature green and mature yellow carambolas. Fresh mature green fruits of 'Golden Star' were found to have a total acid content of 12.51 mg/g consisting of 5 mg oxalic, 4.37 tartaric, 1.32 citric, 1.21 malic, 0.39 α-ketoglutaric, 0.22 succinic, and a trace of fumaric. Mature yellow fruits had a total acid content of 13 mg/g, made up of 9.58 mg oxalic, 0.91 tartaric, 2.20 α-ketoglutaric, 0.31 fumaric.

In 1975, 16 carambola selections and 2 named cultivars were assayed at the United States Citrus and Subtropical Products Laboratory, Winter Haven, Florida. Preliminary taste tests ranked 'No. 17, 'No. 37', 'No. 42' and 'Tean Ma' as preferred. In a later test, 'Dah Pon' was ranked above 'Tean Ma'. 'No. 17' (º Brix 9.9) was described as "sweet, good and apple-like". 'No. 37' (º Brix 6.7), as "sour and sweet". 'No. 42' (º Brix 8.3), as "sour, tart and apple-like". 'Dah Pon' (º Brix 8.0), as "good and mild". 'Tean Ma (º Brix 7.2), as "sweet, good and mild". Analyses showed that these 5 were among those with relatively high ascorbic acid content–'No. 17, 30 mg; 'Dah Pon', 30 mg; 'No. 37', 37 mg; 'No. 42', 37 mg; and 'Tean Ma', 41 mg. 'No. 40' had 43 mg and 'No. 11', 50 mg, whereas 'M-23007' had only 14 mg and 'No. 10' only 17 mg.

Oxalic acid content of the 18 selections and cultivars ranged from 0.039 mg to 0.679 mg and 4 of the preferred carambolas were in the lower range as follows: 'No. 17', 0.167; 'Dah Pon', 0.184; 'Tean Ma', 0.202; 'No. 42', 0.276 mg, but 'No. 37', with 0.461 was 3rd from the highest of all.

Puerto Rican technologists found the oxalic acid content of ripe carambolas to average 0.5 g per 100 ml of juice, the acid being mostly in the free state. They likened the juice to rhubarb juice and advised that physicians be informed of this because there are individuals who may be adversely affected by ingestion of even small amounts of oxalic acid or oxalates. Other investigators have presumed the oxalic acid in fully ripe carambolas to be precipitated as calcium oxalate or in solution as neutral salts. The health risk needs further study.

Food Value Per 100 g of Edible Portion*	
Calories	35.7
Moisture	89.0-91.0 g
Protein	0.38 g
Fat	0.08 g
Carbohydrates	9.38 g
Fiber	0.80-0.90 g

Carotene	0.003-0.552 mg
Thiamine	0.03-0.038 mg
Riboflavin	0.019-0.03 mg
Niacin	0.294-0.38 mg
Ascorbic Acid*	26.0-53.1 mg

* According to analyses made in Cuba and Honduras.

Amino Acids: (shown in Cuban analyses)

Tryptophan	3.0 mg
Methionine	2 mg
Lysine	26 mg

Other amino acids reported by the Florida Citrus Experiment Station at Lake Alfred and expressed in micromoles per g in mature green fruits (higher) and mature yellow fruits (lower), respectively, are:

Asparagine	0.82-0.64
Threonine	0.92-0.79
Serine	3.88-2.00
Glutamic Acid	2.41-1.80
Proline	0.23-0.09
Glycine	0.20-0.10
Alanine	5.40-1.26
Valine	0.17-0.11
Isoleucine	0.03-trace
Leucine	trace
Phenylalanine	trace
Gamma Amino Bytyric Acid	0.77-0.55
Ornithine	0.11-0.13
Histidine	trace

**Analyses in India showed 10.40 mg ascorbic acid in the juice of a "sweet" variety; 15.4 mg in juice of a sour variety. Ascorbic acid content of both waxed and unwaxed fruits stored at 50º F (10º C) has been reported as 20 mg/100 ml of juice. Waxed fruits stored for 17 days at 60º F (15.56º C) had 11 mg/100 ml of juice. Unwaxed fruits had lost ascorbic acid.

Other Uses

The acid types of carambola have been used to clean and polish metal, especially brass, as they dissolve tarnish and rust. The juice will also bleach rust stains from white cloth. Unripe fruits are used in place of a conventional mordant in dyeing.

Wood: Carambola wood is white, becoming reddish with age; close-grained, medium-hard. It has been utilized for construction and furniture.

Medicinal Uses: In India, the ripe fruit is administered to halt hemorrhages and to relieve bleeding hemorrhoids; and the dried fruit or the juice may be taken to counteract fevers. A conserve of the fruit is said to allay biliousness and diarrhea and to relieve a "hangover" from excessive indulgence in alcohol. A salve made of the fruit is employed to relieve eye afflictions. In Brazil, the carambola is recommended as a diuretic in kidney and bladder complaints, and is believed to have a beneficial effect in the treatment of eczema. In *Chinese Materia Medica* it is stated, "Its action is to quench thirst, to increase the salivary secretion, and hence to allay fever."

A decoction of combined fruit and leaves is drunk to overcome vomiting. Leaves are bound on the temples to soothe headache. Crushed leaves and shoots are poulticed on the eruptions of chicken-pox, also on ringworm.

The flowers are given as a vermifuge. In southeast Asia, the flowers are rubbed on the dermatitis caused by lacquer derived from *Rhus verniciflua* Stokes.

Burkill says that a preparation of the inner bark, with sandalwood and *Alyxia sp., is* applied on prickly heat. The roots, with sugar, are considered an antidote for poison. Hydrocyanic acid has been detected in the leaves, stems and roots.

A decoction of the crushed seeds acts as a galactagogue and ernmenagogue and is mildly intoxicating. The powdered seeds serve as a sedative in cases of asthma and colic.

Morton, J. 1987. Bilimbi. p. 128–129 In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Bilimbi

Averrhoa bilimbi

The bilimbi, *Averrhoa bilimbi,* L., (Oxalidaceae), is closely allied to the carambola but quite different in appearance, manner of fruiting, flavor and uses. The only strictly English names are "cucumber tree" and "tree sorrel", bestowed by the British in colonial times. "Bilimbi" is the common name in India and has become widely used. In Malaya, it is called *belimbing asam, belimbing buloh, b'ling*, or *billing-billing.* In Indonesia, it is *belimbing besu, balimbing, blimbing,* or *blimbing wuluh;* in Thailand, it is *taling pling,* or *kaling pring.*

In Haiti, it is called *blimblin;* in Jamaica, *bimbling plum;* in Cuba, it is *grosella china;* in El Salvador and Nicaragua, *mimbro;* in Costa Rica, *mimbro* or *tiriguro;* in Venezuela, *vinagrillo;* in Surinam and Guyana, *birambi;* in Argentina, *pepino de Indias.* To the French it is *carambolier bilimbi,* or *cornichon des Indes.* Filipinos generally call it *kamias* but there are about a dozen other native names.

Description

The tree is attractive, long-lived, reaches 16 to 33 ft (5-10 m) in height; has a short trunk soon dividing into a number of upright branches. The leaves, very similar to those of the Otaheite gooseberry and mainly clustered at the branch tips, are alternate, imparipirmate; 12 to 24 in (30-60 cm) long, with 11 to 37 alternate or subopposite leaflets, ovate or oblong, with rounded base and pointed tip; downy; medium-green on the upper surface, pale on the underside; 3/4 to 4 in (2-10 cm) long, 1/2 to 1 1/8 in (1.2-1.25 cm) wide.

Small, fragrant, 5-petalled flowers, yellowish-green or purplish marked with dark-purple, are borne in small, hairy panicles emerging directly from the trunk and oldest, thickest branches and some twigs, as do the clusters of curious fruits. The bilimbi is ellipsoid, obovoid or nearly cylindrical, faintly 5-sided, 1 1/2 to 4 in (4-10 cm) long; capped by a thin, star-shaped calyx at the stem-end and tipped with 5 hair-like floral remnants at the apex. The fruit is crisp when unripe, turns from bright-green to yellowish-green, ivory or nearly white when ripe and falls to the ground. The outer skin is glossy, very thin, soft and tender, and the flesh green, jelly-like, juicy and extremely acid. There may be a few (perhaps 6 or 7) flattened, disc-like seeds about 1/4 in (6 mm) wide, smooth and brown.

Plate XVII: BILIMBI, *Averrhoa bilimbi*

Origin and Distribution

Perhaps a native of the Moluccas, the bilimbi is cultivated throughout Indonesia; is cultivated and semi-wild everywhere in the Philippines; is much grown in Ceylon and Burma. It is very common in Thailand, Malaya and Singapore; frequent in gardens across the plains of India, and has run wild in all the warmest areas of that country. It is much planted in Zanzibar. Introduced into Queensland about 1896, it was readily adopted and commercially distributed to growers.

In 1793, the bilimbi was carried from the island of Timor to Jamaica and, after some years, was planted in Cuba and Puerto Rico, Trinidad, the lowlands of Central America, Venezuela, Colombia, Ecuador, Surinam, Guyana and Brazil, and even in northern Argentina, and it is very popular among the Asiatic residents of those countries as it must be in Hawaii. Still it is grown only as an occasional curiosity in southern Florida.

Varieties

Bilimbis are all much the same wherever they are grown, but P.J. Wester reported that a form with sweet fruits had been discovered in the Philippines.

Climate

The bilimbi is a tropical species, more sensitive to cold than the carambola, especially when very young. In Florida, it needs protection from cold and wind. Ideally, rainfall should be rather evenly distributed throughout most of the year but there should be a 2- to 3-month dry season. The bilimbi is not found in the wettest zones of Malaya. The tree makes slow growth in shady or semi-shady situations. It should be in full sun.

Soil

While the bilimbi does best in rich, moist, but well-drained soil, it grows and fruits quite well on sand or limestone.

Propagation

Most efforts at grafting and budding have not been rewarding, though Wester had success in shield-budding, utilizing non-petioled, ripe, brown budwood cut 1 1/2 to 2 in (3.8-5 cm) long. Air-layering has been practiced in Indonesia for many years. However, the tree is more widely grown from seed.

Bilimbi trees are vigorous and receive no special horticultural attention. It has been suggested that they would respond well to whatever cultural treatment gives good results with the carambola.

Season, Harvesting and Keeping Quality

In India as in Florida, the tree begins to flower about February and then blooms and fruits more or less continuously until December. The fruits are picked by hand, singly or in clusters. They need gentle handling because of the thin skin. They cannot be kept on hand for more than a few days.

Pests and Diseases

No pests or diseases have been reported specifically for the bilimbi.

Food Uses

The bilimbi is generally regarded as too acid for eating raw, but in Costa Rica, the green, uncooked fruits are prepared as a relish which is served with rice and beans. Sometimes it is an accompaniment for fish and meat. Ripe fruits are frequently added to curries in the Far East. They yield 44.2% juice having a pH of 4.47, and the juice is popular for making cooling beverages on the order of lemonade.

Mainly, the bilimbi is used in place of mango to make chutney, and it is much preserved. To reduce acidity, it may be first pricked and soaked in water overnight, or soaked in salted water for a shorter time; then it is boiled with much sugar to make a jam or an acid jelly. The latter, in Malaya, is added to stewed fruits that are oversweet. Half-ripe fruits are salted, set out in the sun, and pickled in brine and can be thus kept for 3 months. A quicker pickle is made by putting the fruits and salt into boiling water. This product can be kept only 4 to 5 days.

The flowers are sometimes preserved with sugar.

Food Value Per 100 g of Edible Portion*

Moisture	94.2-94.7 g
Protein	0.61 g
Fiber	0.6g
Ash	0.31-0.40 g

Calcium	3.4 mg
Phosphorus	11.1 mg
Iron	1.01 mg
Carotene	0.035 mg
Thiamine	0.010 mg
Riboflavin	0.026 mg
Niacin	0.302 mg
Ascorbic Acid	15.5 mg

*According to analyses of fruits studied in Nicaragua and the Philippines.

Other Uses

Fruit: Very acid bilimbis are employed to clean the blade of a *kris* (dagger), and they serve as mordants in the preparation of an orange dye for silk fabrics. Bilimbi juice, because of its oxalic acid content, is useful for bleaching stains from the hands and rust from white cloth, and also tarnish from brass.

Wood: The wood is white, soft but tough, even-grained, and weighs 35 lbs/cu ft. It is seldom available for carpentry.

Medicinal Uses: In the Philippines, the leaves are applied as a paste or poulticed on itches, swellings of mumps and rheumatism, and on skin eruptions. Elsewhere, they are applied on bites of poisonous creatures. Malayans take the leaves fresh or fermented as a treatment for venereal disease. A leaf infusion is a remedy for coughs and is taken after childbirth as a tonic. A leaf decoction is taken to relieve rectal inflammation. A flower infusion is said to be effective against coughs and thrush.

In Java, the fruits combined with pepper are eaten to cause sweating when people are feeling "under the weather". A paste of pickled bilimbis is smeared all over the body to hasten recovery after a fever. The fruit conserve is administered as a treatment for coughs, beri-beri and biliousness. A sirup prepared from the fruit is taken as a cure for fever and inflammation and to stop rectal bleeding and alleviate internal hemorrhoids.

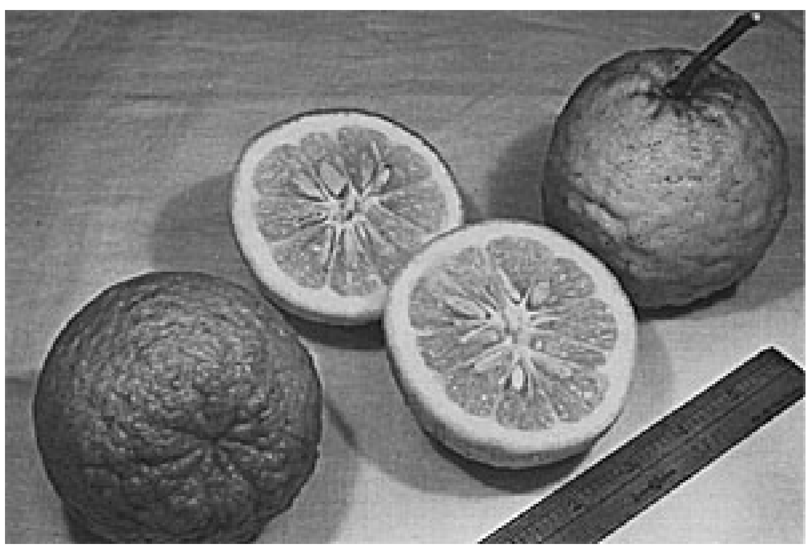
Morton, J. 1987. Sour Orange. p. 130–133. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Sour Orange

Citrus aurantium

A species of multiple uses, the sour orange *(Citrus aurantium,* L.), is also known as bitter, bigarade, or Seville orange. In Spanish-speaking areas it may be called *naranja ácida, naranja agria,* or *naranja amarga.* In Arabia, it is *naranji;* in Italy, *melangolo;* in India, *khatta;* in Samoa, *moli,* in Guam, soap orange.

Description



The tree ranges in height from less than 10 ft (3 m) to 30 ft (9 m), is more erect and has a more compact crown than the sweet orange; has smooth, brown bark, green twigs, angular when young, and flexible, not very sharp, thorns from 1 in to 3 1/8 in (2.5-8 cm) long. The evergreen leaves (technically single leaflets of compound leaves), are aromatic, alternate, on broad-winged petioles much longer than those of the sweet orange; usually ovate with a short point at the apex; 2 1/2 to 5 1/2 in (6.5-13.75 cm) long, 1 1/2 to 4 in (3.75-10 cm) wide; minutely toothed; dark-green above, pale beneath, and dotted with tiny oil glands. The highly fragrant flowers, borne singly or in small clusters in the leaf axils, are about 1 1/2 in (3.75 cm) wide, with 5 white, slender, straplike, recurved, widely-separated petals surrounding a tuft of up to 24 yellow stamens. From 5 to 12% of the flowers are male.

Fig. 35: The sour orange *(Citrus aurantium)*has a rough, fairly thick skin, very sour juice.

The fruit is round, oblate or oblong-oval, 2 3/4 to 3 1/8 in (7-8 cm) wide, rough-surfaced, with a fairly thick, aromatic, bitter peel becoming bright reddish-orange on maturity and having minute, sunken oil glands. There are 10 to 12 segments with bitter walls containing strongly acid pulp and from a few to numerous seeds. The center becomes hollow when the fruit is full-grown.

Origin and Distribution

The sour orange is native to southeastern Asia. Natives of the South Sea Islands, especially Fiji, Samoa, and Guam, believe the tree to have been brought to their shores in prehistoric times. Arabs are thought to have carried it to Arabia in the 9th Century. It was reported to be growing in Sicily in 1002 A.D., and it was cultivated around Seville, Spain, at the end of the 12th Century. For 500 years, it was the only orange in Europe and it was the first orange to reach the New World. It was naturalized in Mexico by 1568 and in Brazil by 1587, and not long after it was running wild in the Cape Verde Islands, Bermuda, Jamaica, Puerto Rico and Barbados. Sir Walter Raleigh took sour orange seeds to England; they were planted in Surrey and the trees began bearing regular crops in 1595, but were killed by cold in 1739.

Spaniards introduced the sour orange into St. Augustine, Florida. It was quickly adopted by the early settlers and local Indians and, by 1763, sour oranges were being exported from St. Augustine to England. Sour orange trees can still be found in Everglades hammocks on the sites of former Indian dwellings. The first sweet orange budwood was grafted onto sour orange trees in pioneer dooryards and, from that time on, the sour orange became more widely grown as a rootstock in all citrus-producing areas of the world than for its fruit or other features. Today, the sour orange is found growing wild even in southern Georgia and from Mexico to Argentina.

It is grown in orchards or groves only in the Orient and the various other parts of the world where its special products are of commercial importance, including southern Europe and offshore islands, North Africa, the Middle East, Madras, India, West Tropical Africa, Haiti, the Dominican Republic, Brazil and Paraguay.

Varieties

There are various well-established forms of the sour orange. In the period 1818-1822, 23 varieties were described and illustrated in Europe. A prominent subspecies is the Bergamot orange, C. *aurantium,* var. *bergamia* Wight & Arn., grown in the Mediterranean area since the 16th Century but commercially only in Italy. Trees grown in California and Florida under this name are actually the 'Bouquet' variety of sour orange (see below). The flowers of the Bergamot are small, sweetly fragrant; the fruits round or pear-shaped, with strongly aromatic peel and acid pulp.

The myrtle-leaved orange (C. *aurantium,* var. *myrtifolia),* is a compact shrub or tree with small leaves and no thorns. It was found as a bud mutation on trunks of old sour orange trees in Florida. It is propagated and grown only on the French and Italian Riviera for its small fruits which are preserved in brine and exported for candying.

Apart from these special types, there are several groups of sour oranges, within which there are placed certain cultivars:

1) *Normal group* (large, seedy fruits)

'African', 'Brazilian', 'Rubidoux', 'Standard', 'Oklawaha' and 'Trabut'. 'Oklawaha' originated in the United States. It has large fruits rich in pectin and is prized for marmalade.

2) Aberrant group

'Daidai', or 'Taitai', popular in Japan and China. Its fruits are large with very thick peel, very acid pulp, and many seeds. The tree is somewhat dwarf and almost thornless; immune to citrus canker in the Philippines. It is prized for its flower buds which are dried and mixed with tea for their scent.

'Goleta' has medium-large fruits with juicy, medium-sour pulp and very few seeds. The tree is of medium size and almost thornless.

'Bouquet' has small, deep-orange fruits, acid, with few seeds. The tree is less than 10 ft (3 in) high and is grown as an ornamental.

3) *Bittersweet group* includes any sweet-acid forms of the sour orange introduced by Spaniards and formerly found growing in the Indian River region of Florida. These oranges are often seen in a naturalized state in the West Indies. The peel is orange-red, the pulp is darker in hue than that of the normal sour orange.

'Paraguay' was introduced from Paraguay in 1911. The fruit is of medium size, with sweet pulp, moderately seedy. The tree is large, thorny and hardy.

Among other forms of sour orange, there is in India a type called 'Karna', 'Khatta' or 'Id Nimbu', identified as *C. aurantium* var. *khatta* (or *C. karna* Raf.) but suspected of being a hybrid of sour orange and lemon. The fruits are typical sour oranges but the flowers are red-tinted like those of the lemon.

Two cultivars are grown as rootstocks for the sweet orange in China:

'Vermilion Globe' has oblate fruits containing 30 to 40 seeds. The tree has long, narrow, pointed leaves.

'Leather-head' has small, oblate, rough fruits with 20 seeds. The tree has elliptic, blunt leaves.

Cultivars grown especially for the production of Neroli oil in France and elsewhere, have flowers in large, more concentrated clusters than the ordinary types of sour orange. One of these, 'Riche Défouille', has unusual, wingless leaves.

Climate

The sour orange flourishes in subtropical, near-tropical climates, yet it can stand several degrees of frost for short periods. Generally it has considerable tolerance of adverse conditions. But the Bergamot orange is very sensitive to wind and extremes of drought or moisture.

Soil

Unlike its sweet relative, the sour orange does well on low, rich soils with a high water table and is adapted to a wide range of soil conditions.

Propagation

Sour orange trees volunteer readily from self-sown seeds. As generally grown for rootstock for sweet oranges, they are raised in nurseries for 1 or 2 years and then budded. Growth of the seedlings, especially in diameter, has been expedited by weekly applications of gibberellic acid to the stems, making it possible to bud them much earlier.

Culture

In the proper climatic and soil conditions, the sour orange is self-maintaining and receives only a modicum of cultural attention. It has an extraordinary ability to survive with no care at all. Some trees in Spain are said to be over 600 years old and one tree in a tub at Versailles, which, of course, must be carefully tended, was reportedly planted in the year 1421.

Pests and Diseases

The sour orange is subject to most of the pests that attack the sweet orange. In addition to its susceptibility to the disease called tristeza, the tree is liable to other viruses -crinkly leaf, gummy bark, psorosis, and xyloporosis. The Division of Plant Industry of the Florida State Department of Agriculture has recorded the following fungal problems as sometimes seen: leaf spot (*AIternaria citri*, *Cercospora penzigii*, *Mycophaerella horii*, *Cladosporium oxysporum*, and *Phyllosticta hesperidearum);* greasy spot *(Cercospora citri-grisea);* tar spot (C. *gigantea);* leprosis *(Cladosporium herbarum);* mushroom root rot *(Clitocybe tabescens);* anthracnose *(Colletotrichum gloeosporioides);* thread blight *(Corticium koleroga* and C. *stevensii);* gummosis and dieback *(Diaporthe citri);* foot rot and root rot *(Fusarium oxysporum, Macrophomia phaseolina, Phytophthora* spp.); heart rot and wood rot *(Fomes applanatus, Ganoderma sessilis, Xylaria polymorpha),* and others.

Food Uses

The normal types of sour orange are usually too sour to be enjoyed out-of-hand. In Mexico, however, sour oranges are cut in half, salted, coated with a paste of hot chili peppers, and eaten.

The greatest use of sour oranges as food is in the form of marmalade and for this purpose they have no equal. The fruits are largely exported to England and Scotland for making marmalade. Sour oranges are used primarily for marmalade in South Africa.

Fig. 36: Dried peel of the locally-grown sour orange yields the essential oil that flavors "Curacao liqueur".

The juice is valued for ade and as a flavoring on fish and, in Spain, on meat during cooking. In

Yucatan, it is employed like vinegar. In Egypt and elsewhere, it has been fermented to make wine.

"Bitter orange oil", expressed from the peel, is in demand for flavoring candy, ice cream, baked goods, gelatins and puddings, chewing gum, soft drinks, liqueurs and pharmaceutical products, especially if the water-or alcohol-insoluble terpenes and sesquiterpenes are removed. The oil is produced in Sicily, Spain, West Africa, the West Indies, Brazil, Mexico and Taiwan.

The essential oil derived from the dried peel of immature fruit, particularly from the selected types -'Jacmel' in Jamaica and the much more aromatic 'Curacao orange' (var. *curassaviensis)-gives* a distinctive flavor to certain liqueurs.

"Neroli oil", or "Neroli Bigarade Oil", distilled from the flowers of the sour orange, has limited use in flavoring candy, soft-drinks and liqueurs, ice cream, baked goods and chewing gum.

'Petitgrain oil', without terpenes, is used to enhance the fruit flavors (peach, apricot, gooseberry, black currant, etc.) in food products, candy, ginger ale, and various condiments.

'Orange leaf absolute' enters into soft-drinks, ice cream, baked goods and candy.

The ripe peel of the sour orange contains 2.4 to 2.8%, and the green peel up to 14%, neohesperidin dihydrochalcone which is 20 times sweeter than saccharin and 200 times sweeter than cyclamate. Potential use as a sweetener may be hampered by the limited supply of peel.

Food Value Per 100 g of Edible Portion

	Fruit (raw)	*Fruit (raw, with only superficial layer of peel removed)**
Calories	37-66	
Moisture	83-89.2 g	77.8-83.1 g
Protein	0.6-1.0 g	0.154-0.167 g
Fat	trace-0.1 g	0.05-0.07 g
Carbohydrates	9.7-15.2 g	?
Fiber	0.4 g	1.8-2.2 g
Ash	0.5 g	0.57-0.69 g
Calcium	18-50 mg	64.3-81.9 mg
Iron	0.2 mg	0.22-0.85 mg

Niacin	0.3 mg	0.282-0.400 mg
Ascorbic Acid	45-90 mg	55.2-103.5 mg
*Sampled in Guatemala and El Salvador.		

Other Uses

Soap substitute: Throughout the Pacific Island, the crushed fruit and the macerated leaves, both of which make lather in water, are used as soap for washing clothes and shampooing the hair. Safford described the common scene in Guam of women standing in a river with wooden trays on which they rub clothing with sour orange pulp, then scrub it with a corncob. He wrote: "Often the entire surface of the river where the current is sluggish is covered with decaying oranges." On the islands of Zanzibar and Pemba, the fruits are used for scouring floors and brass.

Perfumery: All parts of the sour orange are more aromatic than those of the sweet orange. The flowers are indispensable to the perfume industry and are famous not only for the distilled Neroli oil but also for "orange flower absolute" obtained by fat or solvent extraction. During favorable weather in southern France, 2,200 lbs (1,000 kg) of flowers will yield 36 to 53 oz (1,000-1,500 g) of oil.

Neroli oil consists of 35% terpenes (mainly dipentene, pinene and camphene), 30% *1*-linalool, and 4% geraniol and nerol, 2% *d*-terpineol, 6% *d*-nerolidol, traces of decyclic aldehyde, 7% *1*-linalyl acetate, 4% neryl and geranyl acetates, traces of esters of phenylacetic acid and benzoic acid, as much as 0.1% methyl anthranilate, and traces of jasmone, farnesol, and palmitic acid. Orange flower water is usually a by-product of oil production.

Petitgrain oil is distilled from the leaves, twigs and immature fruits, especially from the Bergamot orange. Both Petitgrain and the oil of the ripe peel are of great importance in formulating scents for perfumes and cosmetics. Petitgrain oil is indispensable in fancy eau-de-cologne. The seed oil is employed in soaps.

Honey: The flowers yield nectar for honeybees.

Wood: The wood is handsome, whitish to pale-yellow, very hard, fine-grained, much like boxwood. It is valued for cabinetwork and turnery. In Cuba it is fashioned into baseball bats.

Medicinal Uses: Sour orange juice is antiseptic, anti-bilious and hemostatic. Africans apply the cut-open orange on ulcers and yaws and areas of the body afflicted with rheumatism. In Italy, Mexico and Latin America generally, decoctions of the leaves are given for their sudorific, antispasmodic, stimulant, tonic and stomachic action. The flowers, prepared as a sirup, act as a sedative in nervous disorders and induce sleep. An infusion of the bitter bark is taken as a tonic, stimulant, febrifuge and vermifuge.

The fresh young leaves contain as much as 300 mg of ascorbic acid per 100 g. The mature leaf contains 1-stachyhydrine.

Morton, J. 1987. Orange. p. 134–142. In: Fruits of warm climates. Julia F. Morton, Miami, FL.

Orange

Citrus sinensis

One of the most widely favored of the world's fruits, the orange, sweet orange, or round orange, was for many years known as *Citrus aurantium* var. *sinensis* L. and considered to be a form of the sour orange (q.v.). It is still not universally agreed to be a distinct species, C. *sinensis* Osbeck, but it is usually treated as though it were. One of its first recorded regional names was the Persian *narang*, from which were derived the Spanish name, *naranja*, and the Portuguese, *laranja*. In some Caribbean and Latin American areas, the fruit is called *naranja de China*, *China dulce*, or simply *China* (pronounced *cheena)*.

Description

The orange tree, reaching 25 ft (7.5 m) or, with great age, up to 50 ft (15 m), has a rounded crown of slender branches. The twigs are twisted and angled when young and may bear slender, semi-flexible, bluntish spines in the leaf axils. There may be faint or conspicuous wings on the petioles of the aromatic, evergreen, alternate, elliptic to ovate, sometimes faintly toothed "leaves"–technically solitary leaflets of compound leaves. These are 2 1/2 to 6 in (6.5-15 cm) long, 1 to 3 3/4 in (2.5-9.5 cm) wide. Borne singly or in clusters of 2 to 6, the sweetly fragrant white flowers, about 2 in (5 cm) wide, have a saucer-shaped, 5-pointed calyx and 5 oblong, white petals, and 20 to 25 stamens with conspicuous yellow anthers. The fruit is globose, subglobose, oblate or somewhat oval, 2 1/2 to 3 3/4 in (6.5-9.5 cm) wide. Dotted with minute glands containing an essential oil, the outer rind (epicarp) is orange or yellow when ripe, the inner rind (mesocarp) is white, spongy and non-aromatic. The pulp (endocarp), yellow, orange or more or less red, consists of tightly packed membranous juice sacs enclosed in 10 to 14 wedge-shaped compartments which are readily separated as individual segments. In each segment there may be 2 to 4 irregular seeds, white externally and internally, though some types of oranges are seedless. The sweet orange differs physically from the sour orange in having a solid center.

Origin and Distribution

The orange is unknown in the wild state; is assumed to have originated in southern China, northeastern India, and perhaps southeastern Asia (formerly Indochina). It was carried to the Mediterranean area possibly by Italian traders after 1450 or by Portuguese navigators around 1500. Up to that era, citrus fruits were valued by Europeans mainly for medicinal purposes, but the orange was quickly adopted as a luscious fruit and wealthy persons grew it in private conservatories, called orangeries. By 1646 it had been much publicized and was well known.

Spaniards undoubtedly introduced the sweet orange into South America and Mexico in the mid-1500's, and probably the French took it to Louisiana. It was from New Orleans that seeds were obtained and distributed in Florida about 1872 and many orange groves were established by grafting the sweet orange onto sour orange rootstocks. Arizona received the orange tree with the founding of missions between 1707 and 1710. The orange was brought to San Diego, California, by those who built the first mission there in 1769. An orchard was planted at the San Gabriel Mission around 1804. A commercial orchard was established in 1841 on a site that is now a part of Los Angeles. In 1781, a surgeon and naturalist on the ship, Discovery, collected orange seeds in South Africa, grew seedlings on board and presented them to tribal chiefs in the Hawaiian Islands on arrival in 1792. In time, the orange became commonly grown throughout Hawaii, but was virtually abandoned after the advent of the Mediterranean fruit fly and the fruit is now imported from the United States mainland.

The orange has become the most commonly grown tree fruit in the world. It is an important crop in the Far East, the Union of South Africa, Australia, throughout the Mediterranean area, and subtropical areas of South America and the Caribbean. The United States leads in world production, with Florida, alone, having an annual yield of more than 200 million boxes, except when freezes occur which may reduce the crop by 20 or even 40%. California, Texas and Arizona follow in that order, with much lower production in Louisiana, Mississippi, Alabama and Georgia. Other major producers are Brazil, Spain, Japan, Mexico, Italy, India, Argentina and Egypt. In Brazil, oranges are grown everywhere in the coastal plain and in the highlands but most extensively in the States of Sao Paulo and Rio de Janeiro, where orange culture rose sharply in the years immediately following World War II and is still advancing. Mexico's citrus industry is located largely in the 4 southern states of Nuevo Leon, Tamaulipas, San Luis Potosi and Veracruz. The orange crop is over one million MT and Nuevo Leon has 20 modern packing plants, mostly with fumigation facilities. Large quantities of fresh oranges and orange juice concentrate are exported to the United States and small shipments go to East Germany, Canada and Argentina. However, overproduction has glutted domestic markets and brought down prices and returns to the farmer to such an extent that plantings have declined and growers are switching to grapefruit. Cuba's crop has become nearly 1/3 as large as that of Florida. Lesser quantities are produced in Puerto Rico, Central America (especially Guatemala), some of the Pacific Islands, New Zealand, and West Africa, where the fruit does not acquire an appealing color but is popular for its quality and sweetness. Many named cultivars have been introduced and grown in the Philippines since 1912, but the fruitis generally of low qualitybecause of the warm climate.

Varieties

Most of the oranges grown in California are of 2 cultivars: the 'Washington Navel' and the 'Valencia'. Florida's commercial cultivars are mainly: (early) 'Hamlin'; (mid-season) 'Pineapple'; (late) 'Valencia'.

The 'Washington Navel' (formerly known as 'Bahia') originated, perhaps as a mutant in Bahia, Brazil, before 1820. It was introduced into Florida in 1835 and several other times prior to 1870. In 1873, budded trees reached California where the fruit matures at the Christmas season. It is large but with a thick, easily removed rind; not very juicy; of excellent flavor, and seedless or nearly so. Ease of peeling and separation of segments makes this the most popular orange in the world for eating out-of-hand or in salads. Limonene content of the juice results in bitterness when pasteurized and therefore this cultivar is undesirable for processing. The tree needs a relatively cool climate and should not be grown below an elevation of 3,300 ft (1,000 in) in tropical countries. Today it is commercially grown, not only in Brazil and California, but also in Paraguay, Spain, South Africa, Australia and Japan.

'Trovita', a non-navel seedling raised in 1914-1915 at the Citrus Experiment Station in California and released in 1935, is milder in flavor and has a few seeds, but may be earlier in season, and it has been considered promising in hot, dry regions unsuitable for 'Washington Navel'. There are several other named variations such as 'Robertson Navel', 'Summer Navel', 'Texas Navel', and the externally attractive 'Thompson Navel' which was grown in California for a time but dropped because of its poor quality. Various mutants, more suitable for warmer climates, have been selected and named in Florida, including 'Dream', 'Pell', 'Summerfield', 'Surprise'–the latter being more productive than 'Washington Navel' in Florida but still not grown to any extent. 'Bahiamina' is a small version of the 'Washington Navel' developed in Brazil in the late 1940's. It follows 'Pera' and 'Natal' sweet oranges in importance in tropical Bahia.

'Valencia', or 'Valencia Late', is the most important cultivar in California, Texas and South Africa. It has been the leader in Florida until recently. In 1984, 40% of the oranges being planted in Florida were 'Valencia', 60% were 'Hamlin'. The 'Valencia' may have originated in China and it was presumably taken to Europe by Portuguese or Spanish voyagers. The well-known English nurseryman, Thomas Rivers, supplied plants from the Azores to Florida in 1870 and to California in 1876. In Florida, it was quickly appreciated and cultivated, at first labeled 'Brown' and later renamed 'Hart's Tardiff, 'Hart' and 'Hart Late' until it was recognized as identical to the 'Valencia' in California. It was not propagated for sale in California until 1916 and was slow to be adopted commercially. It is smaller than the 'Washington Navel', with a thinner, tighter rind; is far juicier and richer in flavor; nearly seedless except in Chile where the dry climate apparently allows better pollination and development of many more seeds -up to 980 in 44 lbs (20 kg). It needs a warm climate. In fact, it is the most satisfactory orange for the tropics, even though it may not develop full color in warm regions. In Colombia, the quality is good from sea-level to 5,000 ft (1,600 m). It bears two crops a year, overlapping and giving it the great advantage of a late and long season lasting until midsummer. The fruits on the trees in spring will regreen, lose their orange color and turn green at the stem end, but the quality is not affected. They were formerly dyed to improve market appearance but since the 1955 Food & Drug Administration ban on the synthetic dyes used on oranges, they have been colored by exposure to ethylene gas in storage. The gas removes the chlorophyll layer, revealing the orange color beneath. Degreening does not occur in California where 'Valencia' oranges from one growing area or another are marketed from late spring through fall.

'Lue Gim Gong' was claimed to be a hybrid of 'Valencia' and 'Mediterranean Sweet' made by a Chinese grower in 1886. 'Lue Gim Gong' was awarded the Wilder Silver Medal by the American Pomological Society in 1911 but, later on, his hybrid was judged to be a nucellar seedling of 'Valencia'. Propagated and distributed by Glen St. Mary Nurseries in 1912, this cultivar closely resembles 'Valencia', matures and is marketed with its parent without distinction. It is best cited as the 'Lue Gim Gong Strain' of 'Valencia'. 'Mediterranean Sweet' was introduced into Florida from Europe in 1875, was briefly popular, but is no longer grown.

Certain strains of 'Valencia' are classed as summer oranges because the fruits can be left on the trees longer without dehydrating. One is known as 'Pope', 'Pope Summer', or 'Glen Summer'. It was found in a grove of 'Pineapple' oranges near Lakeland about 1916, was propagated in 1935, and trademarked in 1938. On sour orange or sweet orange rootstocks in hammock soils, the fruit matures in April but is still in good condition on the tree in July and August.
